The apothecary system is clumsy and out of date, and a few examples should readily convince anyone who doubts. There is, of course, a definite relationship between grammes and cubic centimetres, but not correspondingly between grains and minims. The pharmacist, too, has often to distinguish between 1 oz. avoirdupois of 16 drachms which weighs 437½ grains and 1 oz. apothecary which contains 480 grains—i.e., 8 drachms of 60 grains; thus a difference of 42½ grains between the two ounces. Approximately 1 c.cm. of water weighs 1 gramme, but one minim of water does not weigh one grain, for in round figures 110 minims is the volume occupied by 100 grains or, to simplify this, for example, a 1% aqueous solution would contain 1 gramme in 100 c.cm., or 1 grain in 109.7142 minims. Consequently, many errors in calculations, some of which

might be dangerous, could be avoided by the introduction of a simple decimal system. Furthermore the contraction of 1 gr and 1 gm in writing might be easily confused, yet a gramme is $1\frac{1}{2}$ times heavier than a grain. The mental arithmetic involved in first in reckoning and converting grains and minims into grammes and cubic centimetres would not be very difficult.

In conclusion it might be worth while to quote from page x of the preface to the *British Pharmacopoeia* of 1914—i.e., thirty years ago: "The metric system has been employed for the specification of doses, in the expectation that in the near future the system will be generally adopted by British prescribers."—I am etc.

S A W RUSHBROOKE

Liver Function

SIR—In the annotation on tests of liver function (Sept 16, p 378) you deal with the relation between the liver and the serum proteins. Quoting J Post and A J Patek (1943) you state that "in chronic liver disease, notably cirrhosis of the liver, the serum albumin is generally reduced, whereas the serum globulin is normal or increased," and that a defect in the synthesis of serum albumin seems to be the underlying cause qualitative rather than quantitative alterations of the serum proteins being the decisive disturbance.

The full recognition of this important disturbance and of the role of the liver in protein synthesis is fairly recent. Impairment of this function may occur quite early in liver disease, is completely restorable, and is best tested for by means of one of the flocculation tests whose results depend upon the protein pattern of the serum.

When studying the factors which lead to the appearance of a positive Takata reaction I was able to demonstrate already in 1936 and in 1938¹ that, apart from quantitative alterations, changes of a qualitative nature existed in the serum albumin of liver cirrhotics, and I believe that these findings were the first to suggest the existence of such an alteration. Previous investigators had dealt only with alterations of the albumin-globulin ratio in liver disease.

The experiments in question consisted in separating the serum albumin and the serum globulins of normal persons and liver cirrhotics by fractional precipitation, in mixing the albumin fraction of the former with the globulin fraction of the latter, and vice versa, in varying proportions, and in testing the behaviour of these mixtures towards the Takata reagent (a mercury oxychloride formed by interaction of sodium carbonate and mercuric chloride). No differences in behaviour were observed between the two kinds of globulin. The precipitate formed on addition of the Takata reagent to a positive serum is serum globulin, while serum albumin protects the globulin from flocculation. It could, however, be shown that normal albumin affords a definitely greater degree of protection than an equal amount of albumin derived from liver cirrhotics, and also that pure solutions of the two kinds of albumin which can be precipitated by high concentrations of the Takata reagent differ in so far that the serum albumin of cirrhotics needs much less reagent for its flocculation than that of normal persons. The conclusions drawn from these experiments were (1) that a quantitative decrease of the serum albumin with a more or less marked increase of serum globulin occurs in liver cirrhosis, (2) that a physico-chemical alteration of the serum albumin is present, and that these changes are most likely due to an impairment of the protein synthesizing function of the liver.

In a more recent paper,² which dealt with the results obtained by means of a modified Takata reaction³ by different authors on 2,600 cases, the assumption was made that also in certain non-hepatic diseases in which similar protein changes occur in the serum and positive flocculation tests have been encountered (certain cases of pneumonia, hyperthyroidism, rheumatoid arthritis, diabetes, pernicious anaemia, acute nephritis, lymphoecranuloma inguinale, Kahler's disease, etc.) a disturbed protein synthesis by the liver was likely to be responsible for these changes.

It may be argued that the beneficial effect produced by a highly nutritious diet, rich in protein but poor in fat, on experimental and clinical liver cirrhosis is partly due to the liberal supply of protein, which may be helpful in adjusting the protein metabolism deranged by the defect of the liver in protein synthesis.—I am, etc.,

Meeting of Whole-time Specialists

SIR,—A committee has been formed to consider the effect of the White Paper proposal on the consultant and specialist services of the country. The Royal Colleges, the specialist associations, the provincial teaching hospitals, the provincial non-teaching hospitals, and the British Medical Association are represented on the committee.

A large number of specialists attached to hospitals are employed as whole time officers of local authorities, and we think that they, as a group, should be represented on the committee. The President of the Royal College of Physicians as chairman of the committee, is sympathetic to this proposal, and is willing to submit it to the committee. It is therefore proposed to call a meeting of specialists employed whole-time by municipal authorities on Friday, Oct 20, at 5 p.m., at the Royal College of Physicians.

It is hoped that as many as possible will attend to make the meeting fully representative. No individual notices are being sent out, and we ask specialists to draw their colleagues' attention to this letter, and we hope that the medical officers of health will, so far as possible, enable the specialist members of their staffs to attend the meeting.—We are, etc.,

Intramuscular Quinine

SIR—In the *Journal* of Sept 23 (p 413) Dr W L Peacock suggests the use of quinine lactate for intramuscular injection in malaria in place of the hydrochloride. Some years ago (*Lancet* 1934, 2, 1101) I introduced quinine lactate in the injection treatment of varicose veins, when I found it less liable to give rise to painful reactions than the commonly used hydrochloride of Genevriev's solution, and less liable to cause sloughing if it was deposited outside the vein. Since then I have often wondered why it is not in routine use when quinine is given parenterally. A saturated solution of the salt in water is about 16.6%.—I am, etc.,

J W RIDDOCH

Functional Hypoglycaemia

SIR—I have read with interest Dr Prunty's article in the *Journal* of Sept 23 (p 398) and agree with him that the term "functional hyperinsulinism" is not a good one. His term "reactive hyperinsulinism" in my opinion is open to the same objection—namely, the use of the word "hyperinsulinism" in the group of cases he describes. In America and in this country the term "hyperinsulinism" has come to be associated with the presence of a tumour or diffuse hyperplasia of the islets, and its use in connexion with the condition more generally known as "functional hypoglycaemia" seems to me not only to be creating unnecessary confusion but also an impression that this disease is in fact due to the excessive production of insulin, of which there is nothing more than suggestive evidence.—I am, etc.,

London W 1

WILFRID OAKLEY

London Medicine

SIR,—Dr Walshe's article in your issue of Sept 2 is one of the signs of the increasing attention now being paid to post-graduate education in this country, more particularly in London. For many years, as the Goodenough report reminds us, quoting Sir William Osler, London has failed to occupy the leading position as a postgraduate centre for which it has long had the potentialities. Dr Walshe's article adds to one's forebodings. The pendulum seems to be swinging back too far, with the dangers of over-interference and over-planning. It has, of course long been desirable that the lack of organization and cohesion characterizing London postgraduate facilities should be remedied, and, *pari passu*, that the great resources of the Metropolitan in patients, hospitals, and expert medical men should be marshalled and constructively co-ordinated in such a way that all types of practitioner—the general practitioner, and rising consultants and specialists—shall find easily the advanced professional instruction or training which they may need in a

fullness and a form worthy of what should be the greatest school of medicine in the world. To obtain this generous end should be our ideal, but we must be wary of the danger of over-planning particular parts of it to the neglect and imperfection of the whole.

The Goodenough report recommends, as part of the innovations of the National Health Service, university supervision of postgraduate education in London, together with extensive subsidies. If Parliament agrees to this, what immense benefits may flow from wise investment of the grants, and what disappointment and failure of attainment could follow the maldistribution of funds, conditioned by restricted vision, prejudice, or undue sectional influence! To prevent the establishment of possibly obstructive vested interests on the one hand and a starvation of progress on the other, university supervision and financial assistance should be as widespread and inclusive as possible. Only in this way can the full development of the London School of Medicine, in the widest and wisest sense of the term, be assured. Any scheme which bolsters up part of this school (a part which, from the nature of things, would probably contain the more undesirably vociferous and own-trumpet-blowing sections) and neglects the rest might well produce a distorted, ill-balanced result falling far short of London's best. In this connexion, the Goodenough report, with its complicated play upon what are, and what are not, recognized schools of the University of London, causes one some anxiety that limited and destructive discrimination may be made. University recognition in London has hitherto been patchy and unsystematic. In future all voluntary hospitals in the London area staffed by consultants should be invited into the University postgraduate scheme. Those entering can be kept, with financial aid, up to the necessary standards—not that most of them are not clinically up to standard now. Postgraduate teaching in London should be as widely based as possible, and all available resources should be used in order that the highest cultural, as distinct from technical, standard—the importance of which Dr. Walshe rightly emphasizes—should be attained. This can only be done by the inclusive policy just described. Not only should the teaching be cultural in the professional sense; the more educational contacts London postgraduates can make with cultural influences in London outside medicine, so much the better.

Characteristic of London Medicine is its disunity—a state of affairs which detracts greatly from its dignity. It is no secret that high authorities, such as the Voluntary Hospitals Committee of London, King Edward's Fund, and many personalities of standing in the hospital world, have in recent years attempted to introduce some element of greater combination and co-operation between the voluntary hospitals in London. It is also no secret that most of the opposition to this sensible and progressive development has come from the narrow prejudices, jealousies, and dislikes of medical staffs, described to me by one experienced hospital secretary as "childish." The broader the general cultural outlook the less likely is this disunity to persist, and, conversely, the more general unity and co-operation that can be attained the better will be the cultural effect upon the medical men working in the hospitals. The best training for consultants and specialists, the expert clinicians, is surely one as broadly based as possible, taking the form of climbing the ladder of appointments in a number of different hospitals until the highest rank is reached. The contact with hospitals and teachers should be wide, giving the rising men the opportunity to observe contrasts and make comparisons, rather than restricted and confined to some single, highly rarified, and exclusive school. The culture of the latter (rather the type of culture extolled by Dr. Walshe, I am afraid) would be hard, narrow, and self-complacent, breeding consultants with the disdainful outlook of high-caste, humourless Brahmins, contemptuous of all the clinical touchables trained elsewhere, however competent they might be.

Dr. Walshe seems unduly hard on the "refresher" and similar courses. Organized demonstrations and participation in the practice of hospitals, etc., need not be deadening or repetitive (any more than undergraduate teaching is), and are very valuable to men working for the higher general examinations, like the M.R.C.P., the cultural value of which Dr. Walshe rightly stresses. I agree that their value for general practitioners

is not so great, but it is far from being despicable. Such teaching does mean hard work, however, and I suspect that this has something to do with its unpopularity, although some more highfalutin reason has to be found for its overt condemnation. The enormous success and popularity of the Fellowship of Medicine since the last war is evidence of the value of such teaching. I am informed that by the end of 1943 over eleven thousand postgraduate students had made use of the Fellowship's facilities, and the moneys paid in fees by the Fellowship to hospitals and teachers had exceeded £50,000 since the end of the last war. Are not these figures astonishing, and do they not suggest that a real want was met by this organization, having Sir William Osler, Sir Arbuthnot Lane, Sir John McAllister, and Sir StClair Thomson as its fathers? Has it not earned more than the curt footnote that is its only mention in the Goodenough report, and which is a reflection upon the depth and judgment of this report itself?

A distinction needs drawing between the professional consultant practitioner of his subject and the whole-time research worker. Although the former may well make generous original contributions to knowledge, the essentials of training are different for the two. A training suitable for the research worker may well be too intensively narrow to be suitable for the practitioner. Subsidized institutes based on single hospitals would, I feel, suffer from this narrowness and tend to produce the Brahmin-like type of consultant I have described. In the training of specialists great evils lie in the artificial confining of higher education to single officially privileged schools. Apart from those already mentioned, training in a single school will tend to produce a snobbish rigidity of outlook and an artificial set of standards—that is to say, everything and everyone emanating from the privileged institution will necessarily be classified as of the best, like persons of the blood Royal in an age of Divine Right, because of their origin, irrespective of their intrinsic merits. In contrast, merit that is impertinent enough not to originate in the privileged institute (and merit, unfortunately, cannot be confined in or conjured at will, like genii, from any chosen academic bottle) will tend to be defamed and belittled. If a single institution gains official recognition as the sole training school in a subject, it will become, in the new schemes, a very definite financial interest, with all the undesirable temptations associated therewith.

There is clearly much that is attractive in the establishment under university supervision, of institutes in special subjects but there is much that is narrow and short-sighted in the suggestion that these should be based on one special hospital and one general hospital only. To take something less personal than neurology, it is suggested in the Goodenough report that an Institute of Child Health be formed, based on Hammersmith and Great Ormond Street Hospitals. It is revealed that negotiations between these two hospitals have been going on for some time. How much more stimulating, full of broad possibilities and worthier of London would be, on the other hand, a London University Institute of Child Health, including not only Great Ormond Street but also the Belgrave, Victoria Queen Elizabeth, Evelina, Princess Louise, Paddington Green and the Infants' Hospitals, together with a relationship with possibly, several of the voluntary general hospitals in London not teaching undergraduates, such as the Royal Northern and the Prince of Wales's Hospitals, as well as with Hammersmith Hospital. This would, indeed, show the paediatric resources of London at their best, which the restricted proposal of the Goodenough report would not. Broader thinking for London as a whole is needed on this great issue, and sectional interests must not unwittingly be officially favoured.—I am, etc.,

T. ROWLAND HILL.

Postgraduate Medicine

SIR.—The generous hospitality of your columns accorded me on a recent occasion to express some views upon undergraduate instruction encourages me to ask for an extension of your indulgence for some observations on postgraduate medicine, a topic which has stimulated the interest of several correspondents, particularly in regard to "refresher courses" for the general practitioner.

That wide differences of opinion have emerged, varying from unqualified approval to complete condemnation, is not surprising

to those of us who have participated in such courses, both as students and as teachers. The trouble is to satisfy the requirements, indeed the expectations, of such widely different participants. Here is the very old gentleman who has for over forty years been peacefully isolated in the heart of the country, and who desires a sort of Cook's tour which shall be, as comprehensively as possible, representative of all that has happened in the world of medicine and surgery in, say, the last quarter of a century. There is an ambitious youngster on the eve of his M.R.C.P., avid to absorb all the latest biochemical research of examination value. Next is a recently returned Service man intending a return to practice and to recover as rapidly as possible the clinical atmosphere obscured by several years of administrative activity. Then a successful provincial G.P., who has acquired a local reputation as a specialist, and demands the fullest exposition of his particular subject. And here is a breezy man from the Midlands (or elsewhere for that matter) who has no hesitation in admitting that he regards the whole affair as an opportunity for a binge. Clearly the preparation of a schedule on a *table d'hôte* system is going to please nobody, the alternative of an *a la carte* seems theoretically sound but is not so easy to arrange. Moreover, the fare provided may be right enough but the method of pre-entertainment is open to criticism. The more experienced object, and reasonably, to being treated as medical students the assumption by the lecturer of an established acquaintance with his subject brings a protest that he is right above the heads of most of his audience. And anything highly specialized will most probably appeal to nobody at all. I have seen an hour wasted on the elaborate description of vestibular tests which even the expert himself had to work up the night before. I have sat under a recognized leader in the world of pathology dealing with all the technical details of the performance of the Wassermann reaction, and—believe me or believe me not—on his appealing at its conclusion for any questions or remarks, an awkward silence was terminated by an assurance from an enthusiast in the front row that he now understood that the rabbit was a victim of congenital syphilis.

One of your correspondents, Dr Trevor Howell, approaches the "refresher course" from another angle in advocating a prolonged period of practice in hospital in the capacity of clinical assistant. With that I am in hearty agreement, but such a procedure would hardly recommend itself to the official promoters of a "refresher course" which embodies the somewhat pernicious idea of an intensive attempt to "be brought up to date." Comparisons are often made between post-graduate instruction in this country and on the Continent. I know how such instruction is organized in Vienna, or at least how it was organized thirty years ago, and I think that adverse criticism of our performance is not fair. The time and energy unavoidably dissipated by the vastness of the Metropolis and the difficulty of collecting and utilizing our material make adequate organization impossible. But this is outside the present consideration, the "refresher course" for the general practitioner, which we shall certainly be called upon to provide in post bellum reconstruction—I am, etc.,

ADOLPHE ABRAHAMS

L 3 F W 1

Psychological Medicine and the Family Doctor

SIR—Dr R. D. Gillespie (Aug. 26, p. 263), as a specialist himself of long standing, says in effect that the old family practitioner was in a much better position to understand, and therefore to deal with, the psychoneuroses of daily life than is the highly specialized modern expert, by whatever name he styles himself (and perhaps I might add, whether lay or medical). The fact is that in the palmy days of the old family doctor—particularly in the country—these psychoneuroses did not exist, or at least not to anything approaching the modern extent, and this precisely because the family itself still existed as the basis of social life, and self-respecting and sympathetic parents brought up their children intelligently, and so nipped such conditions in the bud. Where parents had difficulty in this they consulted the old and tried friend of the family, the local G.P., who knew every one of them "from father to son," and all their circumstances in space as well as time. Now, however, the family is disappearing swiftly, and never more so than at present, since this world war or unprecedented

brutality has set its seal on a long era of cut-throat "industrial" competition.

The outlook for sanity, let alone ordinary mental and moral equipoise, is black indeed. What, for example, is to be done with all the poor shattered psyches which the global war everywhere is leaving in its slimy train? This at least can be forecast. The problem will not be solved primarily by the psychological specialists, since they, as Dr Gillespie has shown clearly enough, are not in a position to evaluate duly all the factors.

It is just possible that our profession itself might solve the problem, but this only on condition that it foresees the further instalment of slavery which the State now proposes to foist upon it, and that it resolves to restore at once the family doctor to his rightful place as the driving wheel of the *Ars medendi*—I am, etc.,

North Queensferry Fife

A. J. BROCK

Bureaucracy and Wet Babies

SIR—Although I have been engaged in busy medical practice for half a century I have found time to read my *BMJ* every week. But, although I am also a prolific writer, I rarely intrude on pages which are rightly handed over to my senior and junior professional pastors and masters.

This week, a moment's respite coinciding with a touch of the *cacoethes scribendi*, I feel a desire shortly to comment on three items in your issue of Sept. 23. One item is your review of Prof. Mackintosh's *The Nation's Health*, on which the only thing I have to say is that, basing my opinion on experience and first-hand observation, I think that nearly all Prof. Mackintosh says and hopes to do, or see done, is in my opinion sound. The second item is your leader titled "Medicine and Politics." I am an old admirer of Lord Dawson of Penn, and in the present instance intellectually in enthusiastic agreement with his "wise letter" published in the *Times* of Sept. 16. Doctors entered on dangerous ground when they began to play that national game known as party politics. The third item—possibly the most important of all—is Dr S. M. Halliday's letter on "Wet Babies," written from Zennor, a lovely bit of Cornwall, every yard of which bit I know and love. This letter gives us some common sense expressed in plain English. I hope it will act as a model for other letters dealing in a humorous honest way with problems which confront general practitioners every week, war or no war—I am, etc.,

Hawkes Hants

HARRY ROBERTS

Service Medicine

SIR—The letter in your issue of Aug. 19 (p. 255) under the above heading and over the signature "Temporary Serving Officer" seems to have a distinct flavour of "sour grapes." Your correspondent does not specify to which of the three Services he is at present attached, but by thus signing himself he makes it evident that he can have but a very limited knowledge of the many intricacies of administration inseparable from huge organizations such as the Navy, Army, or Air Force Medical Services.

His idea that administration consists of "signing redundant documents unread" may be dismissed as childish petulance. Does he seriously suggest that the enormous amount of work involved in organizing the medical and surgical units operating on all the various fronts can be "devised and operated for the most part by people whose training is far shorter than that required to graduate in medicine" or that this job can be done by men with no previous medical knowledge?

He is incorrect in stating that the Regular officers hold nearly all the key positions. They do hold a large number, of course. That is quite natural. But many non-Regular medical officers, both in the last and in the present war, have risen to high rank in the Army, not through any undue influence, but by virtue of their own outstanding abilities. For instance, the D.M.S. Egyptian Expeditionary Force in Palestine during the last war was a Territorial officer and a non-regular "Temporary Serving Officer" seems to be smarting under a sense of grievance that he has not attained high rank. At least, that is the impression one gains from his letter. But I can assure him that he will not

get very far if he adopts a self-righteous attitude by insinuating that he is one of their "professional betterers." Many Regular officers in the three Services are very well qualified professionally and have deservedly attained their present position by sound and honest work. Surely after the long years of service they are entitled to that rank.

That red tape and other faults exist in the Medical Services cannot be denied, but these will never be remedied by such biased attacks on the senior Regular medical officers, who are in no way responsible for the existing regulations. The spate of documents which have to be signed by all military and naval medical officers are often very irksome, but it should always be remembered that every medical certificate, however unimportant it may seem, may have an important bearing on the soldier's ultimate chances of a pension, and injustice to that soldier may very easily be inflicted by a carelessly worded or illegible certificate. To ensure that this does not occur is the essence of good administration which your correspondent "Temporary Serving Officer" so much derides.—I am, etc.,

J. R. POOLER,
Lieut.-Col., R.A.M.C. (T.A.), retired.

Medical Services—Home and Colonial

SIR,—May I congratulate you on some of the letters published in the current issue. After thirty years' experience, Civil Service, Army, and local government service, I would like Dr. Purcell (Sept. 23, p. 417) to know that it is not necessary to go to the Colonial Service to find a similar state of affairs. I feel that, where medical administrators are appointed by laymen, this kind of thing is likely to happen. If posts of this kind could be filled in some way through selection by one's colleagues a more satisfactory result might be obtained.—I am, etc.,

St Lawrence's Hospital, Caterham.

THOMAS LINDSAY,
Medical Superintendent.

Demobilization and the E.M.S.

SIR,—With the vexed question of demobilization now under open discussion the broad principle of age and years of service can reasonably be accepted as a basis in assessing priority for return to civilian life. I would also advance a plea for the inclusion of other forms of national service when applying such a scheme. In particular I would refer to whole-time E.M.S. service. If one recalls the days of Dunkirk, these hospitals were staffed by virtual conscription, mostly at a few days' notice, of senior residents and junior staff of the large voluntary and municipal hospitals, to meet a very grave national emergency. The Ministry of Health then required a contract to be signed, and at a later date refused to consider any release till a satisfactory substitute had been obtained. This situation continued throughout 1941, and not until the demands of the Services became insistent, at the beginning of 1942, was the situation eased. The E.M.S. Hospital Services during this time cared for the majority of the Service sick and wounded as well as the air-raid casualties, evacuated sick, and industrial accidents. It can be truthfully stated that whole-time service in an E.M.S. hospital was, at this time, of equal importance in prosecuting the war as service in the armed Forces. It is only fair that such service should be counted when assessing the priority of a medical officer for demobilization. It should also count towards the proposed increase in pay after three years' service. I would personally suggest that a year be added to the age for each three months' service in a B1 appointment and for each six months in a B2 post.—I am, etc.,

ROBERT J. RUTHERFORD.

Tapeworm in Trout

SIR,—In his letter (Sept. 16, p. 385) Mr. K. Unsworth refers to the note by Mr. J. R. Harris and myself (Sept. 2, p. 310), and implies that we regard the Dublin outbreak and the outbreak in a South Wales reservoir, which was reported by Guguid and Sheppard, as being similar. The two outbreaks are undoubtedly similar in so far that a widespread mortality of reservoir trout has resulted from heavy infection with plerocercoids of the family Diphyllbothriidae. Beyond this

any similarity which may exist remains a matter for demonstration, and it was for this very reason that we did not suggest that the same species of *Diphyllbothrium* is involved in each case. Indeed our investigations so far point rather in the opposite direction, as we have failed to infect the dog, a mammal which was infected both by Duguid and Sheppard and by Unsworth when fed with plerocercoids from the South Wales fish.

Mr. Unsworth further states that we have not given sufficient evidence to show that the adult tapeworms found in the birds resulted from the ingestion of plerocercoids from the trout, but I feel that he has not attached sufficient importance to our statement that specimens showing all degrees of a gradual development from typical plerocercoids to the fully developed tapeworm were found in the infected birds. Thus in some of the birds a number of plerocercoids, a number of immature tapeworms of varying degrees of development, and a number of mature worms were present. Our article was, as stated, merely a preliminary note, and experimental details would have been out of place. To avoid any possible misunderstandings, however, it may be stated that we have succeeded in infecting black-backed and herring gulls and a shag by feeding them with plerocercoids from the trout. The details will be published in due course.—I am, etc.,

Dublin.

M. D. HICKEY.

Why Vesalius chose Basle

SIR,—Your leading article of Sept. 23 states that "it is a puzzle why Vesalius, working at Padua and often visiting Venice, the great neighbouring printing centre, should risk wood-blocks and MSS. by sending them across the Alps on a journey of 350 miles, to have his work published at Basle." The suggestion that the situation of Basle made it a convenient distributing centre furnishes only a partial solution. There were other reasons for this selection.

From its association with Erasmus, intellectual dictator of his age, the Swiss university town had become something of a literary Mecca, and many famous theological works, the best-sellers of the period, had been published there. Calvin's *Institutio* (1536) and the collected Erasmus (1540) were products of the Basle printers, who had the necessary connexions with the countries to which Vesalius evidently looked for his readers.

Notwithstanding the quality of the Venetian craftsmen, whose skill in art reproduction and fine printings of the classics enjoyed such a high reputation, it is doubtful if Venice was the best centre for the international presentation of original scientific works—your article refers to the fact that Italian medical publications were apparently little known in Paris. The number of foreign copyists of the *Tabulae*, which were printed at Venice, indicated that, with the proper introductions, an illustrated anatomical work was assured of a large public outside Italy. Vesalius, who had already made use of the facilities offered by Basle, decided to have the *Fabrica* published at that centre.—I am, etc.,

Park Hospital, London, S.E.

G. W. RONALDSON.

Early Days at Johns Hopkins

SIR,—Sir Charles Gordon-Watson complains that the article on "Early Days at Johns Hopkins" omits reference to Harvey Cushing. Apparently he forgets that the history so far published ends with 1893, eight years before Sir Charles tells us that he met Cushing when he was a young surgical resident officer. Doubtless ample justice to this distinguished man will be done in a subsequent volume.—I am, etc.,

THE WRITER OF THE ARTICLE.

The annual report for 1943 by the Curator of the Laboratory, Royal College of Physicians of Edinburgh, states that a reorganization of the work and scope of this institution will soon become imperative on account of changes in its relation with the Carnegie Trust. In the future the demand for laboratory verdicts may be expected to increase, and the large-scale reporting work involved will help the research department in two ways—by collecting useful information and by providing financial support. It is hoped that research work in the fields of haematology and statistics may be considerably extended.

Obituary

R HIGHAM COOPER, CBE, LSA

Dr. Robert Higham Cooper, formerly a well known radiologist in London and during latter years at Bournemouth, died on Sept 25 at Bournemouth aged 66. At the Annual Meeting of the B.M.A. in 1934 he was vice-president of the Section of Radiology and Electrotherapeutics. Educated at Macclesfield Grammar School, Owens College, Manchester, and at Charing Cross Hospital, he was for a year assistant to Sir James Mackenzie Davidson before qualifying L.S.A. in 1904. He served for 15 years as medical officer in charge of the electrical and x-ray department at University College Hospital and at Moorfields Eye Hospital, and he had been a member of the visiting staff at the Prince of Wales's General Hospital, Tottenham, the Evelina Hospital for Sick Children, the Royal Waterloo Hospital for Children and Women, and at the West End Hospital for Nervous Diseases, he was also for a time lecturer on radiology at the Seamen's Hospital, Greenwich. For the greater part of the last war he was consulting radiologist to the British Armies in France, with the temporary rank of lieutenant-colonel, R.A.M.C., and in the early part of 1919 became radiology adviser to the London Command. He was mentioned twice in despatches for his war work and awarded the CBE. After the war he held the post of radiologist to the Egyptian Government for three years and became a member of the War office X-ray Committee. Settling in Bournemouth, he was for some years medical officer in charge of the light department of the Royal Victoria and West Hants Hospital, and he served during the present war as radiologist to the E.M.S. at Christchurch. Dr. Higham Cooper wrote a small book in 1909 on *The Uses of X Rays in General Practice*, and contributed papers on his speciality to this and other journals.

SIR HUMPHRY ROLLESTON

SIR EWEN J. MACLEAN WRITES

It was a great privilege to know Humphry Rolleston, and I appreciated this during his Presidency of the Royal College of Physicians, and more intimately during the twelve years I was chairman of the B.M.A. Science Committee. Sir Humphry was one of the most distinguished of the many distinguished men who have been elected members of that committee, and in its camaraderie there was never, on his part, the slightest trace of insistence on any deference to his status—none surely, which based on heredity and recognized achievement represents one of the very brilliant careers of our time.

The main purpose of this short note is to claim that much of the devoted service Sir Humphry rendered to the Association was effected through the medium of the Science Committee, and I recall in particular the weight of his advice and guidance in our conferences with representatives of the Pharmaceutical Society and of the chemical manufacturers regarding the difficult subject of proprietary medicines, then again his close attendance in the various contacts and subcommittees which have resulted in the establishment of a Diploma in Physical Medicine were of the greatest help, and he was an indispensable member of the committee for the allocation of the science scholarships, grants, and prizes. He took an especial interest in the award of the Sir Charles Hastings Clinical Prize for general practitioners, and it became the practice of the committee to refer the award to Sir Humphry in conjunction with Prof. (now Sir) Francis Fraser. The report with the analysis of the works submitted was a delight to read.

With his many commitments it was little short of amazing that Sir Humphry was so consistently regular, an attendant at committees, whether the agenda dealt with special or routine matters. The tragic death in Zanzibar in 1936 of his only surviving son was a great blow, and I remember his saying, somewhat quaintly, at a subsequent date that it must have been when he was with us quietly transacting our committee business that his son was succumbing to the rioters. The Association has lost a great friend and a great supporter in the difficult times ahead.

FRANK DOUGLAS MARSH, F.R.C.S.

H. W. F. sends the following personal tribute, supplementing and correcting the notice printed on Sept. 20.

By the death, at the age of 55, of Douglas Marsh, the staff of the Birmingham Medical School has lost a valued colleague, and the Midlands of England has been deprived of the services of one of the leading consultants. In the 1914 war Marsh served four years, held a D.A.D.M.S. appointment, and received the M.C. After the war he took up the study of ear, nose, and throat surgery, and in due course became surgeon in the ear, nose, and throat departments of the Queen's Hospital, afterwards part of the Birmingham United Hospital, and of the Birmingham Children's Hospital. Marsh threw himself into these duties with energy, sound technical skill, and sane judgment, which was reminiscent of his father, the late Col. Frank Marsh, F.R.C.S., moreover, he rapidly acquired a very large private practice. He sustained, throughout his exceptionally busy life, a high reputation for reliability as a surgeon, and for perfect time keeping. He remained on the Territorial Reserve of Officers, and in September, 1939, he was called to serve as major, R.A.M.C. For the next three years he was stationed at the Royal Victoria Hospital, Netley, as ear, nose, and throat specialist. In this capacity he soon acquired a reputation for hard work and sound practice, which was as high as in civil life. About two years ago arthritis compelled him to return to civil life. He resumed his Birmingham work, and notwithstanding his desire to reduce his labours, the demand for his services was so great that he could obtain but little respite. During the earlier part of this summer his health failed.

Such is the outline of the life work of a remarkable man. Tall, erect, grave, courteous, and rather shy, Douglas Marsh was a man of few words but strong ideals. His admiration for his father, who was a Victorian, and in his day a model of energy and shrewdness, encouraged his own steadfast application to his profession, and consequently he had little time for relaxation—although at golf in his youth he had been more than good. He loved good pictures, good furniture, pleasant people, and a quiet chat. He wrote little, though his articles were characterized by balance of judgment and care in the choice of words. But as a practising surgeon he developed carefully selected and highly polished methods, both in the operating theatre and in the consulting room, which enabled him to carry out an enormous amount of work of a uniform high grade without hurry, and apparently without fatigue. His calm manner betrayed neither weariness nor anxiety nor signs of irritation. This characteristic attitude was well known to a wide circle of patients, doctors, and fellow workers. His intimate friends, however, were fully aware that underlying this achievement of professional skill and manner there was a sensitive man who felt both fatigue and depth of anxiety, and, moreover, a sense of humour which his reticence seldom permitted him to exhibit. To Mrs. Marsh, formerly a brilliant student of the Birmingham Medical School, and to their son our warm sympathy is extended in the loss of a husband and a father, who was not only an invaluable doctor to others but a staunch and beloved comrade to them.

G. FOSTER BARHAM, M.D.

Sir Hubert Bond sends the following tribute to the memory of Dr. Guy Foster Barham, whose career was briefly recorded in the *Journal* of Sept. 23.

For 27 years Foster Barham filled the onerous post of superintendent and physician-in-chief of Claybury Hospital, which, when opened in 1893, was the fifth of the County of London's mental hospitals. After some resident general hospital experience he joined the staff at Claybury, of which Dr. (afterwards Sir Robert) Armstrong Jones then was superintendent. There his interest in psychological medicine was aroused every year deepened it, and it was to his great satisfaction when in 1907 he was appointed deputy superintendent of Long Grove, the ninth and newest of the L.C.C.'s mental hospitals, which then was just about to receive patients. Here for the next ten years he found wide scope for his great talents, and though as senior medical officer of the women's division with its 100 beds his administrative duties were many, it was ever towards the clinical side of his work that his main interests lay. Those were the days when the effect of Freud's work tended to be dominant; they were the days, too, when mental hospitals were far less well equipped than now with x-rays and other means of physical investigation really thorough in character, nor was there attached to any of them an active team of visiting specialists. Barham, while never losing his foothold in the bodily organism as a whole, was attracted strongly towards psychotherapy and spared himself no pains, often with striking success, in using it in accessible psychotic states. This attraction can be seen in the thesis for his Cambridge doctorate—*"The Influence of Emotional Conflicts and of Repressed Emotion in the Causation of Abnormal States of Mind"*—and in many of his case studies. August, 1917, saw him back again at Claybury, this time as superintendent. There, in response

to the ever-increasing demands for further facilities in the treatment of mental disorders, he was able to initiate many improvements. One was the erection of Forest House, to which his name deservedly some time might be given; for, designed with scrupulous care to meet the needs of early and sensitive cases, for whom he felt the large building was unsuitable, it truly was his child. He took, too, an ardent interest in efforts to improve the status and training of mental nurses, and was an active member of the 1922-4 departmental committee on that subject.

An accomplished physician in the best sense of those words, Barham possessed a fastidiousness of taste which led him always to seek the best. He had, too, a tidiness of mind which characterized all his work. These attributes were reflected in his bearing and person and gave the impression, which indeed was true, of some one able to bear responsibility and to direct. These are no mean assets in the control and administration of a big hospital with its 2,300 beds and some 500 staff; likewise of no small value in the handling of patients whose illness, when long continued, tends to neglect of person and deterioration in habits. Perhaps in no other mental hospital in the country were more pains taken in the arrangement of pictures and of other objects of interest to make its wards well kept and attractive.

Medical Notes in Parliament

Pneumoconiosis Report

Mr. J. GRIFFITHS on Sept. 26 asked the Minister of Fuel and Power what action he proposed on the report of the committee on the problem of pneumoconiosis in the South Wales coalfield. Major LLOYD GEORGE replied: The committee's recommendations with regard to the establishment and equipment of a treatment and rehabilitation research centre require discussion with other Departments than my own. These discussions are already proceeding. Concurrently I am examining, and propose to put into effect as soon as the necessary arrangements can be made, other recommendations which can be implemented by strengthening existing machinery. These, I hope, will include the initial radiographic examination of all new entrants into the industry in South Wales; the periodical examinations of selected groups of miners in relation to concurrent assessments of the dust conditions of their employment; and, in association with the Ministry of Labour, an investigation into the present and progressive medical condition of miners who, because of the disease, have left the industry and have taken up other employment, the object being to provide guidance as to what other occupations are best for such cases. The machinery of my Department is to be strengthened for this work by appointing a second mines medical officer in South Wales, and by adding to the testing station a new section of staff to concentrate on the work of dust assessments. I am doing everything possible to deal with this problem within the limits imposed by wartime conditions. It is my intention to pursue the subject vigorously, and to spare no effort in tackling the problems created by this disease.

Penicillin for P.O.W.

Mr. KENDALL asked on Sept 28 whether the Minister of Health, in view of the fact that penicillin was available to German prisoners, would take immediate steps to make it available for British civilians in those cases where death would otherwise result. Mr. WILLINK replied that the Government was required by the Geneva Convention to care for wounded prisoners of war, without distinction of nationality, equally with our own personnel. The bulk of the penicillin at present available was required for Service cases, and the amount which could be released for the treatment of civilians was not sufficient to enable penicillin to be given to every case which might conceivably benefit from it. It was necessary to reserve this small amount for the treatment of cases in which it might be the only means of saving life or of effecting recovery from grave illness and in which the prospects of recovery were high.

Evacuation from London

On Sept. 26 Dr. HADEN GUEST asked the Prime Minister if he would state the Government's present policy in respect of the evacuation from London and Southern England of mothers with infant children, school-children, aged and disabled persons, and in-patients in hospitals. Mr. WILLINK, who replied, said that, as announced on September 7, the Government had decided to suspend further evacuation under the Government evacuation scheme from London and Southern England; it had also suspended the evacuation of hospital in-patients. On the other hand, he had already said on several occasions that the Govern-

ment's advice to those already evacuated from London and Southern England was, "Do not come back."

Battle Casualties and Sickness in Allied Armies

Reviewing the war on Sept. 28 Mr. CHURCHILL said there were now between 2,000,000 and 3,000,000 men in France of the British and American Armies. The British had lost upwards of 90,000 men killed, wounded, and missing, and the United States, including Gen. Patch's Army, over 145,000. Along the eastern frontier of India the 14th British Imperial Army amounted to between 250,000 and 300,000 men. In the first six months of the present year this Army sustained 237,000 cases of sickness which had to be evacuated to the rear and tended in hospital. More than 90% of these cases returned within six months. In addition, there were over 40,000 battle casualties within the same six months. He trusted the inordinately heavy toll of disease would be markedly reduced in future operations. Many preventives of tropical disease had been discovered and safeguards against the onslaught of insects of all kinds. The D.D.T. powder, which had been fully tested and found to yield astonishing results, would henceforward be used on a great scale by the British Forces in Burma and by American and Australian Forces in the Pacific and indeed in all theatres, together with other remedies constantly improving. The Japanese also suffered from jungle diseases, and malaria. Eradication of lice from Naples by strict hygienic measures could be held to have averted a typhus epidemic in the city and neighbourhood when the Allies occupied them.

Col. WICKHAM spoke of the fighting in New Guinea, where even open country was covered with grass infested with the dreaded typhus mite. Even in the hospital tents there the men were cheerful, though in some cases suffering from painful skin affections. A friendly informality existed between doctors, nurses, and patients, but medical discipline and precautions were enforced and observed. It was irksome in that climate to wear long trousers and gaiters, to button wristbands and to take regular doses of atabrin. But the results had been remarkable. Even in fighting conditions the incidence of malaria had been reduced from 100 per 1,000 per week to 2 per 1,000. Prophylactic measures were almost omitted from the Japanese medical programme, and the Japanese were less resistant to tropical diseases such as malaria and dysentery than were men of the white races.

Medical News

The recently formed Edinburgh Branch of the Polish Medical Association in the United Kingdom will hold its first meeting on Sunday, Oct. 8, at 3.15 p.m. at Scottish-Polish House, Greenhill Gardens, Edinburgh. It will be addressed by Dr. G. De Swiet.

The annual meeting and conference of the Tuberculosis Association is being held on Oct. 12 (afternoon, at the London School of Hygiene and Tropical Medicine), Oct. 13 (clinical meeting and discussion at Harefield Sanatorium), Oct. 14 (morning, at Manson House, Portland Place, W.). The annual general meeting will be held on Oct. 12 and Prof. Major Greenwood will deliver an address, "A Retrospect," on Oct. 14.

The Association of Austrian Doctors in Great Britain (14, Craven House, 121, Kingsway, W.C.2) makes the following announcements: A meeting on Friday, Oct. 13, at 6.45 p.m. to discuss jointly with the Austrian Pharmacists Group "Therapeutics in Austria and Great Britain"; Sunday, Oct. 29, 11.30 a.m., jointly with the Association of Austrian Chemists and Scientific Workers, a lecture on life-saving and life-preserving plants (vitamins, alkaloids, penicillin). The meetings will be held at the Austrian Centre, 69, Eton Avenue, N.W.3 (near Swiss Cottage Tube station).

A meeting of the Council of the Medical Superintendents' Society will be held at the Queen's (L.M.S.) Hotel, Birmingham, on Saturday, Oct. 14, at 2.30 p.m., and Sunday, Oct. 15, at 10 a.m.

The Association for Scientific Photography (Tavistock House North, Tavistock Square, W.C.1) announces the following meetings to be held this year: Saturday, Oct. 14, Caxton Hall, Westminster, 2.30 p.m., papers on cinematography. Saturday, Nov. 25, 16, Princes Gate, S.W., 3 p.m., electron micrography. Saturday, Dec. 30, Caxton Hall, 2.30 p.m., choice of materials for scientific photography.

An autumn series of lectures on medical and allied subjects will be given at the Royal Institute of Public Health and Hygiene, 28, Portland Place, W., on Wednesdays, Oct. 18 to Nov. 22, at 3.30 p.m. Seats are reserved for Fellows, Members and Associates of the Institute, but accommodation is provided for others who are interested in health problems. The Museum of Hygiene may be viewed before or after the lectures.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales during the week notifications of scarlet fever exceeded those of last week by 340 and those of diphtheria by 60; there were 271 fewer cases of dysentery, and 140 of whooping-cough.

Scarlet fever is prevalent in the north; Yorks West Riding recorded 105 more cases than last week, and Lancashire 35 more. Whooping-cough showed a lower incidence except in the north midlands, where notifications rose by 30. Although the total notifications of measles went up by only 17, there were local fluctuations: in the combined south-eastern and south-western areas the notifications fell by 93, but there was a rise of 58 in Lancashire.

For the fourth week the notifications of diphtheria have increased, and the total is now 38% higher than a month ago. Gloucestershire notified 25 more cases than last week, Durham 15, and Yorks West Riding 14.

Although there were 271 fewer cases of dysentery than last week the incidence remains at the very high level of 351. The largest returns were Glamorganshire 43 (Cardiff C.B. 41), Essex 30, London 24, Derbyshire 23, Staffordshire 21, Lancashire 21, Hertfordshire 20, Southampton 14, Durham 13, Surrey 12, Dorset 12, Suffolk 10, Kent 10.

In Scotland measles notifications went up by 44, scarlet fever by 29, and diphtheria by 25, while those for whooping-cough fell by 39. The notifications of dysentery were 7 lower than last week, three-quarters of the total cases being returned from the two cities of Edinburgh and Glasgow, which reported 30 and 50 cases respectively. There were 39 deaths from infantile diarrhoea in the large towns, still over twice as many as during the corresponding period last year: 32 of these deaths were registered in Glasgow.

In Eire the incidence of diphtheria rose by 21 cases. Thirty-seven registration areas were involved. 148 cases of diarrhoea and enteritis were recorded in Dublin C.B.

Diphtheria Immunization

A survey by the medical officers of the Ministry of Health, based on the returns made by local authorities published in the monthly bulletin of the Ministry of Health and the E.P.H.L.S., show that mass immunization has affected the prevalence of diphtheria and in particular the mortality. In 1943 the incidence at ages under 15 was 1.16 per 1,000 among the immunized and 4.06 among the non-immunized, while the mortality per 1,000 children was 0.0104 and 0.260 respectively. In other words, the incidence of diphtheria during 1943 among children under 15 was 3½ times greater in the non-immunized group than in the immunized group and the chance of dying from diphtheria was 25 times as great.

The deaths from diphtheria in England and Wales at all ages in successive half years 1938-44 were:

	1938	1939	1940	1941	1942	1943	1944
Jan-June	1,622	1,142	995	1,476	989	801	503
Jul-Dec	1,238	990	1,483	1,165	838	559	—
Year	2,860	2,132	2,480	2,641	1,827	1,370	—

The greatest fall in the number of deaths occurred, as would be expected, in the age groups in which immunization was concentrated. The death rates per 100,000 of the estimated population were:

	Ages								
	0—	1—	2—	3—	4—	5—	10—	15—	—
Average rate 1931-41	10	24	40	53	59	41	10	0.6	
1942	7	17	24	38	41	26	6	0.6	
1943	8	11	19	26	29	17	5	0.7	

Week Ending September 23

The notifications of infectious disease in England and Wales during the week included: scarlet fever 1,696, whooping-cough 1,059, diphtheria 566, measles 1,509, acute pneumonia 435, cerebrospinal fever 33, dysentery 365, paratyphoid 8, typhoid 12, poliomyelitis 16, polio-encephalitis 1.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 16.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available

Disease	1944					1943 (Corresponding Week)				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)

Typhus fever .. Deaths	—	—	—	—	—	—	—	—	—	—
Whooping-cough* .. Deaths	1,083	52	91	61	7	1,531	117	221	63	17
Deaths (0-1 year)	355	30	94	46	28	314	48	70	52	27
Infant mortality rate (per 1,000 live births)	—	—	—	—	—	—	—	—	—	—
Deaths (excluding stillbirths)	3,931	435	650	181	131	3,655	590	536	198	113
Annual death rate (per 1,000 persons living)	—	—	—	—	—	—	—	—	—	—
Live births	6,271	413	822	373	304	5,902	758	858	417	257
Annual rate per 1,000 persons living	—	—	—	—	—	—	—	—	—	—
Stillbirths	191	15	40	—	—	197	25	41	—	—
Rate per 1,000 total births (including stillborn)	—	—	—	—	—	—	—	—	—	—

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

The Services

CASUALTIES IN THE MEDICAL SERVICES

Killed in action in Italy.—Capt. David Halpern, R.A.M.C.

Missing, presumed killed on active service.—Surg. Lieut. Richard Leslie Hall, R.N.V.R.

DEATHS IN THE SERVICES

Lieut.-Col. JOHN TELFER CALVERT, C.I.E., died, aged 80, on Sept. 20 at Eastbourne, where he had lived since retiring, after a distinguished career in the Indian Medical Service. He was educated at St. Thomas's Hospital, graduated M.B.Lond. in 1887, and took the Cambridge D.P.H. in 1889. During leave home he passed the M.R.C.P. in 1906, and was elected a Fellow of the Royal College of Physicians of London in 1917. He gained a high place at the entrance examination to the I.M.S. in 1889, and saw active service at Manipur on the N.E. Frontier in 1891, and on the N.W. Frontier in the Tirah Campaign in 1897, with medals and clasps. Soon after, he joined the Bengal Civil Medical Department and held civil surgeonships, including that of Cuttack, with much surgical experience and charge of a medical school. Later he was appointed physician and professor of materia medica at the Calcutta Medical College and edited the 4th edition of Ghosh's *Materia Medica*. He was subsequently promoted to be Principal of the Medical College and professor of medicine, a very onerous post in which he proved to be a good administrator and teacher. He was a Fellow of the Calcutta University, and became Dean of the Medical Faculty and President of the Board of Health, Calcutta. Col. Calvert was awarded the C.I.E. in 1919 shortly before his retirement. He was a popular officer and had a great fund of good stories, and contributed papers to the *Indian Medical Gazette*. He joined the British Medical Association in 1891 and became vice-president of the Section of Medicine at the Annual Meeting of 1931. He leaves a wife, three sons, one of whom is in the Naval Medical Service and another in the British Army, and a daughter to mourn his loss.

Universities and Colleges

UNIVERSITY OF LONDON

Prof. Frank Goldby, M.D.Camb., has accepted the appointment to the University Chair of Anatomy tenable at St. Mary's Hospital Medical School and hopes to take up his post during the session 1945. Since 1937 he has been Elder Professor of Anatomy in the University of Adelaide.

The following appointments, both tenable at the College of the Pharmaceutical Society, have been made: H. Berry, B.Sc., Ph.C., F.R.I.C., to be Professor of Pharmaceutics; W. H. Linnell, D.Sc., M.Sc., Ph.D., Ph.C., to be Professor of Pharmaceutical Chemistry

UNIVERSITY OF LIVERPOOL

The following candidates have been successful in the Final Examination for the degrees of M.B., Ch.B.:

Part I: Cécile N. Broster, G. B. Brown, J. H. E. Carmichael, P. Hampson, Vivien P. Helme, Maureen M. Hoey, D. T. L. Hughes, J. C. Humber, G. C. Hunter, Olive R. Rodgers, L. Rosenbloom, K. S. Shaw, D. R. Wallace-Jones

Part II: M. M. I. el Haddad, P. R. B. Jones, R. D. B. Williams.

UNIVERSITY OF SHEFFIELD

The following have passed the recent Final Examinations in the Faculty of Medicine:

M.D.—F. Ellis (with distinction); P. M. Inman.
M.B., Ch.B.—Parts II and III: *Marjorie Hallatt, *M. H. Oliver, *L. L. Ralph, *W. J. W. Sharard; *Isabella M. Almond, B. R. Eaton, D. P. Greaves, G. K. E. Inman, J. W. Laws, J. D. Simpson, D. R. Thompson.

* Second-class honours.

UNIVERSITY OF DURHAM

The Court of the University of Durham resolved, on July 31, that Mr. John Hamilton Barclay, M.D., M.S.Dunelm, F.R.C.S., be appointed to the part-time Chair of Surgery as from Aug. 1, 1944.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following demonstrations will be given at the College in Lincoln's Inn Fields at 4 p.m. on each day: Monday, Oct. 16, Prof. A. J. E. Cave, Anatomy of the Pituitary Gland; Tuesday, Oct. 17, Mr. L. E. C. Norbury, Simple Tumours of the Rectum and Colon; Wednesday, Oct. 18, Prof. Cave, Anatomy of the Adrenal Gland; Thursday, Oct. 19, Mr. R. Davies-Colley, Diseases of the Stomach and Intestines; Friday, Oct. 20, Prof. Cave, Anatomy of the Thyroid Gland. The demonstrations are open to advanced students and medical practitioners.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Whooping-cough Prophylaxis

Q.—What is the duration of the immunity that may reasonably be expected from prophylactic inoculation against whooping-cough?

A.—Probably nobody has sufficient data to say much with confidence about the duration of protection from inoculation against whooping-cough. The present position, briefly, seems to run thus. Bell (*Publ. Hlth., Rep. Wash.*, Aug., 1941) and Kendrick (*Amer. J. Hyg.*, 1943, 38, 193) published highly encouraging results of work in the U.S.A. running from 1938 to 1943; vaccination is not yet in general use in America. These authors used alum-precipitated vaccine; this is not yet generally available here. Further experience and evidence is obviously much needed. (See also answer to question on "Mixing Pertussis Vaccine and Diphtheria Prophylaxis" in the *Journal* of Feb. 12, 1944, p. 243).

Snoring in the Shelter

Q.—Can you suggest any cure or alleviation of a patient, male, aged 55, who, by his snoring habits, disturbs all the other shelterers? His upper respiratory organs are quite clear, and there is no nasal obstruction. Sleeping on his back or side makes no difference.

A.—With the conditions as set out in the question the next step in treatment is to ensure nasal breathing by using a mouth shield. This is fitted by a dental surgeon, rests between the lips and teeth, and is more efficient and better tolerated than other mechanical means of preventing mouth breathing.

Otitis Media and Otitis Externa

Q.—Can an external otitis cause an otitis media? A patient had an external otitis which flared up suddenly. The drum was previously intact—no old scars or atrophic patches. Following this acute flare-up there was a small central perforation—discharging pus. The pain during the flare-up, which lasted little more than one day, was that of an external otitis—no mastoid tenderness. The patient had no coryza and no otitis media. The following day the canal tended to widen and was discharging. The drum was not seen, and the perforation found about a week after the flare-up.

A.—Except in cases in which the infection passes through a pre-existing dry perforation, otitis media secondary to otitis externa is of the utmost rarity. When it does occur, it is generally associated with fungus infections.

Vulval Warts

Q.—A married woman, pregnant, had a vaginal discharge, frequent and painful micturition, warts on the vulva. Wassermann reaction was negative and smears of pus did not have gonococci. These findings were confirmed by a specialist on venereal disease. However, she was given a course of treatment with "sulpha" drugs. The question is, What percentage of cases of purulent vaginal discharge with vulval warts are venereal? Was the infection in this case gonococcal in spite of the absence of gonococci? What is the best treatment for these warts in cases of gonorrhoea and, secondly, in cases where gonorrhoea cannot be established?

A.—It is quite impossible to say with anything approaching accuracy what percentage of cases of purulent vaginal discharge with vulval warts is venereal; much depends on what is meant by the term "venereal"; at a guess, perhaps 60% is due to the gonococcus. It is equally impossible to say whether the case in question was gonococcal; if it reacted well to chemotherapy, the betting is that it was because gonococci are more susceptible to "sulpha" drugs than most organisms. The converse does not necessarily hold because there are many resistant strains of gonococci. The fact that gonococci were not found does not rule out gonorrhoea; these organisms are often very difficult to find,

especially in females, and repeated smears and cultures are necessary before their presence can be excluded. The treatment of vulval warts is the same whether they accompany gonorrhoea or not, except that the treatment of the discharge, which is essential, varies with the cause. The most effective local treatment is removal with the electrocautery. See also the answer published on Nov 13, 1943 (p 631).

Pyretotherapy for Gonorrhoea

Q.—Please describe the T.A.B. shock treatment for gonorrhoea. To what extent is this effective for non-venereal infections of the urethral tract and chronic non-venereal prostatitis?

A.—It is assumed that the patient is sulphonamide resistant and that two courses of sulphathiazole or sulphadiazine have failed to establish cure. In the first place it is essential to examine the patient and to exclude serious heart or other visceral disease which would contraindicate T.A.B. therapy. The technique is described in the *Journal* of Aug 28, 1943 (p 288). A different "sulpha" preparation from the original one—e.g., sulphadiazine if sulphathiazole was used first, may be given immediately before, during, or immediately after the pyrexial therapy in doses of about 4 g daily for five or six days. Pyrexial therapy is often effective in nongonococcal infections of the urinary tract and in chronic nongonococcal prostatitis, but should be combined with other measures, especially in the latter—e.g., irrigations and prostatic massage. It should be remembered that this form of therapy involves some, if a very slight, risk to life, it should not, therefore, be undertaken lightly or in the absence of full medical and nursing facilities.

Joss-sticks and Mosquitoes

Q.—In the East before the war it was possible to procure a "mosquito coil" made in Japan, which burnt very slowly, giving off a faint smoke and a pleasant incense like aroma. The burning of a coil for even a few hours in the evening would drive away every mosquito or at least make them so drowsy that they could easily be caught in the hands and destroyed. Is it possible to procure such things in this country now? Alternatively, what is the composition and how are they made? When so many people sleep in shelters—the abode of these night hunters—it would be a boon to be rid of these pests.

A.—Several kinds of pastilles for domestic use as fumigants against mosquitoes are not uncommonly seen in use in India and probably other places in the East. One is in the form of taper like sticks (Chinese joss sticks they are often called), another is moulded into a coil, or they may be small cones like miniature volcanoes, which can be lighted at the top to burn slowly, giving off an incense like smoke. Probably all are dependent for their effectiveness on pyrethrum, the powdered flowers of one or two species of chrysanthemum (*C. cinerariaefolium* or other species containing the active principle), now very difficult to obtain owing to shortage of this material, which formerly came chiefly from Japan and Dalmatia. How far such pastilles are obtainable in this country, or even now elsewhere, is unknown to the writer, but they could easily be home made if the necessary pyrethrum—e.g., Keating's—could be obtained.

Howard and Bishop (*Mosquito Remedies and Preventives* U.S. Farmers' Bull. No 1570) give the following: "The powder (pyrethrum) is heaped up into a little pyramid which is lighted at the top and burns slowly, giving out a dense and pungent smoke. Often the powder is moistened and moulded roughly into small cones, and after drying it burns readily and perhaps with less waste than does the dry powder." Another substance used in the same way is *Datura stramonium* made up with nitre in the proportion of 1 to 3 of datura. Probably some nitre would improve the first mentioned recipe. It is important that the pyrethrum powder should not be too old. Pastilles of this kind are also made from the dry powdered pellitory root (*Pyrethri radix*, the dried root of *Anacyclus pyrethrum*). Such joss sticks, cones, etc., are often effective to a certain extent in clearing living rooms of mosquitoes or keeping them at bay, but they are more a domestic palliative than a serious means of dealing with mosquitoes for public health purposes or in the Army, where spraying with some insecticide of the "fit" type or special insecticide is the usual method employed. Nevertheless, the joss stick enjoys considerable popularity as a domestic adjunct, and it might possibly be developed and used more. The difficulty at present is to obtain pyrethrum or an effective substitute. In Russia anabasine (obtained from the plant *Anabas aphilla* and its hybrids), usually in the form of the sulphate, has been found very effective as a fumigant against mosquitoes. But again it is doubtful if this substance could be obtained in this country.

Dipsomania

Q.—Can increased cerebrospinal fluid pressure be reduced by any simpler procedure than lumbar puncture? An American neurologist maintains that this increased pressure, resulting from an allergic reaction to alcohol is the pathological basis of dipsomania.

A.—It would be well to comment upon the second part of this question first. The statement that dipsomania is caused by high

intracranial pressure resulting from allergic reaction to alcohol is not only novel, but is really, so far as one knows, founded upon no definite evidence. I do not think that this statement should guide one in the treatment of dipsomania. If, however, cerebrospinal fluid pressure is to be reduced for other reasons this may be achieved by medical methods. The simplest of these is to give magnesium sulphate enemas. Use of sodium chloride or sucrose in hypertonic solution intravenously is more rapidly effective. These methods of reducing pressure have the disadvantage that they lead ultimately to reactionary increase in pressure so that the patient's latter state is liable to be worse than the first. It is consequently the practice to reserve medical methods of reducing high intracranial pressure for the immediate pre-operative period where there is structural cause for the high pressure. Because of the reasons already given, these methods are not likely to benefit dipsomania.

Heredity and Involutional Depression

Q.—How far does heredity play a part in the production of involutional depression? A patient whose father has been in a mental home for two years with this condition wishes to know whether he should limit his family in view of the possible transmission of the disease. His father was a normal clever man until the age of 55 when he broke down with profound melancholia. What would you advise?

A.—Heredity is certainly an important factor in involutional depression. A more exact diagnosis is, however, desirable. If the psychosis is of the recurrent type, with evidence of previous depressive phases, even if not of such a degree as to lead to hospital treatment, the hereditary influence is strong, and approximately one fifth of the children of persons suffering from these psychoses may be expected to develop similar trouble. If, however, it is not of this type, the eugenic prognosis is better, and the latest work gives 3% as the expectation of psychosis in the children of the original patient. The actual advice to be given to the son who is now asking advice will depend on his age and mental constitution. If he is very young, one will not be able to assess his constitution very satisfactorily, if he is, say, 35, one will be able to have a fair notion as to whether he is himself unstable. If he is an ordinary sort of man, then we can assess his own predisposition to psychosis as, say, 3%—i.e., not so much greater than the expectation of the average man. The expectation of psychosis for his hypothetical children will be negligibly greater than the average. If, however, he is an odd, psychopathic, neurotic, or otherwise unstable person, and still more if his wife is also unstable, then the outlook for the children would not be so good, and some restriction of the size of the family would be desirable. The Eugenics Society, 69, Eccleston Square, London, S.W.1, has a panel of experts who are prepared to give free advice on problems of this type when the relevant facts are presented, confidentially of course.

Milroy's Disease

Q.—A patient aged 34 has suffered from Milroy's disease since she was 17—hereditary oedema of the legs. An aunt of hers also has "swollen legs." What is the aetiology, prognosis and treatment of this disease? Is it an allergic condition? My patient has fairly frequent attacks of indigestion for which there is no apparent organic cause. Is it possible that these attacks are due to congestion of the gastric lymphatics? Her general health is otherwise good except for slight dyspnoea on exertion—e.g. cycling. No signs of cardiac disease. Urine normal. Elastic stockings and rest give only temporary relief.

A.—The aetiology of Milroy's disease is unknown. Some have suggested that it may be due to an abnormality in the structure of the lymphatics, others favour the view that it is a vasomotor disturbance. Allergy does not appear to play a part in the condition. Only the legs are affected, and this patient's indigestion is probably unrelated to the Milroy's disease. The swelling, once established, persists, and tends to increase, but the duration of life is not affected. No treatment is likely to be of permanent benefit, but massage and bandaging may be recommended. Care should be taken to avoid trauma and infection. The acute erysipelatous attacks which sometimes occur in swollen legs of this type are often associated with fungus infections between the toes and the formation of cracks and fissures which allow the entrance of streptococci.

Postponement of Menstrual Period

Q.—A patient of mine is anxious to know if there is any way in which her menstrual period might be postponed for a few days, as her husband is due for 7 days' leave just when her period is expected. Would progesterone or testosterone be of any use in delaying the onset, and, if so, what is the dosage and method of administration? Is pregnancy likely to result from intercourse during the time?

A.—Ovulation might be inhibited by testosterone or progesterone if given in sufficiently large quantities several days before ovulation is expected—that is, beginning a few days after the end of the menstrual period. Oestradiol or hœstrol has a similar action,

and is preferable. Probably 5 mg. of hexoestrol by mouth, three times daily, would be a dose sufficiently large to inhibit the pituitary-ovulatory mechanism, and the next menstruation would follow some 7 to 10 days after cessation of this therapy. This method of contraception might be justifiable in special circumstances, but is not advisable as a routine; nor could its efficacy be guaranteed. If, however, it does succeed in preventing ovulation, then pregnancy would not result from intercourse during the time the hexoestrol was being given.

Bactericidal Action of Lactic Acid

Q.—When cow's milk is prepared with lactic acid B.P. (45 to 60 drops to the pint) for infant feeding, has the lactic acid any bactericidal action?

A.—The reaction of fresh cow's milk is slightly on the acid side of neutrality—about pH 6.6. If 60 drops of lactic acid B.P. are added to a pint of milk (taking 1 drop as containing 1/20 c.cm.), the pH will be lowered to about 5.4. Though this degree of acidity might have a bacteriostatic effect on some pathogenic species of bacteria—i.e., inhibit their growth—it would probably have no more than a minimal bactericidal action at room temperature, unless the exposure was prolonged for some hours. Many pathogenic organisms produce this, or an even greater, degree of acidity when growing in the presence of a fermentable sugar. If the milk was left at a temperature favourable for bacterial multiplication, the presence of the acid would encourage the growth of lactic streptococci and of lactobacilli at the expense of other organisms.

X-ray Diagnosis of Appendicitis

Q.—If an appendix is not shown up by barium meal and x-ray examination, does it mean that the organ is pathological? The patient, aged 49, has for some years had attacks (lasting from 3 to 6 weeks) of slight pain in the lower abdomen with marked discomfort in the epigastrium 3 to 4 hours after food. The discomfort is eased by food and alkalis. All investigations proved negative except for some gastroptosis and enteroptosis and non-filling of the appendix. The abdominal symptoms have sometimes wakened the patient during the night, which looks as if the visceroptosis is not the cause of the trouble. For some time she has had also general rheumatic pains, and now signs of rheumatism of the arthritic type are appearing—the fingers swelling after gardening, etc. The patient is very active both mentally and physically, and apart from the above enjoys excellent health.

A.—An appendix which is blocked at its base obviously cannot be visualized on the x-ray film, but it would nevertheless be very unwise to accept non-visualization as evidence that the appendix is pathological unless the clinical signs and symptoms are highly suggestive. It must be recognized that a transient muscle spasm may prevent the appendix filling with barium; furthermore, a retrocaecal appendix may fill and empty at the same time as the caecum, and so be completely invisible since obscured by the caecal shadow. Even oblique views may not overcome the difficulty. On the whole, it is the writer's opinion that the x-ray diagnosis of appendicular trouble is not to be trusted, and, further, that large numbers of unnecessary operations are being performed on the basis of an x-ray diagnosis. The ultimate decision should be made on clinical grounds. An x-ray (often nowadays demanded by an "enlightened public") is as likely to mislead as to be of any help. It is advised, therefore, in the case under consideration, that the x-ray findings be ignored and the diagnosis made from clinical findings. While some of the symptoms would fit in with an appendicular colic, the relief afforded by food and alkalis is not common in appendicular cases, nor is the particular periodicity of the attacks. Insufficient data are given to make a tentative diagnosis, but further investigation—e.g., cholecystogram—should be carried out before it is assumed that the visceroptosis explains the symptoms.

Constitutional Obesity

Q.—A patient aged 40 is suffering from obesity. He weighs 16 stone, has large breasts, female in type and extremely hirsute, and has testicles slightly smaller than the average; penis also slightly smaller. Sexual interest is normal; he is married, has two children who are quite healthy, is of more than average intelligence, and is not by any means sluggish in his movements. He has never been ill, except for minor ailments. He does not overeat but drinks, perhaps, abnormal quantities of water. What treatment would bring his weight to normal?

A.—No indication is given as to the duration of the obesity. If it were of recent origin, and if potency had diminished or disappeared and genital size decreased, one would have to consider the possibility of an adrenal tumour, or possibly Cushing's syndrome if other features were present.

Taking the case as described, it is more probably a constitutional adiposity, with a hypothalamic-pituitary basis. If so, there is no specific treatment, but a low calorie diet and thyroid might be helpful. Further, if there is an element of water retention, mercurial

diuretics—e.g., injectio mersalyli B.P., 1 to 2 c.cm. injected intramuscularly, twice weekly, for one month, and repeated after an interval of two weeks, are of benefit. The mercurial diuretic should be preceded the day before by 1 g. of ammonium chloride, in capsule, t.d.s.

Streptococcal Throat Carriers

Q.—A girl aged 13 on returning from boarding school brought a report that all the girls had throat swabs taken at the end of term, and that hers and many others showed a growth of haemolytic streptococci. She was required, before returning to school, to obtain two consecutive negative swabs, with an interval of at least five days between. I should like to know—(1) Does the presence of the organisms in the throat warrant this ruling on the part of the school authorities? (2) What treatment is likely to produce the negative swabs required?

A.—Wholesale swabbing of throats in a boarding school is usually undertaken after an outbreak of diphtheria or scarlet fever or sore throat. In this instance it may have been either of the latter two infections, and apparently a goodly proportion of the symptomless contacts were found to be streptococcal throat carriers. The school authorities have probably no legal power to insist on two consecutive negative throat swabs before the pupil returns to school, but in asking for this evidence of freedom from infection they were doubtless anxious to avoid a recrudescence of the original outbreak. The chances of such an occurrence are slight, for the pupils would already have some specific immunity as a result of the epidemic spread of the infecting streptococcus, and the proportion of streptococcal carriers after a summer vacation of, say, eight weeks would likely be small. The practitioner could therefore ignore the request for negative swabs in his school-girl. If he does have throat swabs bacteriologically examined and if haemolytic streptococci are still present in considerable numbers, the girl must be regarded as a persistent carrier; in which case, nose and throat must be carefully examined, preferably by a specialist, for any pathological abnormality such as septic tonsils or sinusitis. Treatment will depend on the findings.

LETTERS, NOTES, ETC.

Midwifery and Housing

Dr. NINIAN FALKNER writes from the Master's House, Rotunda Hospital, Dublin: As domiciliary midwifery still occupies a most important position in the British Isles, it seems obvious that the homes in which confinements will take place should be planned accordingly. I would, therefore, respectfully suggest that any plans for housing on a large scale should not overlook this aspect of public health.

Wooden Bullets

Dr. L. H. TAYLOR (Maidstone) writes: I was talking over Major Pollard's recent letter (Sept. 23, p. 424) with a combatant officer, and he assured me that in an exercise last summer an officer was hit in the abdomen with one of these "bulleted blanks" and died in hospital as a result of perforation of his intestine. The range was 5 to 10 yards. So perhaps a grain of salt should be taken with Major Pollard's remarks!

Wasp and Bee Stings

Dr. J. BARR STEVENS writes: Regarding the question and answer in the *Journal* of Aug. 26 (p. 295), in 1889 there were some notes in the (June 1, p. 1226, and June 8, p. 1323) *Journal* on the treatment of snake bite with permanganate of potash. That summer I received a very painful sting, presumably from a bee, as the sting was left in my skin. I removed the sting and, inspired by the *B.M.J.* articles, rubbed into the small but obvious aperture a crystal of permanganate, with immediate and complete relief. I have frequently relieved people who have just been stung in the same way. About 1922 Dr. H. Muir Evans of Lowestoft read a paper on the treatment of stings by weavers (a stinging fish) by the injection with a hypodermic syringe of a strong solution of permanganate of potash into the spot stung. Since hearing his paper I have always used the syringe.

Sodium Morrhuate for Injection

ALLEN AND HANBURY LTD., write: The answer under the heading "Varicose Veins" on Sept. 9 (p. 360), mentions that sodium morrhuate has a variable composition. We should like to point out that injection solution of sodium morrhuate A. and H. is prepared from a selected fraction of the fatty acids of cod-liver oil—namely, those fatty acids which are so highly unsaturated that they have an iodine value not less than 300. This preparation is therefore practically free from sodium oleate. As R. T. M. Haines (*Lancet*, April 8, 1933, p. 748) has pointed out, there is reason to believe that sodium oleate is more toxic and also a less active sclerosing agent than are the sodium salts of the more highly unsaturated fatty acids. "Moramin," our preparation of ethanolamine morrhuate, also is prepared from the fatty acids of iodine value not less than 300.

A solution to the problem was not, however, forthcoming. Flexner and Sonne strains behaved in a comparable manner throughout; succinyl-sulphathiazole exercised a definite inhibitory activity on both organisms, but sulphaguanidine proved relatively ineffective; while evidence was not obtained that the persistence of infection was due to the development of sulphonamide-resistant strains of *Bact. sonnei* (Beemer and Fairbrother, 1944). A probable explanation of the uncertain action of the

sequently little doubt that a number of carriers will have developed and that such individuals will be a potential source of infection on return to Great Britain. This has already proved to be the case. *Bact. dysenteriae* has been isolated not infrequently from men returning and giving a history of dysentery some time previously but not at the time showing actual symptoms of the disease. A routine check of all persons returning from abroad is not practicable. It is therefore necessary that

THE CONTROL OF BACILLARY DYSENTERY

BY

R. W. FAIRBROTHER, M.D., D.Sc., F.R.C.P.

Lieut.-Col., R.A.M.C.

Bacillary dysentery is an important endemic disease of this country, and is characterized by frequent localized outbreaks which are usually unrelated in origin and are caused almost exclusively by the Sonne and Flexner organisms. Its incidence has increased considerably since the outbreak of the war, but this is not unexpected, as under wartime conditions it is often necessary to accept relatively low standards of hygiene; this applies particularly to troops under active-service conditions.

The failure to control bacillary dysentery in this and other countries has not been satisfactorily explained, but, following recent developments in laboratory technique, evidence is now accumulating which may provide a solution to this problem. The isolation of *Bact. dysenteriae* has been greatly facilitated, and as a result it has been possible to establish several facts which indicate that the procedures at present adopted to control the disease require careful and critical examination. Knowledge of the epidemiology of dysentery was previously derived from media with little, if any, selective action for *Bact. dysenteriae*, and was consequently often inaccurate, owing to the frequent failures to isolate the causative organisms not only from convalescents but also from actual cases of the disease. By the use of the highly selective desoxycholate-citrate medium the following points have been firmly established by many independent workers: symptomless carriers are common during an outbreak of dysentery; convalescent and symptomless carriers may excrete intermittently the organisms for long periods; sulphonamide therapy has proved satisfactory in Flexner infections, but not particularly successful in clearing Sonne infections (*E.P.H.L.S. Bull.*, 1942, 1943; Watt, Hardy, and De Capito, 1942; Fairbrother, 1943; Hardy and Watt, 1944).

The epidemiology of bacillary dysentery is thus a complex problem, but considerable progress has been made during the past two years. It is now clear that rigorous control measures and a long-term policy are necessary if the disease is to be eradicated from this country. In dealing with outbreaks it is essential that a thorough bacteriological investigation should be carried out on all clinical cases and close contacts, particularly persons concerned with the handling of food, and that all infected persons should be treated and, if possible, segregated until free from infection.

Several important questions, however, remain unanswered: one is the number and frequency of negative faecal examinations required before an individual can be declared free from infection; the second is the treatment of Sonne dysentery. The results given below confirm previous observations about the persistent but intermittent excretion of *Bact. dysenteriae* and provide further data for consideration in discussing these problems.

Technique

Samples of faeces, usually received within one or two hours of collection, were thoroughly suspended by means of sterile glass rods in small amounts of physiological saline. The thick suspensions were then plated on to desoxycholate-citrate (D-C) plates: in the case of fluid faeces, cultures were prepared directly with flakes of mucus. After overnight incubation at

37° C. suspicious colonies were selected for biochemical and serological tests; all plates were then reincubated for a further 24 hours, after which, if suspicious colonies had not been found, a negative result was reported.

The results of this investigation will be considered in two sections: (1) the carrier rate in bacillary dysentery; (2) the treatment of Sonne dysentery.

1. The Carrier Rate in Bacillary Dysentery

A favourable opportunity of studying the incidence of dysentery carriers was afforded by the arrival in this country of Italian P.O.W. from the Middle East campaign. In order to provide some sort of hygienic control the faeces of all giving a history of dysentery or enteric fever during the past three or four years were subjected to bacteriological investigation. Many samples of faeces were consequently examined, and, rather contrary to accepted opinion, it was found that the carrier state was not infrequent. From some 2,500 individuals *Bact. dysenteriae* was isolated on 245 occasions—i.e., the carrier state existed in approximately 10% of those with a recent history of bacillary dysentery. Even this figure must be considered a low estimate, since in many instances it was only possible to examine one sample of faeces from each man; as it is well established that the excretion of *Bact. dysenteriae* by carriers is intermittent, some carriers were almost certainly missed because of the limited scope of the examinations. The types of *Bact. dysenteriae* isolated from the 245 carriers are given in Table I.

TABLE I—Types of *Bact. dysenteriae* isolated from 245 Italian Carriers

Flexner ..	170	Schmitz	11
Shiga	57	Sonne	7

The majority of these carriers did not show any dysenteric symptoms, looseness of the bowels was uncommon, while the presence of blood and mucus was exceptional. There was thus no clinical indication of the infection in most of the carriers. Cultures prepared on MacConkey plates from these cases were almost invariably negative.

All carriers were given a routine course of sulphaguanidine—6 g. three times on the first day, and then 3 g. three times a day for the next five days, making a total dosage of 63 g. in six days. In order to ensure the complete elimination of the drug clearance tests were not started until five days after completion of the course, and consisted originally of three successive negative examinations of the faeces (*A.M.D. Bull.*, 1942; *E.P.H.L.S. Bull.*, 1943). During later stages of this investigation abundant evidence was, however, forthcoming that 3 successive negative results did not constitute a reliable criterion of freedom from infection: *Bact. flexneri* was isolated on one occasion after 8 successive negative results, *Bact. shigae* after 6 successive negatives, while *Bact. sonnei* was frequently isolated after 3 and on one occasion even after 10 previous negative results. In consequence, more rigorous tests consisting of 12 successive negative results were introduced to determine clearance of the infection. It follows from these observations that the earlier results of sulphaguanidine therapy in this series were not adequately controlled. However, according to the different standards used, the treatment appeared to

A solution to the problem was not, however, forthcoming. Flexner and Sonne strains behaved in a comparable manner throughout, succinyl-sulphathiazole exercised a definite inhibitory activity on both organisms, but sulphaguanidine proved relatively ineffective; while evidence was not obtained that the persistence of infection was due to the development of sulphonamide-resistant strains of *Bact sonnei* (Beemer and Fairbrother, 1944). A probable explanation of the uncertain action of the sulphonamides in Sonne infections is that, as Sonne dysentery is usually a mild disease, the organisms multiply on, rather than in the mucous membrane and do not produce the severe ulceration which is usual in the other types of bacillary dysentery. The Sonne organisms thus tend to lead a more saprophytic existence than the other members of the dysentery group, this biological variation is probably reflected in the biochemical activity of *Bact sonnei*, which is the only pathogenic member of the genus *Bacterium* to ferment lactose. In consequence of its relatively saprophytic existence, contact with the organisms by the drug is more difficult to effect than in the case of the more parasitic members, which multiply in the damaged mucosa. During sulphonamide therapy most of the organisms are eliminated, but a few, perhaps protected by faeces, escape the action of the drug and propagate when the inhibitory action of the sulphonamide is removed. There appears to be an analogy between Sonne dysentery and streptococcal tonsillitis in both conditions the clinical response to sulphonamide therapy is often good, while the bacteriological response is poor. In neither case is the failure to effect a bacteriological cure essentially due to the development of drug resistance by the organisms.

Discussion

These results confirm previous observations and indicate that in order to control bacillary dysentery it is essential that (1) all outbreaks of the disease must be subjected to thorough bacteriological investigations, and (2) stringent clearance tests must be satisfied before a case can be considered free from infection.

The eradication of the disease from this country requires the detection and treatment of all carriers of *Bact dysenteriae*. The important part played by the carrier in the persistence and spread of bacillary dysentery in the community is now firmly established and is well illustrated in the epidemic reported by Hailwood (1944). In this outbreak 292 cases of diarrhoea occurred in a unit of some 900 men while at a practice camp. The faeces from only 81 cases were positive for *Bact sonnei* but bacteriological investigations were not started until some 14 days after the onset of the outbreak, by which time the infection would have cleared spontaneously in many cases. The source of the infection was proved to be a chronic symptomless carrier who had had no symptoms of dysentery since a moderately severe attack some 12 months previously, but whose stools still yielded a heavy growth of *Bact sonnei*. This man had been mainly employed in cutting bread-and-butter.

The detection of carriers is unfortunately a matter of considerable difficulty, as many exist and some have never shown the symptoms of the disease and can only be discovered by laboratory methods which should consequently be widely applied as soon as an outbreak is reported. The introduction of highly selective media, such as desoxycholate citrate, has greatly simplified the isolation of *Bact dysenteriae* and has revealed an unexpectedly high incidence of carriers. Results obtained by the use of old media such as MacConkey's, are completely valueless in dealing with convalescent or symptomless carriers, and it is doubtful if these media fulfil any useful function in the examination of faeces.

The high incidence of carriers particularly of Flexner strains, found in Italian soldiers indicates that the development of the carrier state in bacillary dysentery is a common feature of the disease. This raises a hygiene problem of great importance. Bacillary dysentery has been widespread among our troops in N Africa, and in some 70% of cases in which bacteriological investigations were carried out (incidentally only a small percentage of the total number) *Bact flexneri* was the responsible organism. Sulphaguanidine therapy was not universally applied, little or no attempt was made to discover symptomless carriers, and in the majority of cases bacteriological control in the form of clearance tests was not possible. There is con-

sequently little doubt that a number of carriers will have developed and that such individuals will be a potential source of infection on return to Great Britain. This has already proved to be the case. *Bact dysenteriae* has been isolated not infrequently from men returning and giving a history of dysentery some time previously but not at the time showing actual symptoms of the disease. A routine check of all persons returning from abroad is not practicable. It is therefore necessary that if such individuals are involved in any outbreak they should be subjected to rigorous tests before being considered free from infection.

Another essential factor in the control of dysentery is the establishment of a satisfactory standard for the clearance tests. It is obvious that the criterion of freedom from infection at present generally accepted—i.e., three successive negative results—is quite unreliable. During this investigation positive results have been obtained in Shiga, Flexner, and Sonne infections after as many as 6, 8, and 10 successive negatives respectively, while positive results after 3 successive negatives have been encountered with great frequency in Sonne infections. Stringent measures must therefore be adopted in order to provide a satisfactory criterion of bacteriological cure, and it is recommended that (i) where laboratory facilities are readily available at least 12 successive daily negative results should be obtained, and (ii) where laboratory facilities are poor 12 successive negatives should be obtained over a period of at least 3 weeks, in all cases tests should not be started until 6 days after cessation of treatment if sulphonamides have been used. The need for a more exacting criterion of freedom from infection in cases of Sonne dysentery was pointed out by the Emergency Public Health Laboratory at Oxford (*EPHLS Bull.*, 1942) during an investigation of a small outbreak in children, they required 8 consecutive negative stools in 4 weeks or at least 6 negatives in 6 weeks before a case was discharged from isolation hospital. A few carriers may still be missed by these exacting tests, but less rigorous standards are certain to produce erroneous results and a position of false security owing to the intermittency of excretion of *Bact dysenteriae* by carriers, particularly in the case of Sonne infections. It is admitted that the segregation of apparently healthy individuals for relatively long periods is a serious proposition, but such a measure is unfortunately essential in the case of any person involved in the handling or preparation of food, or in dealing with the disease in nurseries, schools, and mental institutions where minor epidemics are prevalent and difficult to control.

The intermittency of excretion of *Bact dysenteriae* also presents difficulties in the detection of carriers during an investigation of an outbreak. Unless several faecal examinations are made from each close contact it is possible for a carrier to escape detection. Therefore, when individuals are strongly suspected of being carriers, repeated tests must be carried out before a final opinion can be given.

The control of bacillary dysentery is thus a formidable proposition. The disease is widespread and, while many carriers already exist in the community, the number is likely to increase when troops return from service overseas. Recent epidemiological studies clearly indicate that, unless the problem is tackled rigorously and a long term policy adopted hygienic control will have little effect on the incidence of the condition. Efforts to limit the disease by directing attention to personal hygiene and sanitation have not proved particularly successful, for, while these measures are simple and fundamental, they are difficult to enforce. These factors are without question of great importance in restricting transmission, but as long as the causative organisms are prevalent in a community they constitute a potential source of danger. Hardy and Watt (1944), during an extensive investigation of acute diarrhoeal disease in the U.S.A., found that dysentery bacilli could be isolated with ease from the fingers and from under the finger nails of culturally positive cases and carriers.

Under active-service conditions overseas the control of dysentery presents a much more difficult problem. The disease is often widespread in the native population, flies are abundant, hospitals are soon filled with cases, and, as laboratory facilities are relatively meagre, bacteriological control of the disease is impossible and is no longer attempted. In this country, particularly under normal conditions, the problem is much less

complex, but nevertheless careful consideration is necessary in deciding whether bacteriological control of bacillary dysentery is a practical proposition, because only thorough and intensive measures are likely to be successful. The main objections to embarking on an energetic campaign to control bacillary dysentery are: In this country the disease in adults is usually trivial, perhaps of comparable incapacitating value to the common cold, and many cases do not report for medical attention; many carriers exist; apparently healthy people may be segregated for relatively long periods; and the clinical course of the disease is readily controlled by sulphonamide therapy. It is, however, recognized that dysentery in infants, particularly undernourished infants, may be a serious and even fatal disease. Moreover, recent developments in laboratory technique have provided valuable information on the epidemiology of the disease and the detection of carriers has been greatly simplified; while the sulphonamides have proved extremely valuable in clearing all types of infection except *Sonne*. It should therefore be possible for us eventually to control bacillary dysentery provided all outbreaks are subjected to strict bacteriological control. Dramatic results must not be expected, as, in view of the wide distribution of the disease, its elimination from this country will undoubtedly prove a slow process.

Summary

The frequency of the carrier in bacillary dysentery and the intermittent excretion of *Bact. dysenteriae* have been readily demonstrated by the use of the desoxycholate-citrate medium.

Sulphaguanidine and succinyl-sulphathiazole have not proved successful in clearing persistent carriers of *Bact. dysenteriae* (*Sonne*).

The control of dysentery has been discussed and more stringent criteria recommended to determine freedom from infection—viz., 12 successive negative results.

I wish to thank the many persons who have provided valuable assistance during this investigation, particularly in the collection of the numerous specimens and the administration of the sulphonamides, and also Col. J. S. K. Boyd for much helpful criticism.

PLASMA ACID PHOSPHATASE IN CARCINOMA OF THE PROSTATE AND THE EFFECT OF TREATMENT WITH STILBOESTROL

BY

JEAN M. WATKINSON, B.Sc., M.R.C.S., L.R.C.P.

G. E. DELORY, M.Sc.

E. J. KING, M.A., Ph.D.

AND

A. HADDOW, M.D., D.Sc., Ph.D.

(From the Royal Cancer Hospital (Free), Fulham Road, and the British Postgraduate Medical School, London)

Kutscher and Wolbergs (1935) found large amounts of a phosphatase, having an optimum activity in the region of pH 5.0, in normal human prostate tissue and seminal fluid. Pursuing this investigation, Gutman, Sproul, and Gutman (1936) detected the enzyme in carcinomatous prostatic tissue and at the site of skeletal metastases secondary to carcinoma of the prostate.

Gutman and Gutman (1938) further observed an increase of "acid" phosphatase in the serum of patients with metastatic carcinoma of the prostate gland, and suggested that its estimation was of diagnostic value: patients with carcinoma of the prostate without bone metastases did not show an increase of acid phosphatase. Huggins and his collaborators (1941, a, b, c), at the University of Chicago then gave evidence that carcinoma of the prostate, in common with adult prostatic epithelium, is responsive to alterations in the level

of androgenic hormones in the organism. Injection of androgen caused a rise, and castration or injection of oestrogen a fall, in the plasma acid phosphatase. A study of the effect of castration and of oestrogen administration as a means of clinical management of advanced prostatic carcinoma showed that the improvement obtained was more than a palliation. Only 5% of the cases treated derived no benefit. Of the remainder, half showed a pronounced improvement, which was not, however, sustained for longer than 18 months. The others showed a more prolonged improvement.

The above work has been amply confirmed by other American authors: Sullivan *et al.* (1942) on the effect of castration; Kahle, Ogden, and Getzoff (1942) on the effect of stilboestrol; and Munger (1941) on that of x-irradiation of the testes. A review of the whole field has recently been given by Haddow (1943).

In preliminary investigations in these laboratories acid phosphatase estimations were performed on the plasma of normal controls, of patients with conditions other than carcinoma of the prostate, and of cases of carcinoma of the prostate with and without metastases in bone. Estimation were also carried out on normal human seminal fluid and in a case of eunuchoidism. In later work at the Royal Cancer Hospital more detailed investigations have been made on cases of carcinoma of the prostate and the effect of treatment with stilboestrol.

The cases now presented are unselected, although in one respect atypical in that they include a high proportion with osseous spread. No case was treated by x-irradiation of the testes or by castration, and in order to obtain clear results in cases in which the prostate had been irradiated previously, time was allowed for the full effect of this procedure to be assessed before oestrogen therapy was begun.

Method of Estimation of Acid Phosphatase: Principle

The pH optimum of acid phosphatase is between 4.5 and 5.0; that of alkaline phosphatase is between pH 8.4 and 10.0, depending upon the substrate used. Because of this great difference it is possible to estimate one phosphatase in the presence of the other merely by allowing it to act upon the substrate at its characteristic optimum pH. Thus the alkaline phosphatase in blood plasma is inactive at the reaction at which acid phosphatase operates best, and vice versa.

Method

The procedure for acid phosphatase determination is identical (and the solutions are the same, with the exception of the buffer) with that for alkaline phosphatase (see King, Haslewood, Delory, and Beall, 1942). An incubation time of 1 hour at 37° C. is normally used. The results are expressed in terms of units which are equal to mg. of phenol liberated in 1 hour. The calculation is carried out in the same way as for alkaline phosphatase. There are normally 1 to 5 arbitrary acid phosphatase units in 100 ml. of serum or plasma.

The colours are somewhat pale in the case of normal blood and in cases of carcinoma of the prostate in which the acid phosphatase is not greatly elevated, and it may be preferable in these instances to use a longer incubation period—e.g., 3 hours. If this is done the weight of phenol liberated (in mg.) is divided by 3 to reduce the figure to 1-hour unitage.

Solutions

Citric Acid-Sodium Citrate Buffer, pH 4.9.—21 g. of crystalline citric acid are dissolved in water, 188 ml. of N NaOH added, and the solution made up to 500 ml. The pH should be checked, and adjusted to pH 4.9, if necessary, by dropwise addition of N NaOH or N HCl. This solution should be preserved with a few drops of chloroform and kept in the ice-chest. The other solutions are identical with those described by King *et al.* (1942).

Results

Acid Phosphatase in Plasma.—The values (Table I) for normal controls are somewhat higher than those given by Gutman and Gutman (1938), which range from 0.5 to 2.5 units per 100 ml. This may be explained by the fact that these authors prefer to employ a 3–5 hours' hydrolysis, and obtain a figure for 1 hour's hydrolysis by division.

TABLE I.—Plasma Acid and Alkaline Phosphatase in Various Clinical Conditions (Average Values)

	No. of Cases	King-Armstrong Units per 100 ml.*	
		Acid	Alkaline
Normal controls	9	2.8 (1 to 5)	7.3 (3 to 10)
Heart disease	5	3.4 (1 to 5)	7.2 (5 to 12)
Anaemia	4	3.0 (2 to 4)	8.8 (5 to 13)
Cholecystitis	2	3.0 (2 to 4)	9.0 (8 to 9)
Catarrhal jaundice and hepatitis	15	3.8 (1 to 5)	16.1 (8 to 31)
Obstructive jaundice	20	3.5 (1 to 5)	56.9 (10 to 163)
Primary carcinoma (stomach)	4	4.0 (2 to 5)	10.3 (6 to 14)
Enlarged prostate	12	3.3 (1 to 5)	6.1 (3 to 9)
Carcinoma of prostate (without bone metastases)	8	3.1 (1 to 6)	8.0 (4 to 11)
" " (with bone metastases)	7	11.5 (6 to 19)	42.0 (7 to 57)

* Range in parentheses.

Acid Phosphatase in Seminal Fluid.—The method used was that described, except that the seminal fluid needed to be suitably diluted with normal saline. The results for 12 normal persons are given in Table II, which also includes two esti-

TABLE II.—Acid Phosphatase of Human Seminal Fluid

Case	Units per ml.	Case	Units per ml.
1	2,100	8	2,100
2	2,100	9	1,900
3	1,950	10	1,800
4	3,300	11	2,000
5	1,500	12	2,300
6	2,700	Eunuchoid case	24
7	870	"	20

mations on a case of eunuchoidism. They are in good agreement with those of Gutman and Gutman (1941), who reported figures varying from 570 to 3,700 units per ml. in 10 normal specimens. The eunuchoid specimens contained relatively negligible amounts of acid phosphatase. These results are expressed as units per ml., while the plasma results are as units per 100 ml., so that the quantities in the seminal fluid are relatively enormous—i.e., about 100,000 times greater.

Plasma Acid Phosphatase in Cases of Prostatic Carcinoma treated with Stilboestrol.—Table III shows the initial values.

TABLE III.—Plasma Phosphatases in Cases of Prostatic Carcinoma before Treatment with Stilboestrol

Case No.	Age	Initial Plasma Phosphatase Value (King-Armstrong Units)		Basis for Diagnosis	Site of Bone Metastases
		Acid	Alkaline		
1	66	12.2	8.9	Section	Pelvis and spine
2	68	41.0	15.0	Clinical, X-ray	Pelvis

8	57	1.3	—	"	Nil
9	77	2.9	5.5	Clinical	Nil
10	61	3.9	10.0	"	Nil (abnormal opacity ischium)

Six of the cases had a raised acid phosphatase content, and in 5 of these there was radiographic evidence of metastases in bone. Although Case 5 had an initial value of 37 units, we have as yet found no evidence of skeletal metastases, detection of which was made difficult here, as in Case 7, by the presence of osteitis deformans in pelvis and spine.

Several of the results do not show any marked distinction between prostatic carcinoma and Paget's disease. Gutman, Gutman, and Robinson (1940) also found that some cases of advanced Paget's disease had high acid phosphatase values, but in their whole series 26 sera, from a total of 32 cases of Paget's disease, gave normal readings. It is therefore possible that the few results given here are not truly representative of Paget's disease. Gutman considered the possibility that the high acid phosphatase results in Paget's disease were due to

the incomplete inactivation of the alkaline phosphatase at pH 4.9, but excluded this possibility because of the lack of proportionality between the values of the two pH's.

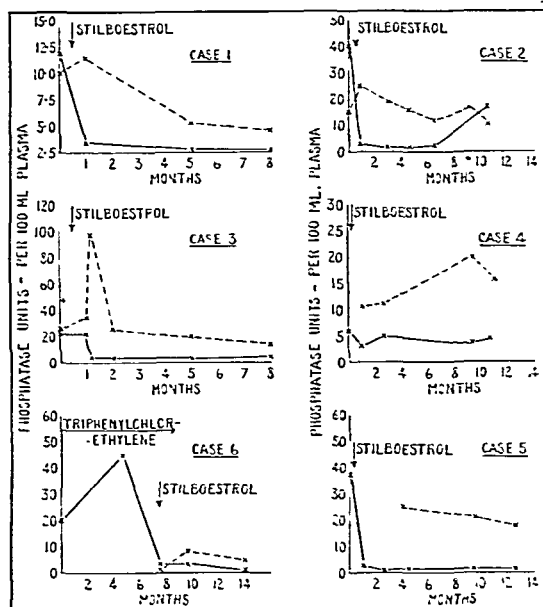

For comparative purposes 3 cases of malignant disease, other than carcinoma of the prostate, are shown in Table IV.

TABLE IV.—Plasma Phosphatases in Bone Diseases other than Carcinoma of the Prostate with Metastases

Case No.	Age	Initial Plasma Phosphatase Value (King-Armstrong Units)		Diagnosis	Site of Bone Metastases
		Acid	Alkaline

13	58	1.7	42.0	Osteitis fibrosa cystica	—

The acid phosphatase value of one case of carcinoma of the breast is higher than those recorded by the Gutmans, in which values did not exceed 4.2 units (normal taken as 2.5 units).

The accompanying graphs show the behaviour of the plasma phosphatases during treatment with stilboestrol. The acid phos-

Graphs of cases in which the plasma acid phosphatase was originally raised —, acid; ---, alkaline.

phatase falls abruptly to a normal value, which is then maintained for considerable periods, with a rise in alkaline phosphatase followed by a gradual fall. In Case 3 the phosphatases were estimated 1 week after stilboestrol therapy began, by which time 35 mg. had been given. No change had then occurred in the acid phosphatase level, but the alkaline phosphatase had begun to rise. The next set of values was obtained 10 days later, by which time 75 mg. of stilboestrol had been given and the characteristic fall in acid phosphatase had taken place.

Intramuscular administration was employed initially to obviate variations in absorption and because it gave an accurate record of the quantity administered. Dosage was very high in the first few cases treated and was reduced in

cases treated later. In spite of high dosage it appears to take an appreciable time for symptoms to improve and for a change in the prostate to be detected. The earliest improvement in back pain occurred on the 5th day of treatment, and no case showed a palpable change in the prostate before the 9th day. A full 6 months elapsed before secondary glandular masses diminished in size in Case 5. Since no case has been studied for more than 18 months (under stilboestrol therapy) it is not possible to say to what extent the dose may be reduced without detriment. There seems to be no advantage, other than that already stated, in giving the drug by intramuscular injection.

Case Records: Carcinoma of Prostate

Case 1.—Aged 66; when first seen in May, 1943, complained of backache of some years' duration and frequency of micturition for 9 months. The general condition was fair, and haemoglobin level and blood picture were normal. The prostate was coarsely nodular, enlarged, and hard, extending laterally, chiefly on the right. Firm lymph nodes were present in both groins. The right lower limb was oedematous. Biopsy of an inguinal node was compatible with a metastatic deposit of prostatic carcinoma. X-ray examination of the pelvis and lumbar spine showed osteoplastic deposits. The initial plasma phosphatase values were: acid phosphatase 12.2 units, alkaline phosphatase 8.9 units. A total of 525 mg. of stilboestrol was given by intramuscular injection in 21 days and thereafter 5 mg. t.i.d. orally. During the first three weeks of treatment a progressive oedema of lower limbs, scrotum, penis, and abdominal wall developed, with an increase of weight of 14 lb. Injections were discontinued, and in two weeks the body weight had decreased by 12 lb., with disappearance of most of the oedema. A palpable shrinking and softening of the prostate was first noticed on the 9th day of treatment, while back pain was almost completely relieved in 1 month. Nocturnal frequency lessened from 3 times to once. The case was last seen in March, 1944, when improvement was maintained, although the x-ray appearances in the bony pelvis showed an increase in the number and size of secondary deposits.

Case 2.—Aged 58; first seen in April, 1943, when he complained of back pain, dysuria, and frequency of micturition for 2 years, with a loss of weight of 2 st. in 6 months. The general condition was poor, with a haemoglobin value of 46%. Blood films showed occasional nucleated red cells. The prostate was hard, irregular, and fixed. No regional lymph nodes were palpable. X-ray examination of the pelvis revealed early osteoplastic deposits. The initial plasma phosphatase values were: acid phosphatase 41 units, alkaline phosphatase 15 units. A total of 828 mg. of stilboestrol was given by intramuscular injection in 5 weeks, and thereafter 5 mg. t.i.d. orally. Back pain was improved on the fifth day and shrinking and softening of the prostate took place in 1 month. Frequency was less in 2½ months. At the end of June, 1943, the haemoglobin level was 64% and the prostate showed a further reduction in size. In Oct., 1943, the haemoglobin was 78%. Improvement in the back pain and in the condition of the prostate was maintained, and the patient returned to his work. He was last seen in March, 1944, when he was still at work and symptom-free, although the plasma acid phosphatase had risen and there had been a progressive increase in the number of bone deposits.

Case 3.—Aged 72; first seen in Oct., 1942, when he had acute retention. Treatment was by suprapubic cystostomy and high-voltage therapy to the prostate, biopsy of which showed an alveolar adenocarcinoma of a high degree of malignancy. Early osteoplastic deposits were present in the ribs. Stilboestrol therapy was begun in June, 1943, when there were no symptoms referable to the prostate. The general condition was very poor, the haemoglobin value being 37%. Suprapubic cystostomy was satisfactory, but the urine was thick and offensive. The initial plasma phosphatase values were: acid phosphatase 21.6 units, alkaline phosphatase 24 units. The prostate was hard and fixed but not greatly enlarged. A total of 75 mg. of stilboestrol was given by intramuscular injection in 19 days and thereafter 5 mg. t.i.d. by mouth. In July, 1943, the patient was readmitted complaining of intense pain in the left calf and shoulder, of sudden onset 2 days before. The temperature was 104° F., the pulse rate 130 a minute. The left calf showed a firm tender swelling, the overlying skin being reddened and hot. The left shoulder was held fixed and was tender to palpation over a wide area. One week later a similar swelling appeared over the left deltoid. The general condition improved gradually and both swellings subsided with symptomatic treatment: they were thought to be embolic in origin. In Nov., 1943, the haemoglobin level was 72% and the general condition was still improving. No alteration was detected either in the size or in the consistency of the prostate. When the patient was last seen in Jan., 1944, the haemoglobin had fallen to 58%. The condition otherwise appeared unchanged.

Case 4.—Aged 62; first attended hospital in May, 1940, for a course of high-voltage therapy after an incomplete prostatectomy, performed elsewhere. Section of the prostate gland showed an

adenocarcinoma. In April, 1942, a firm mass appeared in the abdomen, and a further course of high-voltage therapy was given. At this time the patient complained of back pain, but x-ray examination of spine and pelvis failed to reveal secondary deposits. By Feb., 1943, back pain was constant, and radiographs now showed early osteoplastic deposits in the vertebrae. The general condition was fair, with a normal blood picture. A hard fixed residual mass was present in the prostatic bed. Frequency of micturition was pronounced. The initial acid phosphatase value was 5.3 units. A total of 315 mg. of stilboestrol was given by intramuscular injection in 14 days, and thereafter 5 mg. t.i.d. by mouth. After one month back pain had lessened, and there appeared to be some improvement in diurnal frequency. The local findings remained unchanged throughout. The patient returned to light work, but after 9 months back pain recurred, and x-ray examination of the lumbar spine and pelvis showed the secondary deposits to have increased in number and size in all areas. When last heard of he had been admitted to a local hospital on account of retention of urine.

Case 5.—Aged 70; first seen in Nov., 1942. Suprapubic cystostomy has been performed one month previously on account of acute retention. The general condition was fairly good. Haemoglobin values and blood picture were normal. The prostate was hard and moderately enlarged, with an ill-defined margin on the right. There were firm enlarged lymph nodes in both groins, with oedema of the lower limbs. Biopsy of the prostate showed an adenocarcinoma. X-ray examination of pelvis and spine revealed advanced osteitis deformans but no definite evidence of secondary deposits. The initial phosphatase values were: acid phosphatase 37 units, alkaline phosphatase 25 units. A total of 34 mg. of stilboestrol was given by intramuscular injection in 28 days, and thereafter 1 mg. t.i.d. by mouth. No change was detected in this case for 4 months, when some urine was passed per urethram (for the first time since the beginning of treatment). The prostate was slightly smaller and softer, but the change was not marked. At the end of 6 months the inguinal nodes were smaller. One year after the beginning of treatment this condition was maintained.

Case 6.—Aged 60; when first seen in April, 1941, complained of frequency of micturition. The general condition was good, with haemoglobin level and blood picture normal. Rectal examination showed a prostate of normal size, although possibly firmer than is usual, and with a suggestion of ill-defined borders. X-ray examination of the pelvis suggested secondary deposits. Diagnosis at this time was uncertain. In Sept., 1941, a biopsy of the prostate showed a columnar-cell adenocarcinoma. The plasma acid phosphatase was 17 units. The condition remained stationary for some 18 months under treatment with triphenylchloroethylene (see Haddow *et al.*, 1944), when generalized pain in the chest developed. X-ray examination showed multiple osteoplastic deposits in ribs, spine, pelvis, humeri, and femora. Stilboestrol was first given in March, 1943, in doses of 5 mg. t.i.d. orally. This was later reduced to 10 mg. daily. In 2 months pain in the chest was much less troublesome, and has remained so. The prostate has gradually become softer and smaller, although there is still lack of definition of the right lateral border.

Case 7.—Aged 71; when first seen in Jan., 1943, complained of backache for 4 months and frequency and slowing of the urinary stream for 2 months. The general condition was good. A hard nodular mass continuous with the right lobe of the prostate was detected by rectal examination. A freely mobile firm lymph node was present in the left groin and was excised. Section showed a highly cellular carcinoma, the appearances being consistent with a metastatic deposit from a primary prostatic carcinoma. X-ray examination of the pelvis revealed osteitis deformans but no secondary deposits. The initial acid phosphatase level was 2 units. A total of 117 mg. of stilboestrol was given intramuscularly in 4 weeks. After 2 weeks slight regression of the prostatic tumour was thought to have taken place. Backache had disappeared in 1 month. No further observations could be made, as the patient died at his home 2 months after treatment began.

Case 8.—Aged 37; first seen in Aug., 1942, when he complained of frequency and incontinence of urine for 5 months and intermittent haematuria for 5 weeks. The general condition was fair. The prostate was enlarged and hard. A clinical diagnosis of carcinoma of the prostate was made and a course of high-voltage therapy given in Aug. and Sept., 1942. In Feb., 1943, the patient was readmitted complaining of diarrhoea and anorexia. The general condition was now poor. A large and indurated prostate projected into the rectum, causing partial occlusion and spreading laterally into the pelvis. The lower abdomen was filled by a hard mass. Punch biopsy of the prostate showed a well-differentiated carcinoma. X-ray examination of the pelvis revealed no secondary deposits. The plasma acid phosphatase value was 1.3 units. A total of 450 mg. of stilboestrol was given by intramuscular injection in 4 weeks. Within 12 days there was a slight palpable decrease in the size of the prostate, but apart from this the general condition deteriorated rapidly. The patient died 2 weeks later. Necropsy was not performed.

Case 9.—Aged 77; first seen in Dec., 1942, complaining of frequency of micturition and haematuria. The general condition was good. The prostate was indurated, with extension to the right pelvic wall. X-ray examination of the pelvis showed no abnormality. A course of high-voltage therapy was given in Jan., 1943. By July, 1943, the prostate was still hard and fixed and enlarged to the right. The plasma phosphatase values were: acid phosphatase 2.9 units, alkaline phosphatase 5.5 units. Stilboestrol dipropionate was administered from the end of July, 1943, in doses of 5 mg. daily by mouth. After one month frequency was less, but no change was observed on rectal examination. This was the condition when the patient was last seen in March, 1944.

Case 10.—Aged 61; first seen in Sept., 1942. A suprapubic cystostomy had been performed elsewhere 20 months previously. The general condition was good. On rectal palpation the prostate was found to be enlarged and extremely hard. A clinical diagnosis of carcinoma of the prostate was made, and a course of high-voltage therapy given in Nov. and Dec., 1942. X-ray examination of the pelvis was normal. By Aug., 1943, there was little change in the size and consistency of the prostate. Radiographs showed an abnormal opacity in the left ischium, but plasma phosphatase values were now: acid phosphatase 1.2 units, alkaline phosphatase 8 units. Stilboestrol was given in doses of 5 mg. b.d. orally. On re-examination at monthly intervals the condition remained unchanged.

Discussion of Clinical Results

Palpable changes in the prostate were not produced in all cases. In Cases 1 and 2, in which the original condition was that of an enlarged hard nodular gland, both softening and shrinkage took place, the changes being well marked. The same type of alteration occurred in Cases 5 and 6, but to a less striking degree. No change whatever took place in Case 8—in which the disease rapidly proved fatal—and the findings were equivocal in Case 7. The remaining patients (Cases 3, 4, 9, and 10) had all been treated by high-voltage therapy previously, and in them no definite alteration in the prostate was detected. Hence of the 10 cases only 4 have so far shown definite regression of the primary tumour.

Palpable lymphatic spread was present in 3 of the series (Cases 1, 4, and 5), in each instance with an attendant swelling of the lower limbs. In all three cases a regression of the secondary masses took place, together with a reduction in the oedema.

Metastases to bone, in all 5 cases in which they occurred, were of the osteoplastic type. The appearance of radiographs taken at three-monthly intervals showed in some cases a progressive increase in density, while in others the deposits seemed to become more numerous during treatment, or increased in size.

Pain referable to bone occurred as a symptom in 4 of the series. In 3 cases it was a presenting symptom, while in the fourth it arose after the patient had been attending hospital for 2 years but before there was radiographic evidence of skeletal deposits. It was noted that some amelioration of such pain occurred in hospital with rest alone. Final assessment of the influence of stilboestrol on such pain is, therefore, best made when the patient returns to his normal routine. These four cases all secured a partial or complete relief from pain, and this has so far been maintained in three of them.

With the exception of Case 8 all showed some measure of betterment in general condition. This revealed itself in an improvement in appetite, a gain in weight, and, in the two cases with severe anaemia, by a gradual increase in haemoglobin. At the onset of treatment the haemoglobin values were 46% in Case 2 and 37% in Case 3. It required between 5 and 6 months for the haemoglobin values to reach 78% and 72% respectively. As each patient was given ferrous sulphate during the earlier period of his treatment the part played by stilboestrol in bringing about this improvement is not known.

Of all the symptoms associated with carcinoma of the prostate, frequency of micturition is likely to be the most uncertain in its response to any form of therapy. Even if a shrinking and softening of the prostate takes place, the extent to which micturition returns to normal must depend finally upon the degree of secondary changes in the bladder. Clearly it is only rarely that these changes will be so slight as to allow of a return to normal function. On the whole there appeared to be some measure of improvement in all the cases in which frequency was a symptom.

Summary

Details are provided of the method employed for estimation of acid phosphatase, and of the values obtained for plasma acid and alkaline phosphatase in various clinical conditions and in normal controls, and for acid phosphatase in seminal fluid. Two specimens of seminal fluid from a case of eunuchoidism contained relatively negligible amounts of acid phosphatase.

Of 10 cases of prostatic carcinoma, 6 showed a raised acid phosphatase content in the plasma: in 5 of these there was radiographic evidence of metastases in bone. Several of the results do not show any marked distinction between prostatic carcinoma with metastases and Paget's disease.

The behaviour of the plasma phosphatases, in cases of carcinoma of the prostate in which the plasma acid phosphatase was originally raised, was followed during treatment with stilboestrol. The response shows a uniformity of pattern, the acid phosphatase falling abruptly to a normal level, which is then maintained for considerable periods, with a rise in alkaline phosphatase followed by a gradual fall.

Of 10 cases of carcinoma of the prostate 4 showed some degree of regression of the primary tumour under treatment with stilboestrol, and secondary deposits in lymph nodes underwent regression in 3 cases. X-ray examination at 3-monthly intervals in those cases with metastasis to bone revealed in some a progressive increase in density, while in others the deposits became more numerous during treatment or increased in size.

With one exception all cases showed some measure of symptomatic and general improvement, in relief from pain, lessening of frequency of micturition, or gradual increase in haemoglobin level, and in improvement in appetite and gain in weight.

This investigation has been supported by grants, for which we express our thanks, from the British Empire Cancer Campaign and from the Anna Fuller Fund. We are also indebted to the Medical Committee of the Royal Cancer Hospital (Free) for permission to publish details of those cases under their charge, and to Prof. R. H. A. Plimmer for many of the phosphatase determinations.

MEDICAL EXPERIENCES IN NORTH AFRICA, 1943-4*

BY

Brigadier T. C. HUNT, D.M., F.R.C.P.

Consultant Physician, Persia/Iraq Force

At the time of El Alamein the hospital sick rates, largely due to infective hepatitis, were at least as high as the battle casualties, and during the Sicilian campaign more men went down with malaria than from enemy action. In my experience at general hospitals in North Africa during almost exactly a year from the Tunisian fighting in March, 1943, till after the Anzio landing in 1944, hepatitis and malaria were again the two most serious medical problems. Bacillary dysentery was on the whole mild, and, though on occasion I had over 300 cases in hospital at a time, most of the men responded at once to sulphguanidine, and were back on duty very quickly. The average stay in hospital was only ten days.

Infective Hepatitis

Infective hepatitis was at its worst in the autumn months of 1943 and dropped rapidly with the frosts in Jan., 1944. It was a serious problem in the spring among both our own and enemy forces, and I had in hospital a number of German prisoners who had been still fighting while suffering from jaundice. During Oct., Nov., and Dec., 1943, there passed

* A lecture read to the Teheran Medical Association, June 24, 1944.

through my division of 1,100 beds well over 1,000 cases of infective hepatitis. This compared with just over 1,000 cases of respiratory diseases—mainly "coughs and colds"—some 600 cases of malaria, and an almost equal number of cases of dysentery. During the same period some 300 skin cases were admitted, and nearly 250 cases of faucial and skin diphtheria. These figures, of course, give only an idea of the work done at my own particular hospital near Algiers. Among all the cases of infective hepatitis there was not a single death. Though it was possible to discharge many from hospital, often after only 15 days, even while the skin was still yellow, in most cases the illness lasted considerably longer; at the same time, only two or three were really critically ill, and none required invaliding home.

The *prodromal period* was variable, the average time elapsing between the onset of symptoms and the appearance of jaundice being 5½ days. In some cases, however, this period was as long as three to four weeks, the longest occurring in a case in which the first signs of jaundice took 42 days to appear. A number of cases never showed jaundice at all, and these are perhaps the most interesting and the most important. We were able to make an almost certain diagnosis of hepatitis without jaundice in over 30 cases, and I have no doubt that many mild abortive cases occurred and remained unrecognized. The clinical picture is, however, often highly characteristic, with pyrexia, nausea, vomiting, constipation, and extreme anorexia, so that in an epidemic the suspicion of hepatitis should be at once aroused, though in such cases proof of the diagnosis may be impossible. Hepatitis without jaundice may well be a major cause of the spread of the disease, and some observers have made the guess that for every case with jaundice there is at least one without. When jaundice does develop, its appearance is often coincident with great general improvement in the symptoms, and if the serum bilirubin is estimated daily a rapid fall is usually found soon after, followed then by a much more gradual drop to normal levels.

Infective hepatitis is, at its onset, one of the important causes of "P.U.O."—sometimes resembling malaria, sometimes like typhoid, or sometimes with severe headache, rigors, and intense vomiting, even suggesting a meningitis. Just under 10% of my cases began with severe coryzal symptoms, and this mode of onset is recorded as occurring in over 30% of cases in other epidemics.

In some cases the fever may be only slight, but in others it is severe. Constipation occurred in 70% of my cases, while diarrhoea was present at the onset in 8%. It was an interesting observation, which may be of no significance at all, that several patients recorded attacks of severe and unexplained abdominal pain with vomiting lasting for one to two days, occurring almost exactly four weeks before the onset of their illness. Itching of the skin was very rare, but urticarial rashes occurred at the onset in four cases.

I can give no good indication as to the mode of infection. Though hepatitis is to some extent a wartime disease, there is not yet any clear proof of its mode of transmission. I have no doubt that droplet infection does not account for the whole story. In our hospital, where over 1,500 cases were nursed, the incidence among the staff of the medical division was nil. The only members of the unit as a whole (about 300 in number) who contracted the disease were the theatre sister, one of the surgeons, two surgical medical officers, two operating-room assistants, three clerks, and four orderlies working in the surgical wards. I could not help having a suspicion that actual contact with blood had some causal relationship in these cases, and the transmission of hepatitis by blood transmission, as well as by infected syringes, would suggest this as a possibility.

Many interesting tests have shown that the virus of infective hepatitis in blood is able to survive most simple measures of disinfection, and that nothing short of careful boiling of syringes, for example, is effective in preventing possible transmission by such procedures as intravenous therapy. Here traces of blood drawn into the syringe at a first injection may subsequently be injected with the next and thus infect the patient. This accounts for at least some of the cases of "arsenical" jaundice in syphilitics, in which the cause is not in fact the arsenic but the virus given with it. In some clinics

with imperfect sterilization the incidence of jaundice has been as high as 40 to 50%, and in these cases the incubation period has seemed to be about 100 days; a similar period has been suggested from a study of cases of jaundice following serial blood-sedimentation-rate tests.

Inoculation of animals and human volunteers has not yet given conclusive results. Canaries, pigs, and other animals have been tried without success, but suggestive experiments in man have indicated that blood, duodenal juice, and faeces probably contain the virus up to some time after the appearance of jaundice. It has, of course, been the hepatitis virus in the serum—either given for treatment or used for the preparation of vaccines—which has been responsible for the occurrence of jaundice following inoculations of convalescent serum for measles and mumps and of yellow fever vaccine, after which over 28,000 cases occurred in the American Army in 1942; here again the incubation period varied between 40 and 150 days.

Among my own cases the *incubation period*, so far as I can judge, seemed to be from 21 to 28 days, though others have thought it to be as long as 6 to 12 weeks.

In one interesting incident two officers admitted to my division under Major Keele, R.A.M.C., had escaped from a P.O.W. camp in Italy, and had wandered for several weeks in the countryside, keeping hidden and avoiding all contacts with human beings, barely even meeting or speaking to a soul. Their only real contact during this time had been on Nov. 10, when they were joined for one night by a partisan who was feeling ill and for warmth slept between them in a barn. They noticed that he looked a little yellow when he left them in the morning, and exactly 22 and 23 days later respectively the two officers went sick with infective hepatitis.

There is no definite proof yet of transmission by faeces-contaminated food or water, or of any insect vector, and flies, fleas, and bed-bugs have not yet been incriminated. Officers in general show a higher incidence of hepatitis than do other ranks—this was so in my cases—and it has been suggested that this is because officers' mess kitchens have more flies than anywhere else, though not, I think, that officers have more bed-bugs than other ranks!

Treatment.—Though I feel confident that it will not be very long before the mode of transmission of infective hepatitis is demonstrated and that prevention may then soon follow, I am more doubtful how far successful treatment of the established disease is likely to result. Up to now the hoped-for benefits from the administration of cystine, methionine, casein digests, choline, or other amino-acids have not developed, though at least it seems certain that adequate protein as well as carbohydrate is important during and after the illness. Restriction of diet may be necessary symptomatically owing to anorexia and nausea, but as soon as possible full allowance of all constituents in the diet, including protein and fats, is, in my opinion, advisable.

Malaria

Nothing surprised me more about malaria in North Africa than its difference from malaria in West Africa. In North Africa we saw both benign tertian and malignant tertian. There were many relapse cases—some severe, persistent, and resistant to treatment—but in over 1,000 patients admitted to my division there was not a single death. This was certainly better than in West Africa, where I had one death from cerebral malaria and one from blackwater fever in roughly the same number of cases, but for clinical severity the M.T. malaria of North Africa was unquestionably the more alarming. In North Africa the condition was more polysymptomatic, the need for treatment more urgent, and the response often less satisfactory: here intravenous quinine injections became a frequent and almost usual procedure, while in West Africa it was rare. During the malaria season over 1,000 injections were given in my hospital with only minor symptoms on two or three occasions. This timely intravenous quinine no doubt saved many lives among desperate cases, even though a considerable number would almost certainly have recovered with oral treatment alone. Of the many well-known and important lessons about malaria—often learnt, perhaps, at a price—these were some that we learnt once more in North Africa.

1. In a malarious country headache is not to be regarded as due to psychoneurosis until malaria has been excluded.

2. Malaria with low fever may be more dangerous than with high, because it is more easily missed

3. To wait for a positive blood slide or a palpable spleen costs more lives than to treat a suspicious case on an unproved diagnosis

4. The exact date of onset of malaria is not the same thing as the date of admission to a medical unit where a man lives may be much more important than what he does

5. To transfer a case of active malaria without treatment and without full precautions for continuation of treatment is a medical crime

6. Other diseases do not exclude malaria, and malaria, especially relapsing malaria, has often some complicating disease

7. Diarrhoea with blood and fever is not always due to dysentery, jaundice with fever is not always infective hepatitis malaria may mimic both Asthma, fibrositis, neuritis, urticaria, and nephritis are only some of the less well recognized conditions that malaria may cause, while it may simulate at least a dozen others

Diphtheria

Both in the Middle East and in North Africa, faucial, nasal, and cutaneous diphtheria were important causes of sickness, prolonged stay in hospital, serious complications, and deaths

The diagnosis of faucial diphtheria was, as always, easily missed, and a number of cases appeared clinically to be merely simple quinsy or tonsillitis with no definite membrane that could be seen. Among my own unselected cases the incidence of complications was low—only 5%, out of 35 cases with complications 16 showed peripheral neuritis, the average time of onset being 64 weeks from the time of the sore throat. One faucial case ended fatally, this in spite of receiving 216,000 units of serum within the first three days of the infection. The average dose of serum used in throat cases was 85,000 units, but the complicated cases, on analysis, were found to have had serum considerably later in the disease than the uncomplicated. Massive dosage seemed in these cases to be undoubtedly less important than early dosage—at least in preventing complications. One fifth of all the cases showing complications received no serum at all, and among uncomplicated cases 56% received serum within the first two days of their illness, as compared with only 29% among the complicated cases.

Cutaneous diphtheria is a most interesting and important condition. In my own cases it was not always possible, for various reasons, to distinguish between skin lesions infected with avirulent organisms and those infected with true *C. diphtheriae*. An analysis of over 76 lesions from which organisms morphologically resembling *C. diphtheriae* were cultured gives some interesting findings. Only a few of the lesions show characteristic features: they may be in the form of ulcers, superficial weeping or crusting "dermatitis," or purulent infections of wounds, abrasions, burns, or superficial injuries. They all show a notable chronicity and failure to heal, the average duration of the cases before diagnosis was 50 days and the average stay in hospital before healing 35 days. Of the lesions 40% were on the legs, 25% on face or ears, only 10% on hands or arms, and the remaining 25% either generalized over the body or on isolated parts such as scrotum, groin, or buttock. The lesions were frequently multiple, in one case as many as 31 separate ulcers, varying in size from 1 in to 3 in in diameter, being present all over the body.

Diphtheritic ulceration sometimes shows a black crust or slough which leaves a bleeding surface if removed, and these cases often clear up rapidly and completely after injection of quite small doses of serum such as 24,000 units. The chronic desert sores so common in the Middle East and North Africa are more common on hands and arms, and rarely show the dark crusting of diphtheritic ulceration, seborrhoeic or eczematous lesions present few characteristic signs when infected with *C. diphtheriae*.

Complications—In 12 of my cases there was coincident infection of skin and of the throat or nose, and in 9 of these the skin infection definitely preceded that of the throat or nose. Auto-infection from "hand to mouth" thus appeared to be a frequent occurrence, arising in approximately 10% of the cases, though the reverse process—from nose or throat to skin—can also of course, occur. The virulence of the organisms could not always be tested, but infection of ward personnel is an appreciable risk, one sister and one orderly in the skin

wards contracting faucial and the medical officer in charge contracting a cutaneous diphtheria. The incidence of complications, too, is not low—probably due, in part, to the long time-interval often elapsing between infection and recognition of the organism. Five proved cases showed complications, 2 patients died, and 19 cases of polyneuritis were almost certainly due to skin diphtheria, though they were not proved bacteriologically. These cases were, however, too selected to afford an accurate estimate of the percentage incidence of complications, which probably lay between 5% and 10% of all cases.

The lesions associated with complications were in the main large, and involved soft tissues, both deaths occurred in patients with extensive infection in regions with considerable areolar tissue—buttock and neck. In the first of these, infection apparently arose spontaneously as a boil on the buttock, which rapidly developed into an abscess and was incised. No suspicion of diphtheritic infection was aroused and, of course, no serum was given. The patient was first seen on the 34th day of the lesion, when a marked triple rhythm was heard at the apex of the heart and the pulse rate was persistently rapid—100 to 120, I at once suspected a diphtheritic myocarditis, and cultures of the abscess showed *C. diphtheriae*. On the 36th day diplopia developed, and 12 days later a palatal palsy and peripheral neuritis of arms and legs. Death occurred on the 60th day, post mortem examination showing an intense toxic degeneration of the heart muscle. The second patient showed similar changes at necropsy, death occurring on the 43rd day of illness. In this case a long-standing seborrhoeic dermatitis was secondarily infected with *C. diphtheriae*, and an extensive brawny cellulitis of the neck developed, from which the organisms were cultured.

Severe polyneuritis following chronic cutaneous ulceration was often seen, though some cases showed only paraesthesiae, loss of reflexes, and very slight weakness. In most cases the polyneuritic symptoms began between 6 and 10 weeks after the skin lesions were noticed, a typical case history is as follows:

Pre M, aged 37. Whitlow on right toe noticed Nov 18, incised Nov 22. Small ulcer formed with black adherent slough—resistant to treatment. Dec 18. Ulcer swab showed *C. diphtheriae*, 32,000 units antidiphtheritic serum given Jan 1. Ulcer healed Jan 20. Blurring of vision further 32,000 units given Jan 28. Paraesthesiae of hands and legs noticed Feb 20. Gross paralysis of both legs, with loss of reflexes, arms weak, marked loss of sensation. Heart good. Skin lesions healed. Routine throat and nose swabs negative for *C. diphtheriae* throughout.

Peripheral Neuritis

Peripheral neuritis occurred relatively often in North Africa, either as a symmetrical polyneuritis or as isolated individual lesions, such as winged scapula, foot drop, or a brachial neuritis. Many cases undoubtedly followed skin diphtheria. Some seemed to be due to malaria or dysentery, in others treatment with such drugs as emetine possibly played a part. Cases of sudden acute infective polyneuritis also occurred, often resembling poliomyelitis, but with gross sensory changes. This disease was also seen in the war of 1914–18. In North Africa it began with severe backache, headache, and fever, weakness and sensory loss in the limbs, both proximal and distal, appeared within a few days or a week. It is interesting that German writers (Wilke, 1944) report a high incidence of polyneuritis among their troops on the Russian front, similarly involving muscles such as serratus, deltoid, or quadriceps, as well as peripheral types, and attribute the conditions almost entirely to infection with the Flexner or Shiga-Kruse bacillus. Though this is certainly a cause in some cases, it is doubtful whether it is quite as frequent as they maintain.

Immersion Foot

Most of the men coming to my hospital for trench or immersion foot had not had their boots off for over 10 days, having been forced, as at the Sangro River, to remain almost stationary in mud and rain for many days owing to constant shelling.

In immersion foot the initial signs are of coldness of the foot and leg, followed by hyperaemia and severe oedema, with loss of most forms of skin sensation. It is vital not to provoke

hyperaemia by warming the leg up in any way; the worst cases occurred among those who, against instructions, had put their feet by a fire as soon as they took off their boots. The damage caused by the wet and chill leads to stagnation of the circulation and then hyperaemia, with oozing of fluid from the capillaries and diminished vitality of nerves, skin, and muscle; in severe cases irreparable loss of function may result, but in the milder cases the tingling, pains, and oedema subside in one or two weeks. The hyperaemic stage may last many weeks with sometimes intense hyperaesthesia, but in most of my cases full recovery occurred within 6 weeks. In some men there had been a lifelong tendency to cold hands or feet; and in the worst cases lasting sequelae, including hyperhidrosis and extreme sensitivity to cold, may persist.

As a rule immersion for periods of many days is necessary to produce symptoms, as has been the case with numbers of men torpedoed at sea and remaining afloat for a long time in open boats; but sometimes minor degrees follow shorter periods. This occurred, for example, in the case of an officer who fell into the sea during the glider landings in Sicily and had to stand in the water hidden under a cliff for about 10 hours, after which he walked some 18 miles in a hot sun; later his feet swelled and became anaesthetic—symptoms which still persisted when I saw him 8 days later.

No specific treatment was given, but strict avoidance of any artificial heat, as by hot-water bottles, was essential, and cooling by fans has often been adopted. Careful Buerger's exercises seemed to do good.

Anxiety States

In the fighting in North Africa, as in other theatres, many acute anxiety states and conditions of severe physical exhaustion or terror occurred, as well as gross sensory and motor manifestations of hysteria. Few things in the future may be of more far-reaching importance than the development of personnel selection and the attempt to prevent psychological breakdowns under stress and strain. How far the art of selection of men and women may go in education, industry, or social life no one can foretell, but war psychiatry has certainly shown the way in its insistence upon the testing of a man's personality and intelligence, as well as his physique, before choosing him for any special appointment.

To me, however, it was almost more remarkable to see, not how many men broke down in battle, but how much the human mind and body were able to stand without collapse. A soldier lay under a truck with his friend while being bombed; his friend crawled half out to look around, and when, a little later, the first man pulled him back, his head had completely disappeared. Is it surprising that the survivor developed an intense hysterical blindness?

Most breakdowns at or near the battle-front occurred in the psychologically predisposed, and it should therefore be possible to some extent to detect the mentally unfit by careful selection before they get so far. War is teaching us more and more just how much we are able to select and judge in advance, and just how near the real thing methods of trial and training have got to be before we can eliminate early the psychologically unfit.

Wilke (1944). *Trop. Dis. Bull.*, 41, 131.

The *Housing Manual*, 1944 (H.M. Stationery Office; 2s), which has been prepared by the Ministry of Health and the Ministry of Works and sent to all local authorities in England and Wales, gives technical guidance to local authorities, architects, builders, manufacturers, and others on the lay-out, planning, construction, and equipment of permanent houses to be built under the Government short-term housing programme covering the first two years after the end of the war in Europe. In the light of this technical guidance local authorities will now prepare their own plans. In general, the standards recommended are those proposed by the Design of Dwellings Subcommittee of the Minister of Health's Central Housing Advisory Committee (the Dudley Report). The ground covered in detail by the manual includes: Site planning and lay-out, plans of houses and flats, plans for special occupants—e.g., old people—efficiency in building, new materials and methods, services and equipment. The great majority of houses built by local authorities under the short-term programme are likely to be of the three-bedroom type.

ANALGESIA IN LABOUR

A RECORD OF 102 CASES TREATED WITH PETHIDINE

BY

J. A. RAE CRIPPS, M.B., Ch.B.

BARBARA HALL, M.B., Ch.B.

AND

W. F. T. HAULTAIN, O.B.E., M.C.,
F.R.C.S.Ed., F.R.C.O.G.

Obstetrician and Gynaecologist, Royal Infirmary, Edinburgh

It is now nearly a century since Simpson discovered the use of chloroform as an anaesthetic and advocated it as an analgesic in labour. At that time there was a public outcry against a drug being used for the relief of labour pains, and it was on one might say, by a Royal Warrant, that chloroform was accepted as an analgesic in labour. Times have changed, and there is now a growing tendency in this country for the expectant mother almost to demand that her doctor arrange it she should not feel pain during her delivery. In the United States of America this public demand has been so great that the use of analgesics in labour has been considered one of the causes of the high maternal mortality and morbidity rate from which that country suffered some years ago, as uterine contractions were interfered with to such an extent that operative deliveries were very often required. Since Simpson's advocacy of chloroform many other drugs have been tried, and up to now, though each has had its advocates, none has been found acceptable to all authorities; this is because the ideal analgesic has not yet been discovered. In 1906 Gauss, Freiburg, advocated "twilight sleep,"—with a combination of morphine and hyoscine—and, though this was widely used for a number of years, reports of its apparent bad effect on the baby came from different sources, and for this reason it fell into partial disuse. We doubt, however, if all the allegations against twilight sleep are true, for it is common knowledge that not every baby cries immediately—it is delivered; but, if twilight sleep was used and the babe was a little difficult to bring round after birth, this was immediately attributed to the analgesic. Series of cases have been reported from Edinburgh (Johnstone, 1917; Haultain, 1920-1; Greenwood and Hirschman, 1922) and elsewhere (*Proc. roy. Soc. Med.*, 1918) of excellent results with twilight sleep in the accomplishment of amnesia and analgesia without any really bad effect on the baby. As with many other treatments, there is a right and many a wrong way of administration, and if the correct rules as formulated by Gauss are observed, then the results, in our opinion, are good, whereas if they are departed from accidents may occur, and with twilight sleep it is the baby who may suffer. There is little doubt that if twilight sleep is employed properly it is a most useful and safe analgesic in the long tedious labour.

Nearly 20 years after Gauss's discovery Gwathmey (Gwathmey *et al.*, 1923) described his synergistic method, but though it has its advocates it has never found much favour in this country. In 1924 a barbiturate—somniafene (Cleisz, 1924)—was first tried in labour as an analgesic, and since that time a large number of derivatives of barbituric acid have been used, especially in the United States of America (Gould and Hirst, 1935), and each separate hospital and clinic which was visited there in 1939 seemed to be enthusiastic over its own special barbiturate, or combination; but this enthusiasm was usually confined to its sponsors, and was not shared by other hospitals.

Conditions for the Ideal Analgesic

A most comprehensive treatise on the relief of pain in labour was read before the eleventh British Congress of Obstetrics and Gynaecology by Sturrock (1939), showing, as well as does this short preamble, that the ideal analgesic in labour has still to make its appearance. That being so, one is always on the look out for any new preparation that might fulfil the conditions essential for the ideal analgesic. These conditions might be summarized as follows:

1. That the analgesic does not endanger the life of the mother or have any harmful effect upon her.
2. That it does not harm the child.

3. That the strength of the uterine pains are not diminished by administration and that labour is not delayed by its use.
4. That there is no effect on the expected co-operation of the patient in the second stage of labour, and that operative intervention is not increased by its use.
5. That the third stage of labour is not prolonged after its use, or is there any undue tendency to post-partum haemorrhage.
6. That the analgesic is easy to give and that no risks are associated with its administration.
7. That the analgesic is always successful in its action.

This standard is indeed a high one, but the perfect analgesic could fulfil all these conditions.

It was with great interest, therefore, that we learnt that a new analgesic had been discovered in 1939—namely, pethidine hydrochloride—and that it was found by various scientific workers to have an analgesic effect comparable to morphine and also to have a spasmolytic and sedative effect as well. On account of these properties there seemed to be a good chance that this analgesic might prove to be of great value during labour and might even approach the ideal. It was thus with some gratification that we were afforded liberal supplies of ethidine hydrochloride with which to carry out a preliminary investigation on its action in labour.

It would be superfluous to go into the chemistry and pharmacology of pethidine, as this has already been done adequately by Gallen and Prescott (1944), who also published their results in a series of 150 obstetrical cases; and Spitzer (1944) recorded results in a series of 80 cases, the drug being given entirely by mouth in his series, whereas it was administered chiefly intramuscularly in the former. Previous to this, several observers in America (Gilbert and Dixon, 1943; Roby and Schumann, 1943; Schumann, 1944) had reported promising results of its analgesic action in labour; but as it is only by means of different series of results published by several observers that the full value of a drug can be assessed, we make no apology for adding a further account of the use of ethidine in 102 cases in which it was given intramuscularly during labour.

In this series 91 of the women were primigravidae and 11 multiparae, all having been admitted under our charge during period of eight months; each was observed carefully by one of us, who made notes regarding the strength of the pains and the dilatation of the cervix, and decided when pethidine injections should be started and when further doses were required. After labour each case was assessed not only by a consideration of the observations made but also by conversation with the patient, so as to discover her evaluation and appreciation of the drug.

Dosage of Pethidine Hydrochloride

The first dose of 100 mg. was usually given intramuscularly when the os was 3 to 4 fingers dilated and the pains were coming on about every four to five minutes. The second dose of 100 mg., when required, was given 45 to 60 minutes later. In all, 44 cases received no injection and 40 two injections. A third injection of 100 mg. as necessary two hours later in 10 cases, and a fourth after another two hours in 2 cases. Pethidine was combined with hyoscine—r. 1/150 with the first injection and gr. 1/450 with each succeeding injection in 6 cases.

Effect on the Mother

Of the primiparous patients 66 had normal spontaneous labours, whereas 22 babies were delivered by forceps and 4 by the breech (Table I). This would seem to be a high forceps rate (21.6%), but can be explained by the fact that the patients were primigravidae, and also that the hospital where the investigation was carried out

TABLE I.—Deliveries

Primiparae (91)			Multiparae (11)

66	22*	4*	10	1	Nil

* One patient was delivered of twins.

takes practically all the emergency and difficult cases from the vicinity, and therefore the average forceps rate for all cases is always inclined to be high (13.6% for 1941). Among these 22 cases the forceps were indicated for occipito-posterior positions in 9 cases, or contracted pelvis in 3 cases, and for deep transverse arrest of

the head in 1 case. In 4 cases forceps were applied to lift the head over the perineum, and in 5 for maternal or foetal distress. Among the multiparae 10 had normal deliveries and 1 was delivered by forceps for an occipito-posterior position.

In only 2 cases did the mother present any abnormality after delivery; 1 had a slight post-partum haemorrhage, and 1 suffered from marked tachycardia, which came on 30 minutes after labour and lasted for several hours. The latter patient had 4 doses of pethidine, the final dose being given 4½ hours before a difficult forceps delivery for an occipito-posterior position. There was no maternal mortality, and none of the patients suffered any toxic effects from the injections either during labour or subsequently. Thus it can be stated that, from this series, conditions 1 and 5 for an ideal analgesic, mentioned above, have been fulfilled, but that the fulfilment of condition 4 is doubtful.

Effect on Child

As regards the effect on the infant, there were no stillbirths in the 103 babies born (Table II). In only 4 cases was there any marked asphyxia: in two of them the asphyxia could be accounted for by a difficult forceps delivery, in one to eclampsia and a forceps delivery, and in another to the cord being held tightly round the baby's neck; all these babies responded to treatment and survived without giving any further cause for anxiety. In 22 cases the child did not cry immediately on delivery but responded in a few minutes; in only 8 of these cases was there no other possible reason found for the slight oligopnoea. None of these babies gave any cause for anxiety at birth or later. Thus it can be stated quite definitely from this series of cases, which includes many complications that might have caused asphyxia and possibly stillbirth, that pethidine had no deleterious effect on the infant; condition 2 was therefore fulfilled.

TABLE II.—Effect on Babies

Cried on Delivery	Sl. Oligopnoea	Asphyxia	Total	Mortality
77 (1 set of twins)	22	4	103	Nil

Effect on Labour Pains

With regard to its effect on labour pains, the administration of pethidine would seem definitely to have hastened delivery in 33 cases (Table III), the average time from the first dose to delivery in these

TABLE III.—Acceleration of Labour (33 Cases)

Primiparae 25	Multiparae 8
-------------------------	------------------------

being 2.6 hours. The clinical explanation for this effect seemed to be that the "edge" was taken off the pains, thus allowing them to be more effective and the patient to co-operate more easily in the second stage of labour; these were the statements that we obtained from interrogation of many of the patients, given quite on their own initiative without any prompting or suggestions by us. To these views of the patients themselves might be added another—namely, that the injections seemed in many cases to relieve spasm of the cervix and to enhance uterine polarity. The cervix therefore dilated more easily and the uterine contractions seemed to be accentuated, but were not so painful. On the other hand, the pains stopped in 9 cases, and in some of these did not return for several hours, the patient having apparently gone completely out of labour, even when she had evidently been in good labour previously. This was probably due to pethidine being given before the os was dilated sufficiently (2 to 3 fingers), but it is interesting to note as well that 6 out of the 9 cases had some abnormality present: 1 was a breech, 2 were occipito-posterior positions, 2 had contracted pelves, and 1 was a case of twins. Therefore there might have been some disharmony of uterine action, as tends to happen in such cases. On the other hand, such abnormalities occurred in successful cases when pethidine was given with the cervix slightly more dilated, and the uterine contractions were not interfered with in any way. In a few cases uterine contractions did not seem to be affected by the drug, although in most there was some improvement in the efficacy of uterine action. Thus condition 3 is not invariably fulfilled, although it usually is, especially when no abnormality is present.

Analgesic Effect

The analgesic effect of pethidine was assessed under four separate headings:

(i) *Good*.—The result was considered good if pain was relieved, the contractions regular and efficient, dilatation of the cervix quick, and the patient rested well (usually slept) between the pains. (Amnesia was not an expected result with pethidine alone, and though it was obtained in some cases it was not considered as an essential to be achieved.)

(ii) *Satisfactory*.—The analgesia was considered satisfactory if the strength of the contractions was not interfered with, the cervix

dilated normally, and the patient rested well between pains which were bearable.

(iii) *Poor*.—Analgesia was considered poor when only slight analgesia was obtained and there was little rest between pains.

(iv) *Unsatisfactory*.—The result was considered to be unsatisfactory when the drug gave no benefit at all or caused the uterine contractions to cease.

Under these headings (Table IV) 47 results were considered to be good, 33 satisfactory, 11 poor, and 11 unsatisfactory. Thus 78.4% were definitely benefited by pethidine, and in 46.1% the result achieved was really good. Of the 47 cases classed as "good," 41 had spontaneous deliveries, 4 had occipito-posterior positions, 1 was a breech, and 1 a face presentation; only 4 of these patients required forceps. Among the 33 "satisfactory" cases 22 were spontaneous, 6 had occipito-posterior positions; 1 was a breech presentation; 1 had eclampsia; 1 had a contracted pelvis, and there was one set of twins; forceps were used in 10 cases. Among the 11 "poor" cases 8 were spontaneous, 1 had an occipito-posterior position, and 3 were delivered by the forceps. In the "unsatisfactory" cases, as previously detailed, 6 were normal.

TABLE IV.—Analgesic Effect on Mother

	Cases	Prim.	Mult.	Spont.	Abnormal
Good	47	40	7	42	5
Satisfactory ..	33	30	3	22	11
Poor	11	11	0	8	3
Unsatisfactory ..	11	10	1	5	6

Dosage Required

With regard to dosage the figures in Table V would seem to show that one injection of pethidine is very often sufficient to produce a good result, but if it does not then a second injection, given about an hour later, is usually all that is required. Of the "good" and "satisfactory" cases 72 required only two injections at the most; on the other hand, in cases in which, for some reason or other, labour is slow, the effect may be continued by third and fourth injections.

TABLE V.—Number of Injections Given

	Good				Satisfactory				Poor				Unsatisfactory			
No. of Injections	1	2	3	4	1	2	3	4	1	2	3	4	1	2	3	4
Cases	20	21	6	—	17	13	2	1	3	6	1	1	6	4	1	—

Hyoscine and Pethidine Combination

Of the six cases which received hyoscine in addition, to try to produce a degree of amnesia as well as analgesia, two were classed as "good," one as "satisfactory," one as "poor," and two as "unsatisfactory." These cases were treated fairly early in the investigation, and as very little benefit seemed to result from the addition of hyoscine its use was not continued. Possibly, however, we were wrong in not giving hyoscine a more extended trial, as, theoretically, the addition of hyoscine should increase the benefit, and, as will be shown later, pethidine and hyoscine together would seem to be very efficacious in producing amnesia for Caesarean section performed under local anaesthesia.

General Conclusions

Summing up the facts obtained from the treatment of these 102 patients with pethidine, we can state that the ideal analgesic drug for labour has not yet been found, but that pethidine fulfils the conditions quoted comparatively well. It has apparently no harmful effect on either mother or child; there is no tendency to produce post-partum haemorrhage; and it usually does not retard uterine contractions—in fact, in one-third of the cases it seemed to enhance uterine action appreciably. It is not always successful in producing analgesia, but it did so in enough cases (78.4%) to make it a valuable drug to use in labour. Its administration involves no difficult routine, any slight deviation from which might be dangerous, as is so definitely the case with twilight sleep. It is possible that the forceps rate is slightly increased by its use.

In comparison with twilight sleep, analgesia is obtained in approximately the same number of cases as those quoted by observers of that form of treatment, but twilight sleep has the advantage in that it produces amnesia as well in a larger proportion of cases; the forceps rate is, however, higher with twilight sleep owing to the fact that the co-operation of the patient in the second stage of labour is not so satisfactory as with pethidine.

There is apparently no undue excitability under pethidine, such as may occur with twilight sleep or the barbiturates.

Premedication with Pethidine and Hyoscine

For a number of years one of us (W. F. T. H.) has been trying to find a really efficient drug or combination of drugs to employ in the premedication of a patient before carrying out a Caesarean section under local anaesthesia. Caesarean sections under local anaesthesia are associated with less risk than under a general anaesthetic, and for women suffering from cardiac lesions, pre-eclampsia, chest conditions, etc., it is certainly the ideal method. Under local anaesthesia the operation is as a rule most satisfactory provided the woman receives adequate premedication; but often patients awaiting a Caesarean section are very alert, being unduly excitable because of the immediate prospect of having a baby, and even strong doses of hypnotics and sedatives have not the usual effect. Premedication with morphine and hyoscine in the accepted dosage before an operation under local or spinal anaesthesia is contraindicated, as such a dose may have a bad effect on the baby, making it difficult to resuscitate, and in some cases might cause stillbirth. We considered, therefore, that pethidine and hyoscine should be given a trial in such cases, and up to now we have used it in 6 cases, with excellent results. 100 mg. of pethidine and 1/150 gr. of hyoscine are injected 45 minutes before the operation, and just before the patient is taken into the theatre she is given another 100 mg. of pethidine and 1/450 gr. of hyoscine. In all cases this premedication has acted well and analgesia and amnesia were perfect, the patient usually sleeping throughout the operation and remembering nothing about it when she woke up. In each case the baby cried as soon as it was delivered, and the uterus contracted down excellently, as it always does when local anaesthesia is being used alone. These cases may be just the "fortunate first" that often occur with any new therapy, but it would seem to be worth while to give this form of premedication an extended trial in such cases.

We desire to thank Messrs. Burroughs Wellcome for the supply of pethidine, and Messrs. Bayer Products Ltd. for the supply of dolantol—the two preparations used in this investigation. We also thank Sister Anderson and Sister Mackenzie, the day and the night labour ward sisters, for their great help and co-operation.

SPONTANEOUS LOBECTOMY

BY—

J. W. TAYLOR, M.B., Ch.B.

Thoracic Surgical Officer, the General Infirmary at Leeds

During recent years it has become increasingly difficult to differentiate between a lung abscess and an empyema. There is no doubt that in many cases the infection is primarily in the lung tissue and only secondarily invades the pleural cavity. This has given rise to the term "pleuro-pulmonary abscess." In the following case the infection was so great that a complete upper-lobe lung slough became free in an empyema cavity.

Case Record

A man aged 43 was admitted to the General Infirmary at Leeds on Dec. 14, 1942, under the care of Mr. P. R. Allison. He gave the following history. On Oct. 17, 1942, he was seized with a sudden acute pain in the middle of the back while at work and rapidly developed a severe cough. He became so ill that he had to be taken home and put to bed. He was febrile, and on Oct. 20 was removed to a nursing home with a diagnosis of lobar pneumonia. A course of sulphapyridine was given: 2 g. stat. and 1 g. four-hourly

for 48 hours, and then 0.5 g. four-hourly for 24 hours—a total of 17 g. in 3 days. His temperature fell to normal on the second day, and on Nov. 3 he was discharged apparently cured.

The man improved for about a fortnight; then his cough returned with added severity and he brought up much foul-smelling greenish-yellow sputum. Cough was his main symptom at this time. Vomiting occurred on several occasions, and his cough became almost incessant. A noticeable feature was that the cough was made worse by movement; he was more free from the paroxysms of coughing when supine than when in an upright position. His temperature varied from 99° to 101°, and clinical examination on Dec. 8 showed that there was an effusion at the right apex. X-ray examination on Dec. 10 confirmed this. Aspiration of the right chest in the sixth interspace in the mid-axillary line produced pus which on culture gave a profuse, nearly pure growth of *B. friedländeri*. The patient was admitted as a case of post-pneumonic empyema on Dec. 14: temperature 99.6°, pulse 84, and respirations 26.

Operation Notes.—Premedication consisted of morphine gr. 1/4, atropine gr. 1/100, and scopolamine gr. 1/150. The skin and subcutaneous tissue in the right upper chest were infiltrated with 0.5% plain cocaine, and aspiration of the chest in the sixth interspace in the mid-axillary line produced pus. A portion of the sixth rib was removed and the parietal pleura was opened. A large apical cavity was entered and 45 oz. of thick green pus was withdrawn. During a violent fit of coughing a slough of the whole of the right upper lobe was expelled from the wound, being followed by a gush of foul-smelling pus. A large drainage-tube was inserted into the cavity, and the skin lightly sutured and a light dressing applied. The lung slough measured 20 by 8 by 6 cm. It had a grey ragged appearance and was pitted with small holes.

Post-operative Progress.—On return from the theatre the patient's general condition was good: temperature 99.6°, pulse 96, and respirations 32. Cough, which was spasmodic, was relieved with linctus heroin 2 dr. t.d.s. Drainage was profuse, and his temperature, pulse, and respirations reached normal levels on the third post-operative day. X-ray examination at this time showed that the tube was in good position and that there was no fluid level in the cavity. Satisfactory progress was maintained, and on Dec. 22 a thoracoscope was passed into the cavity. Clean pink pleura could be seen all round except on the lower and posterior part, where the dappled surface of the lower and middle lobes could be made out. The root structures were plainly visible, and at least three large bronchial openings could be seen. There was a polypoidal projection from what seemed to be the pulmonary artery, which was presumably organizing blood-clot.

Convalescence continued to be satisfactory and drainage gradually decreased. Apart from a slight morning cough the patient was now entirely free. On Jan. 23, 1943, he was allowed to get up, and on Feb. 19 was discharged from the hospital with a self-retaining catheter in position in the cavity. The tube was changed frequently, and x-ray examinations were made at intervals of about three weeks. The tube was finally removed on June 2, and the sinus rapidly closed. X-ray examination showed that there was then still a cavity at the right apex, with at least one patent bronchus at its lower end. The patient is now (June 20) quite well, free from cough and dyspnoea, is gaining weight, and has started work.

Comment

The illness began with an attack of lobar pneumonia, which was followed by a period of recovery. This was interrupted by the appearance of excessive cough, which was productive of thick greenish-yellow sputum, with attendant symptoms of malaise and pyrexia. Clinical examination some two months later suggested an empyema, and drainage was indicated. At this time the cough was noted to be positional: the patient coughed more when he was upright than when flat in bed. The presence of *B. friedländeri* in the pus from the cavity was a rare and unexpected finding. Removal of the tube six months after drainage was started still left a cavity in the right upper zone. This cavity is draining into a patent bronchus on its lower and medial aspect. Up to now the presence of a cavity has not given rise to any symptoms. The question of an apical thoracoplasty must, however, be kept in mind, so that the cavity may be closed completely if it should again give rise to any symptoms.

Summary

One case of spontaneous lobectomy is described. The finding of a nearly pure culture of *B. friedländeri* in the pus from an empyema is noted as a rare event.

For permission to describe this case I have to thank Mr. P. R. Allison, under whose supervision it was while in hospital.

Medical Memoranda

"Spinning the Occipito-posterior"

In a fairly concentrated experience of obstetric practice (hospital, consulting, and private) spread over 25 years, at least 500 cases of occipito-posterior presentation, at a very moderate estimate, must have been treated (probably many more). During this period a method of treatment, feasible in a limited number of cases only, has been thrust upon me by Nature's own ordinance rather than by any skill or genius on my own part. I have termed this method, perhaps rather fancifully, "spinning the occipito-posterior."

The method depends upon the combination of several favourable circumstances, some of which are partly under medical control. These are as follows:

1. The membranes must be intact.
2. The head must not be absolutely jammed in the lower strait.
3. There must be at least two to three fingers dilatation.
4. There must be no disproportion between the head and the pelvis.
5. The attempt should be made within 24 hours (probably) of the onset of "painful contractions of poor quality" so characteristic of occipito-posterior presentations.

In such cases the usual approved method of treatment is by analgesics and psychological control of the patient.

There is an alternative. In the course of examination, to determine position and progress, a two-finger vaginal examination should, if possible, be made. With a knowledge of "intact membranes," the head may be pushed upwards, between pains, possibly half an inch or more into the cavity of the pelvis. The result is that liquor amnii can pass down on all sides of the head, so that, for practical purposes, it again floats in the lower part of the amniotic sac. Should the pressure upwards be timed to coincide with the onset of a contraction, the head will sometimes spin completely round to occipito-anterior practically instantaneously. Retaining this position by fundal pressure and promptly rupturing the membranes and letting off liquor will lead to a reasonably rapid and normal delivery.

It is obvious that this method has a limited application, but might possibly be used much more often if the necessary conditions were looked for and the attempt made.

Fracture of the Neck of the Femur after Amputation

Fracture through the neck of the femur due to hyperaemic decalcification—the fatigue type of fracture—is allied architecturally to the lesion described below. A search of the literature being fruitless, it was thought worth while to record the following case both as a matter of interest and as a warning.

CASE RECORD

A shunter aged 43 was admitted to the orthopaedic department of Peterborough Memorial Hospital on July 24, 1943, an express train having run over his right foot, amputating it close to the ankle-joint. After resuscitation, as he was profoundly shocked, an amputation was performed 5½ in. from the inner side of his knee-joint. Three weeks later he was discharged from hospital, but attended for a considerable time for stump and hip exercises. In due course he was measured for his artificial limb by one of the best makers. On Dec. 8 this arrived, and on the following day he walked over to the hospital to show me his prowess. On Dec. 11, when some miles outside Peterborough, he felt something give in his hip-joint while stepping from a high pavement to the road. As he could not move he was brought to hospital again by ambulance. Radiographs showed a typical transcervical fracture and also the typical appearance of a disuse atrophy. A few days later a vitallium nail was driven across the fracture. After three months, as there was sound bony union, weight-bearing was started—this time very gradually. Now he is doing everything a modern artificial limb permits.

COMMENT

This case, in my opinion, is a mixture between the fatigue type of fracture and that due to disuse atrophy, the precipitating factor no doubt being the latter, the hyperaemia caused by the unaccustomed activity helping to decalcify still further the weakened bony structure. This case serves as a warning—to me, at any rate—that weight-bearing should be given in graduated doses after an amputation, and no such warning or similar cases to this has been recorded.

Memorial Hospital.

Reviews

SYPHILOLOGY

Essentials of Syphilology. By Rudolph H. Kampmeier, M.D. With chapters by Alvin E. Keller, M.D., and J. Cyril Peterson, M.D. (Pp. 518; illustrated. 25s) Oxford: Blackwell Scientific Publications, Ltd.

Kampmeier's *Essentials of Syphilology* is exactly what it claims to be—a complete account of the commoner aspects of syphilis, leaving out or saying little about its rarer manifestations. As such we can say without hesitation that it is just the sort of book the average practitioner wants—and this is what gives it value, as apparently much more syphilis is treated by the general practitioner in the U.S.A. than in Great Britain. Readers will do well to study the preface, since there Dr. Kampmeier sets out his principal aims, which are to present a concept of syphilis as a systemic disease, to insist that every diagnosis of early syphilis must be verified by pathological examination, to raise the index of suspicion of syphilis, to improve methods of treatment, and to stress the need for regarding every case as part of a public health problem.

The book deals first with the biology of syphilis, examination of the patient, and therapy; then primary, secondary, latent, and late benign syphilis are followed by a consideration of the disease as it affects the various systems and organs of the body; finally, syphilis and pregnancy and congenital syphilis complete the clinical section. There follows a chapter on marriage and syphilis and a discussion of the various aspects of the disease as a public health problem, by Dr. Keller; this latter adds considerably to the value of the book, because if there is one disease more than another which should, theoretically, be capable of control by epidemiological methods it is syphilis. Only if those who see the disease in its early stages take a broad view and realize that at least two, and often many more, persons are involved in every case can the problem be tackled with any hope of success.

The subject-matter is clearly set out, there are numerous illustrations—most of which are quite first-class—and case summaries with comments which will prove helpful. Treatment of early syphilis is on the usual lines employed in the U.S.A.—i.e., alternating-continuous—but the necessity for employing adequate bismuth in the early stages is very wisely stressed; there can be no doubt that reliance on arsenic only at first has in the past been the cause of many relapses. Neoarsphenamine and mapharsen are named as arsenicals of choice without any particular preference being shown for either, and bismuth subsalicylate in oil is the routine heavy-metal preparation. Incidentally the individual doses of bismuth recommended seem to be on the small side.

If the literary standard is not as high as could be wished, and if a better knowledge of the classics would have precluded such expressions as "labium minor or majus," "condyloma accuminata (venereal warts)," "many *T. pallidum*," "vena cavae." These are venial errors, and are more than off-set by such gems, which appear here and there, as: "No method [of staining *T. pall.*] is of practical value in the accurate diagnosis of syphilis"; "The diagnosis of a syphilitic chancre on the basis of its clinical characteristics is inexcusable"; "No technician no matter how experienced is superhuman, and no laboratory no matter how good is infallible"; "Nor can it be estimated how many families have been broken up nor how many affianced couples have been estranged through lack of the proper interpretation of reports of a test. . . ."

PSYCHOLOGY IN TERMS OF ANIMISM

Food for Thought. A Treatise on Memory, Dreams and Hallucinations. By Bernard J. Duffy, M.A. (Pp. 160. 10s. 6d.) London: Longmans Green and Co. 1944.

This is a plea for an animist approach to psychology. The author is quite certain he is right and expects the reader to accept his convictions with the same ardent faith as he himself enjoys. He states: "The more honestly science is applied to psychology, the more unassailable becomes the animist position. Mechanistic theories are many, and their very variety is proof of their individual inadequacy. The materialist is constantly

shifting his ground, but the animist stands fast to what introspection, science, and common sense tell him is the truth of the matter." Mr. Duffy begins by recording the unsatisfactory nature of existing theories of memory and the relationship of body and mind. With this most people agree. He then states that mind is an aura which can be seen and photographed. He quotes unconfirmed experiments in which the phantoms of grasshoppers were photographed at the moment of the insects' death. Also he is satisfied that a separate existence of mind is proved by the observations that a medium showed differences in haemoglobin and biochemical reactions when "herself" and when controlled by different "spirits," though, if the observations were confirmed, it is possible that emotional states may alter autonomic reactions. He goes further and states that the human body loses 2 to 2½ oz. at the moment of death, and that this is the weight of the soul.

Having established the independent existence of the soul, Mr. Duffy accepts much of the modern observations of electroencephalography and maintains that the human brain is used by the mind as a very delicate receiver and transmitter of high-frequency waves. He says, "My hypothesis is that every psychic activity, whether cognitive or conative, results in a discharge in the brain of electrical impulses, the frequency of which is constant for that particular activity; and that these impulses are the determining factors both in the integration of the motor nervous system and in the physiological processes of memory. This electrical receiver receives, records, and reproduces sensory impressions, and the mind can also initiate vibratory responses." Further than this the author accepts as scientifically proved the reality of telepathy, and explains its uncertainty by supposing that only a few people are capable of sufficiently sensitive and accurate tuning to receive thought transference. Memory is then a reproduction of these electrical recordings; dreams are similarly explained, but the reproduction is faulty and incoordinated and complicated by the reproduction of telepathic communications. Hallucinations are reproductions from a brain injured by physical and chemical (but apparently not emotional) agencies.

If the reader is convinced by the author's reasoning he will probably consider that he has presented a coherent argument explaining memory, but all will not be so convinced.

PRACTICAL THERAPEUTICS

Methods of Treatment, with chapters on special subjects by various authors By Logan Clendening, M.D., and Edward H. Hashinger, M.D. Eighth edition. (Pp. 1,033; illustrated. 50s) London: Henry Kimpton.

This book, first published in 1924, has now reached its eighth edition. The authors are professors of medicine in the University of Kansas. The first part consists of chapters on drugs, anaesthetics, serums and vaccines, extracts of the ductless glands, dietetics, physical therapy, and radiotherapy. The second part deals with the treatment of special diseases. An impression is obtained in different parts of the book that there has been no complete revision since the original edition, so that in many places the book is out of date. In the chapter on extracts of the ductless glands there is no mention, for example, of stilboestrol or of methyl testosterone. A very incomplete account is given of desoxycorticosterone acetate. Thiouracil is not referred to. Myasthenia gravis is dismissed in eleven lines, and is explained as being a disease due to excessive action of choline esterase. Carbinoylcholine is not mentioned. Thus the book has not a very modern point of view. Moreover, it exercises caution in criticism, where sometimes unhesitating condemnation seems required. Thus a regular American pick-me-up is bromo-seltzer, which contains acetanilide. The authors point out that long-continued use of coal tar products, especially this substance, leads to the formation of methaemoglobin and sulphhaemoglobin, but they say nothing of the danger of agranulocytosis, cases of which have now been described after the use not only of amidopyrine but also of phenacetin.

There is a useful chapter on physiotherapy, which though short gives details of the method of applying cold baths and wet packs. It is stated that the wet pack is a valuable remedy for insomnia among other conditions, and certainly it is probable that physical methods of treatment should be given wider trial in this common complaint, which is often so difficult to treat.

ANACARDONE

Trade Mark

(NIKETHAMIDE B.D.H.)

Nikethamide, over a period of years, has won an established position for the treatment of collapse from shock and poisoning, also for the control of the depth, or duration, of basal anaesthesia, particularly that induced by intravenous barbiturates.

Recently nikethamide has been recommended for the treatment of syncope in blood donors [Journ. Amer. Med. Assoc., May 27th, 1944, p. 314, (abs.)], the incidence of which, it was stated, is about 7 per cent. In this report nikethamide was described as being 'the most effective single pharmacodynamic agent for the treatment of donor syncope.'

For parenteral administration nikethamide is available as Anacardone, in 2 c.c. and 5 c.c. ampoules (Injection of Nikethamide B.P.) and for oral administration as Anacardone (oral), a flavoured 25 per cent. solution of nikethamide.

Details of dosage and other relevant information will be gladly supplied on request.

'KEPLER' TRADE MARK

COD LIVER OIL WITH MALT EXTRACT

Helping to build the men and women of tomorrow

'Kepler' provides valuable supplementary Vitamins A and D together with readily-assimilable fat and carbohydrate.

There is no finer product of its kind. The high standards of quality for which more than one generation of medical men has esteemed 'Kepler' have in no way been lowered because of wartime difficulties. 'Kepler' Cod Liver Oil with Malt Extract contains Cod Liver Oil 23% v/v with Malt Extract; each tablespoonful provides not less than 3000 International Units of Vitamin A and 300 International Units of Vitamin D.

TRADE MARK

'SVC'
BRAND

acetarsol vaginal compound

in leucorrhoea

In the treatment of leucorrhoea associated with the presence of *T. vaginalis*, formerly so intractable a condition, 'SVC' brand of acetarsol vaginal compound is frequently effective. The product is available in two forms; tablets of elongated shape for insertion containing grains 4 of acetarsol in each and powder for insufflation containing 12.5% of acetarsol. In response to a number of requests the volume of the latter preparation has recently been doubled, the total acetarsol content remaining the same. Vaginal insufflations are contraindicated during pregnancy.

Tablets available in containers of 25 and 100, powder in containers of 6 x 6 Gm.

MARRIAGE AND BIRTH CONTROL

Modern Marriage and Birth Control By Edward F. Griffith M.R.C.S. L.R.C.P. (Pp. 26, 6d.) London: Victor Gollancz, 1944.

Dr Edward Griffith has made a name for himself as a teacher on the ideals of human marriage, preparation for it, and contraception in it. *Modern Marriage and Birth Control* was first published in 1935 and has been reprinted thirteen times since then. Now he has rewritten much of it added a very useful chapter on the causes and possible treatment of sterility and brought the section on contraceptives up to date in view of accumulated experience. References to other literature, both scientific and social are given, there is an index, some plates, and a list of clinics where advice can be obtained. Much of the information would not be new to a doctor, but the manner of conveying it might prove very helpful. Clergymen, social workers, magistrates, school teachers, and others who need accurate information for themselves would find in this book all the facts they require.

The close connexion between man's spirit and the high creative possibilities of sex is constantly before the author's eyes. His style is simple, factual, and direct intended for the general reader and intelligible to anyone serious enough to tackle so much material. The description of the initial approach to intercourse and the art of love making is well done. Dr Griffith holds strongly that if study in this matter precedes practice much disappointment and even disaster would be avoided.

While no two writers would agree about every word or every emphasis in such a book, in which didactic statement is suitable it can be said that there is moderation and accuracy throughout. If the format is not very attractive, owing to wartime restrictions, the size is comfortable and the price low. Dr Griffith can be congratulated on his work.

Notes on Books

The Training of the Nursery Nurse, an interim report of the National Council for Maternity and Child Welfare, is published by the National Society of Children's Nurseries, 117, Piccadilly, W.1. This pamphlet reports the findings of a committee. Recruitment, type of candidate, conditions of service, and particulars of training are duly considered. The final diploma gained by examination is intended to qualify the candidate for the post of staff nurse in a children's nursery or as a children's nurse in private households. The majority report of the committee recommends that the course, which is to train the girl in the care of healthy children from infancy up to school years, should be extended over two years. A minority report states that in a properly constituted nursery training college the course could be adequately covered in one year. Possibly this difference of opinion is more apparent than real, and if more specially qualified teaching staff were employed in the ordinary nurseries, the proposed course might be shortened without detriment. This question of staff should receive consideration when wartime exigencies render it possible. These girls have the charge of children during the most important and formative years of life, and it is important to try to maintain in post war years the general standard of personnel and training of the present nursery training colleges. The training of a nursery nurse which is here contemplated for girls from 16 to 18 years of age is a useful and pleasant occupation for any girl besides being a valuable preliminary to a nursing career.

In the autumn of 1943 the British Medical Students' Association whose office is at B.M.A. House, Tavistock Square, W.C.1, organized a series of lectures on war surgery. It has now been possible to publish these in pamphlet form. The lecturers were Sir James Walton (recent advances in the treatment of war wounds), Prof. J. Trueta (biological treatment of war wounds and fractures), Mr. A. Tudor Edwards (early treatment of wounds and injuries to the chest), Major Gen. C. Max Page (surgery in the field), Mr. A. H. McIndoe (injuries of the face), Sir E. Rock Carling (burns), Surgeon Rear Adm. G. Gordon Taylor (surgery and Russia), and Col. Elliott C. Cutler (American views). This publication (price 2s. 6d.) may be had from the secretary of the B.M.S.A., or from Messrs H. K. Lewis and Co., 136 Gower Street, W.C.1.

'Dr JOHN DREW' is apparently a pseudonym for a medical man who is obviously familiar with his subject. He has written for the general public to give information about human biology, sex, and venereal diseases which are closely associated with sex (*Human Reproduction and Venereal Disease* (Faber and Faber, 3s. 6d.)). The average man or woman is extraordinarily ignorant about these

matters, much of the V.D. now so prevalent is contracted through ignorance, instruction in sex matters and the dangers of V.D. is all too rarely given to children and young adults. This little book, therefore, should help to lift the veil, and it can be recommended to all laymen because education is the keystone of any antivenereal campaign.

Preparations and Appliances

SIMPLE DEVICE FOR CONTROL OF TENSION PNEUMOTHORAX

Major H. FULD, M.D., M.R.C.P., R.A.M.C., writes

Tension pneumothorax (valvular) is rarely seen in civilian practice, but is a frequent complication among chest injuries in battle casualties. The customary method of dealing with this emergency is by needling, a long rubber tube being attached to the needle. The end of the tube is placed under water. This is somewhat complicated, requires frequent supervision, and is unsuitable for use in forward areas and during transport of the patient. To overcome these drawbacks the following device has been designed and has proved itself simple, efficient, and safe.

A transfusion needle from the Army set is passed through the centre of a rubber disk as supplied in the screw cap of a glucose saline bottle. The needle is inserted into the second

intercostal space. Local anaesthesia is unnecessary because the extreme distress and anxiety in patients suffering from tension pneumothorax make them oblivious to the slight discomfort caused by the insertion of the needle. The needle is firmly secured by strapping adhesive plaster across the disk. A rubber tube 8 in. long is attached to the needle by a metal connexion piece. A non return valve (air inlet valve) from the transfusion set is inverted and attached to the rubber tubing. This non-return valve allows air to be blown out of the pleural cavity but none to be sucked in. The valve is stuck to the skin over the sternum. Eight inches of tubing allows the valve to lie flat. It is an advantage to leave half an inch of tubing on the distal side of the inverted valve as it permits attachment to the pump of Potain's aspirator if rapid removal of air is required. Penicillin can be injected into the pleural cavity after detaching the rubber tube with the metal connexion from the needle.

This device can be put in almost immediate use wherever there is an Army transfusion set. It is simple enough for use in the regimental aid post, during transport of the patient in an ambulance, and for further treatment in C.C.S.s and general hospitals.

INHERITANCE AND TUBERCULOSIS

Stocks¹ has recently remarked: "There is a modern tendency to ignore the existing statistical evidence about heredity, derived from the incidence of conjugal and familial tuberculosis, studies of twins, and laboratory work on animals. For this attitude there is no justification, but further statistical research is needed to elucidate the importance of inherent resistance in primary and secondary infection." It is, of course, true that deductions from human observations must be drawn with great care. Unless researches are particularly well designed, an element of doubt may reasonably remain as to whether the inter-family resemblances observed are to be ascribed to the inheritance of a similar genetic constitution or to such factors as the increased chances of infection among close relatives. There has appeared, very opportunely, a paper by Kallmann and Reisner² on a twin and family study of tuberculosis which can be described without hesitation as the most skilful and unequivocal piece of research yet undertaken on human twins. The care taken in the planning and execution of this study leaves nothing to be desired from the point of view of human genetics, of the medical aspects of tuberculosis, or of statistical treatment.

The first, and perhaps the most important, requirement is a good sample. This was secured through the co-operation of the tuberculosis hospitals and clinics of the State and City of New York, which notified over a period of nearly five years the cases of pulmonary tuberculosis coming under their care when the patient was one of a pair of twins. Investigation of the patients themselves—the index-cases—and of their relatives was detailed and thorough. (The individual who brings the family into the investigation is described as the "index-case.") The investigators finally had for analysis 308 twin pairs, including 334 index-cases (for some pairs were ascertained through both members), with manifest reinfection (adult) type pulmonary tuberculosis. In addition, there was investigated an unselected sample of relatives comprising 930 full brothers and sisters, 74 half-sibs, 688 parents, and 226 marriage partners. It is an indication of the efficiency of the sampling that the proportion of identical to fraternal pairs, 78 to 230, is almost exactly the same as the known proportion in the population generally. A satisfactory technique was used for adjusting for differences in age, sex, and colour, so that comparable proportions and rates were obtained for the various groups to be contrasted. The average age of the twin pairs at the time of investigation was 31 years, and where they were discordant—i.e., where the co-twin was free from pulmonary tuberculosis

—they had been discordant for an average period of 6 years. The adjusted morbidity rates (essentially the chance of developing manifest pulmonary tuberculosis by the age of 29) are as follows: For the general population of the State and City of New York the rate is 1.4%; for the husbands and wives of the index-cases, 7.1; for their half-sibs, 11.9; for their parents, 16.9; for their full-sibs, 25.5; for their fraternal co-twins, 25.6; for their identical co-twins, no less than 87.3. The husband-wife figure is interesting and doubtless reflects a considerable incidence of direct infection. It is pointed out, however, that as Pope, Pearson, and Elderton³ showed many years ago, there is a selective factor also. The tuberculous tend to marry each other, just as like attracts like in physical and mental things generally. In spite of the intimate contact of husband and wife, however, the rate even for half-sibs is much higher. Altogether, the progression of the figures is just what would be expected on genetic grounds.

Identical twins have an identical genetic constitution, for they were once a single individual; fraternal twins are no more alike genetically than brothers and sisters born at different times. It is true that identical twins tend to share a more similar environment than do fraternal (especially psychologically), but in the same way fraternal twins have a more similar environment than ordinary brothers and sisters. Yet in this collection fraternal co-twins are not affected more often than the other sibs of index-cases. This makes it very unlikely that the even more similar environment of identical twins could account for more than an insignificant part of the great difference in morbidity rates which is therefore to be ascribed to heredity. In any event, a difference so great that identical co-twins are three and a half times more likely to be affected than fraternal co-twins could not conceivably be explained in such a way. The general conclusion is reinforced by much else, including an analysis of the histories of exposure to infection, the evidence in regard to which is somewhat too intricate to be summarized here.

When index-cases and their co-twins were classified not merely according to whether they were affected or not, but in addition according to differences in the extent and course of the disease, a far more striking contrast emerges. Instead of the identical co-twins being three and a half times more like their index-cases than are the fraternal co-twins, the concordance is now no less than sixteen times as great. Thus, while genetic influences are clearly potent in determining whether or not manifest tuberculosis is contracted, they are much more potent in determining the resistance of the individual to the established disease. It is a remarkable illustration of this finding that the chances of death from pulmonary tuberculosis of a person with the disease who has a healthy identical twin are practically nil. At this point the evidence is closely linked with that provided by the work of Lurie on rabbits.⁴ In his experiments the infection rate was high (60 to 80%), and much the same in all strains. In resistance to the established disease, however, there were big inherited differences between resistant, intermediate, and susceptible strains. Lurie, who took

¹ *Practitioner*, 1944, 153, 1.² *Amer. Rev. Tuberc.*, 1943, 47, 549.³ *Drapers' Company Research Memoirs*, No. III, London, 1908.⁴ Noticed in this *Journal*, 1943, 1, 196.

part in the discussion following Kallmann and-Reisner's paper, stated that in new experiments with greatly reduced intensity of exposure the results closely paralleled the human findings. Certain rabbits of high genetic resistance acquired an infection which healed completely, while others of low genetic resistance, similarly exposed to the same low intensity of contagion, developed fatal tuberculosis.

The discussion on Kallmann and Reisner's paper was opened by Barbara Burks, whose early death has unfortunately robbed human biology of one of its finest and most critical minds. Her opening words were: "This is a historic occasion." There could be no greater tribute; if the evidence satisfied her there will be few indeed who could detect a flaw in it. Previous work has been suggestive, and more than suggestive, but now no reasonable doubt can remain that human pulmonary tuberculosis is a disease influenced to a notable extent by inborn, inherited constitution—influenced, moreover, to a greater degree in regard to its behaviour when once contracted than in regard to whether it is contracted at all. But there is nothing in all this to discourage those who are combating it by devising improved preventive, diagnostic, and therapeutic measures. The exact reverse should be the case. To quote once again from Barbara Burks:

"This does not discount the environmental factors which an organization like this one [the American National Tuberculosis Association] emphasizes. It doesn't discount cod-liver oil or tomato juice, or fresh air, or any of the other environmental factors which have undoubtedly been greatly responsible for reducing the tuberculosis death rate. . . . It means, if it is not possible to segregate a tuberculosis case in a hospital or sanatorium, it is at least advisable not to have the nearest relatives of the patient take care of him. . . . It means that it is better to have a tuberculosis case taken care of by husband or wife than by parent, child, brother, or sister. . . . Prophylaxis should begin in regions where there is a history of heavy infection. . . . Nurses who undertake tuberculous nursing should be selected, if possible, as being free from tuberculosis histories in their families. . . . If . . . vitamins and other reinforcing elements of the diet . . . are limited . . . they should be routed first to the families who need them most."

A clear appreciation of the role of genetic constitution in pulmonary tuberculosis and all that this implies should fortify all the diverse lines of attack designed to control and prevent one of the most important of human diseases.

NEW JOURNALS AND OLD

In spite of—or in some cases because of—the war, new medical journals come and old ones go, the first being a more difficult procedure than the second, if only because no new periodical may be launched without permission from the Government. Publishers of medical journals have had their fair share of difficulties, quite apart from the long-drawn-out rearguard action they have had to fight with the Paper Controller. The printing industry suffered severely at the hands of the enemy in the air raids of four years ago, and there has of course been a steady drafting of their skilled operatives into war work; and the flow of Government publications—many of them designed, so the cynic might suspect, to keep employed the numerous scribes housed in the Ministry of Information—has tended

to crowd out less ephemeral work. So anyone starting a new periodical in wartime has to take his courage in both hands.

At the beginning of 1944 the first issue of the *British Journal of Industrial Medicine* was brought out by the B.M.A., and in the short space of less than a year it has, under the editorship of Dr. Donald Hunter, established a reputation for excellence and high scientific standing that may be the envy of older journals.

The beginning of the year, too, saw the appearance of the *Proceedings of the Nutrition Society*, under the general editorship of Dr. S. K. Kon. The Nutrition Society, founded during the war, has gone from strength to strength, and its successive meetings have attracted a growing number of those interested in this all-important subject. The Nutrition Society has an English group and a Scottish group, and so we find in the official organ of the Society a division of the proceedings into two parts, with separate editors for the English group and the Scottish group. The *Proceedings* is published "in order to record the papers and discussions of the scientific meetings of the Society . . . to place these before as large a public as present circumstances will permit." The first volume shows that the Editor has surmounted his many difficulties with skill. In a volume aiming at a wider public than members of the Society it cannot have been easy to know how much of a discussion should be included after the opening papers. The layout and choice of headings, too, becomes rather complicated in a volume of this sort, especially when there are two groups of the Society, necessitating such a heading as, "Fourth Scientific Meeting—Second Scottish Meeting." It might have been simpler to put as a footnote to the article the kind of meeting it was, whether English or Scottish, and details of the place and date of meeting. The typographical purist might object to mixing a sans-serif with a serif type, but the former certainly brings out the names of the readers of papers and participants in discussion—this type being used nowhere else. The remarkable success of the Nutrition Society, and the interest displayed in the accounts of its work published in the medical and scientific press, suggest that something more ambitious than a *Proceedings* should be published, that, in fact, there is plenty of room for a *British Journal of Nutrition*—a journal that might well grow out of the *Proceedings* under the same distinguished auspices. The beginning of this year also saw the appearance of a new American journal—*Journal of Neurosurgery*—a witness to the growing activity of a highly specialized branch of surgery. On this side of the Atlantic the sign of the surgical times was shown in the changing of the title of the *Journal of Neurology and Psychiatry* to include in it the word *Neurosurgery*. We note with much sympathy and interest what will presumably be an ephemeral publication under the title of *Polish Science and Learning*, this being described as a series of booklets edited by the Association of Polish University Professors and Lecturers in Great Britain, under the honorary editorship of Prof. A. V. Hill, Sir W. D. Ross, and Sir E. J. Russell. No. 4, issued in March this year, was devoted to medicine, and opened with an account by Prof. A. Jurasz (Dean of the Polish Faculty of Medicine in Edinburgh) of the Polish Medical School and the Paderewski

Hospital in Edinburgh. Among the departures from the scene of medical journalism is the *British Journal of Children's Diseases*, which now ceases to be published separately and is to be incorporated in the *Archives of Disease in Childhood*.

This month for the first time the British Medical Association publishes the *Annals of the Rheumatic Diseases*, the lineal descendant of the Annual Report first published ten years ago by the British Committee on Chronic Rheumatic Disease appointed by the Royal College of Physicians and edited by Dr. C. W. Buckley. Four annual numbers of this report were issued, and in 1938 the work of the committee and the publication of its reports was transferred to the Scientific Advisory Committee of the Empire Rheumatism Council. For these past ten years Dr. Buckley has maintained the high editorial standard which has made the journal widely appreciated. He now leads the Editorial Committee jointly appointed by the B.M.A. and the Empire Rheumatism Council. As Lord Horder points out in a foreword to the current volume: "Rheumatism, because of its wide prevalence, and its resulting pain and disablement, is perhaps the most serious enemy of social well-being." He observes that the facilities for treating rheumatism have been grossly inadequate in the past, and are so indeed at the present, when "treatment appropriate to their needs is available to only about 10% of rheumatic sufferers." Lord Horder considers that if the Ministry of Health is to see that appropriate treatment is provided there will in the first place be "a great additional demand on the medical profession and its auxiliaries." When treatment is freely available on a nation-wide scale, facilities should also be provided for intensive clinical research, the recording of which in the *Annals of the Rheumatic Diseases* will, we may hope, bring essential knowledge before the medical public in this and other countries.

"DISSIDENT DOCTORS"

Silence is often the most effective answer to a vociferous and misguided minority," writes Gordon Malet in the *Spectator*. Gordon Malet's name does not appear in the *Medical Register*, but one presumes this is a pen-name for a medical man who has his own reasons for hiding his identity. The article from which the quotation comes is headed "Dissident Doctors," and is an effective attack on the Medical Policy Association. Previous articles by Gordon Malet in the same paper suggest that he, too, is among a group of "dissident doctors" and also belongs to a vociferous minority. He may belong to that small minority of doctors who find themselves within the fold of the Socialist Medical Association, who have become vociferous through undeniably skilful use of a propaganda machine driven by men no doubt ardent and sincere in the beliefs they hold. Equally sincere is the belief of a large number of doctors that the introduction of doctrinaire politics into medicine is doing untold harm to a profession which has never held it to be its duty to act as political proselytizers. One of the drivers of the S.M.A. machine seems to be Dr. Samuel Smith, who practises in the East End of London. A cyclostyled letter with his signature, and addressed to a doctor in another part of London, has come into our hands. Dr. Samuel Smith is apparently

worried about correspondence on the White Paper in the medical and lay press—"and particularly in the *British Medical Journal*. Until recently," he goes on, "there has, however, been very little correspondence of a progressive nature to counterbalance the spate of vicious anti-White Paper statements." Dr. Smith evidently regards himself as being in the van of progress and in a position to offer guidance to colleagues who might like to join with him in becoming progressive. "It is in the hope," he continues modestly, "that you will agree to assist by sending a letter to the Press that I enclose a few notes on last week's report in the *B.M.J.*" (This refers to the *Journal* of Sept. 16.) It should be made quite clear at this point that Dr. Smith's cyclostyled guide to letter-writing was not addressed to the Editor of the *Journal*. The recipient was plainly one of that vociferous minority of doctors belonging to the Socialist Medical Association, and we assume that the other cyclostyled copies go to the rest of the small band of progressive companions. It is more than disquieting to notice that, at a time when the shortage of doctors is acute, a number of them are prepared to spend time, money, and paper in fomenting political activity and indeed in directing it. These medical men, while parading the fact that they are members of the B.M.A., are not content to work within it in a democratic way. In the *Supplement* to the *Journal* of Sept. 16 a letter signed by ten doctors appeared under the heading of "The White Paper and the Good Will of the Profession," and among the signatures is S. Smith. On looking once more at this, we find that the letter was printed and sent to us for publication by Dr. Smith from the same address as his guide to letter-writing.

"You will appreciate," Dr. Smith writes, "these notes can be used to develop arguments, and a number of replies from different people along these lines would have an excellent effect" (our italics)—the effect, no doubt, of making people as progressive as Dr. Smith is himself. The notes he supplies on the back of his cyclostyled document are assembled under the heading, "B.M.A. Council and the White Paper." "Council well advised to give up fighting against National Health Service and concentrate on securing good administrative machinery" is the call to action trumpeted by Dr. Smith in his most progressive mood. He ends his notes with confident assurance and an encouragement to the B.M.A. to be as progressive as himself. "Government intent on bringing in National Health Service, public wants it; full public and professional support for B.M.A. if more public-spirited approach shown." How reminiscent of Mr. Alfred Jingle at his best! Of course the B.M.A. Council is scolded when its views do not coincide with those of Dr. Samuel Smith, and he refers scornfully to "these Fabian tactics," and asserts in a challenging note: "Attitude and tactics of Council have also surely encouraged such people as M.P.A., whose disgustingly unscrupulous methods Council correctly opposed. Progressive people will support Council against attacks of M.P.A., but would do so more readily if Council did not make it so easy for M.P.A." It appears that the B.M.A. Council is remarkably impartial, at least according to the interpretation of Dr. Smith, because it makes it easy for the M.P.A. and at the same time correctly opposes it.

Has it occurred to Dr. Smith and his fellow-propagandists that the formation of such bodies as the M.P.A. may be the inevitable reaction to the existence and activities of the Socialist Medical Association? If one small politically minded group in the medical profession begins to use professional status as an opportunity for spreading political doctrines, then other dissident groups will assuredly spring up and do likewise, to the infinite harm of the

profession whose interests they claim to have at heart As Gordon Malet says, when a "minority is succeeding in persuading a substantial number of worthy people that there is something in what it says, the time for silence has passed."

PNEUMONIA: A STATISTICAL APPROACH

Pneumonia is a disease of variable incidence. Twin studies¹ indicate that inherited differences in susceptibility are at best of small account. Hence a favourable opportunity is provided for analysing the part played by occupational differences and other environmental factors in determining the occurrence of an important disease. In an interesting paper W. J. Martin² presents a statistical analysis of one of the most remarkable features of the disease—its much higher incidence among males. He shows that this is a fruitful line of approach which leads to important conclusions. The sex ratio of deaths from pneumonia is very different at different ages. Taking female deaths as 100 in each instance, the corresponding male death rates in England and Wales during 1924–38 were as follows: under 1 year, 133, from 1 to 15 years, 114, from 15 to 65 years, 208, over 65 years, 123. It is shown that variations in the sex ratio of deaths during infancy are related to the total incidence of deaths from the disease, when pneumonia is prevalent the excess of boys affected rises. Variations in social conditions and degree of urbanization have little effect on the sex ratio. The discrepancy between the sexes is least in childhood. Such variation as there is is not affected by degree of urbanization. Moreover, the factors making for male excess in infancy and childhood respectively are not the same, for they vary independently. In old age the discrepancy between the sexes has fallen once again, and a study of its variations yields no clear indication of any important association.

The chief interest of this study lies in the period of working life, 15–65 years. In sharp contrast to the periods of life which precede and follow it, more than twice as many men die of pneumonia as do women. The first point examined is the possible influence of social class. Although the total incidence of deaths from pneumonia rises steadily as social class falls, being nearly twice as great in the lowest as compared with the highest, there is little, if any, corresponding effect upon the sex ratio of deaths. The male excess is much the same in all. A likely guess—that variations in the male excess are occupational—is examined by comparing the rates among men in different occupational groups with those among their wives. It is found that in general wives tend to share the high or low rate of their husbands' group. There is, however, an indication of two significant exceptions—in hotel-keepers and furnacemen—where the male rate was high, the rate for the wives not differing from the rate for wives generally. Thus, apart from the indication of special risks associated respectively with high consumption of alcohol and big changes of temperature, it would appear that variations in the male excess are not directly occupational. Causes are to be sought, rather, among the indirect risks associated with the general conditions of life usually characteristic of particular occupations. One factor of evident importance is the degree of urbanization. In rural districts the discrepancy is much less. During 1924–38, in England and Wales, the number of male deaths from pneumonia per 100 female deaths was only 174, compared with 208 for the two countries as a whole.

Like so many fruitful statistical studies, this example points to the beginning and not the end of research. The question why there should be a great excess of male deaths from pneumonia, this being largely confined to the working years, is tentatively answered by the hypothesis of an indirect occupational risk, coupled with the greater prevalence of alcoholism among men (for a small proportion of men carrying a specially heavy risk would influence the sex ratio of deaths considerably). But the most important result of this paper should be the stimulation of further research into the factors which underlie susceptibility and resistance to pneumonia.

MIDWIVES IN WARTIME

The report on the work of the Central Midwives Board for England and Wales during the year ended March 31, 1944, is a stencilled document mentioning briefly some matters of interest and importance. The Board pays tribute to the magnificent service rendered by midwives to the community. The increasing birth rate and the shortage of staff, both medical and nursing, have pressed heavily upon the maternity service of the country. The shortage of practising midwives, which has caused anxiety for some time, was dealt with as a matter of high priority by the National Advisory Council of the Ministry of Labour and National Service, and the measures taken have led to a slight improvement in the position for the moment. A certain number of midwives not in active employment were encouraged to return to the work, and the Board has co-operated in securing vacancies for refresher courses when required. In Sept., 1943, the Control of Engagement Order was extended to midwives. All newly qualified midwives were required to do a year's midwifery practice after enrolment, and practising midwives had to continue with midwifery work until May 31, 1944. On that day the Roll of Midwives contained the names of 68,859 women, being 1,747 more than at the end of March, 1943, but the total number listed as practising was only 16,071. The examination arrangements again proceeded without interruption, the wartime expedient of holding written tests at the hospitals and oral tests at a large number of centres being adhered to. On March 31, 1944, the number of institutions approved for instructing midwives in the use of recognized apparatus for nitrous oxide and air analgesia was 91. Compilation of a register of midwives qualified to give gas-and-air analgesia continues, and so far some 2,400 midwives are known to hold the qualification. In consequence of a letter from the Medical Officer of Health of the L.C.C. drawing attention to the existence of a widespread custom among midwives of making arbitrary deductions from the birth weight of infants, and of comments from the secretary of the College of Midwives on this matter, the Board issued a statement to all approved training schools for pupil-midwives stressing the importance of strict accuracy in the keeping of records, and drawing particular attention to the need for accuracy in weighing infants. This matter was raised in the correspondence columns of the *British Medical Journal* of June 5, 1943 (p. 706), by Dr. Letitia Fairfield.

Prof. Charles Bruce Perry will deliver the Bradshaw Lecture before the Royal College of Physicians at London on Thursday, Nov. 9, at 2.30 p.m., at the College, Pall Mall East. Subject: "The Aetiology of Erythema Nodosum."

¹ O. von Vershuer, *Erbspathologie*, Dresden, 1934.

THE UNDERGRADUATE PERIOD

ADDRESS BY SIR JOHN FRASER

The address inaugurating the new session at Westminster Hospital Medical School was delivered by Sir John Fraser, Principal and Regius Professor of Edinburgh University. Speaking first of the influence of undergraduate training on personality, he said that in the discussions on the medical curriculum he had noticed very little comment upon the psychological influences of the university upon the undergraduate mind. The practice of medicine was something more than the treatment of disease: it was a great moral enterprise; and called for more than the application of scientific knowledge and technical procedures: it demanded the exercise of that subtle factor, personality.

Personality sprang from two roots—intelligence and the influence of environment. He assumed that all his listeners possessed the first; but there was something more, and unless it was acquired and developed the full measure of future success might be withheld. What was this mysterious ego which one either gained or missed during the years of professional training? It was the moulding and development of personality by the influence of the environment in which the student lived and worked. All medical schools possessed their distinctive environment: the tradition of the hospital and school, the influence and example of teachers, and contact with fellow students. The Westminster traditions were many and colourful; its teachers, past and present, had a high place in the annals of the profession; and the opportunities for student contacts and discussions which sharpened the wit and stimulated the ambition were abundant.

A Need to Redress the Balance

Sir John Fraser went on to suggest that there was some need for a readjustment of the balance of undergraduate teaching:

"The experience gained in thirty years of teaching has left me with the impression that we are apt to pay undue and growing attention to the presentation of detail and minutiae at the sacrifice of fundamental and general conceptions. . . . Forty-two years ago I began the study of medicine; from that date until now the length of the curriculum has remained unchanged, but when I review the demands which are made upon the undergraduate body and contrast them with those which I encountered, I realize that there is one outstanding dissimilarity between the periods—it is the degree to which detail, often meticulous in amount, is given an increasingly prominent place in the teaching programme."

e suggested that the presentation of the physical and biological sciences—the introduction to medicine—should be concerned with those principles which had a bearing upon the problem of health and disease rather than with detail which had no direct association with medicine, and in the preclinical subjects the detail should be restricted to facts that were related to clinical considerations.

Insistence upon minutiae not only impaired the primary object of undergraduate training, which was to provide the student with a comprehensive and well-balanced knowledge of the problems that were likely to confront him in average general practice, but it also, if pursued to an undue extent, diminished the powers of logical thinking and deductive reasoning, and offered little or no encouragement to the development of imagination. Imagination was the heritage of youth. In childhood it was pleasurably creative; in school days it underwent a temporary eclipse, because it did not flourish in an atmosphere of regimentation and routine; but it should find its "second wind" in the spacious fields of undergraduate occasions, and if at that time its development was smothered it was unlikely to reassert itself in later years.

Practitioners of To-morrow

In a short while those to whom he spoke would possess the qualifications which permitted them to practise the profession they had elected to follow. From whatever aspect they viewed it, they would find that the practice of medicine would yield them satisfaction.

"To you will be granted the privilege of practising a profession which is scientific in its basis and logical in its applications, which is creative and constructive in its aims, and which has as its ultimate object the provision of that which is surely the most precious of all possessions, mental and physical health."

Finally, Sir John Fraser spoke of the future. When the Government scheme for a National Health Service came into operation, he said, it was certain to offer a considerable enlargement of the field of medical opportunity. A service universal in range and complete in provision would demand a big increase in the present number of doctors. The increase would apply to every section and department of medical activity, though no doubt the expansion would be greater in some branches than in others. But there had never been an unemployment problem in medicine; taken all over, the demand had exceeded the supply, and, if he read the omens aright, future demands would be so many and so heavy that for a time at least they would tax the available resources to the utmost.

It was probable that there would be a sharper distinction between different types of professional work than at present. The specialist category would be more clearly defined, and inclusion in that group would demand the fulfilment of obligations which had not existed hitherto. While experience has shown that the combination of a certain amount of specialism with general practice might be successful and useful to the community, he believed that the ambit of specialism would be so clear-cut and defined that it would be difficult to pursue the "combination" system.

Work under the new scheme was likely to proceed under more favourable conditions than to-day. It would be so arranged and integrated as to ensure to the medical man the gift of leisure. He knew that there was another side of the picture, and that apprehensions had been expressed that there might be some interference with liberty of action, that the sense of security might lessen initiative, and that the exercise of the art of medicine might become increasingly impersonal.

"There may be some justification for these fears; but, after all they may prove to be unfounded, and if experience shows them to be real and prejudicial it will be the business of the individual affected to do what they can to remove them. And I would remind you that developments which postulate advantages to the many are likely to imply some degree of sacrifice by the few."

MEDICAL DEFENCE UNION

The annual general meeting of the Medical Defence Union was held on September 19 under the presidency of Dr. James Fenton.

In his address from the chair Dr. Fenton announced that 1,861 members had been elected during the year—the highest figure recorded in the history of the Union—and the total membership was now 27,439. He alluded to the termination of the Spackman case, which had been reheard by the General Medical Council in the way in which the legal advisers of the Union had always claimed that it should have been heard—namely, that evidence should be allowed which was not tendered at the Divorce Court. It was satisfactory that in similar cases the Council would have to follow the lines laid down by the House of Lords, necessitating sometimes a more complete hearing before the verdict was given. He went on to state that a certain number of deaths under anaesthesia had given rise to disquiet. The Union had looked into the matter and was satisfied that manufacturing difficulties arising from wartime problems were contributory to mistakes in the identification of gas cylinders. A subcommittee had been appointed to confer with the Society of Anaesthetists, and this joint body had consulted the manufacturers of anaesthetic gases and also the British Standards Institution. A short-term policy to meet the immediate wartime difficulties and a long-term policy to remove all uncertainties and ambiguities in regard to the marking of cylinders had been elaborated, and it was hoped that the result would be to prevent the occurrence of such accidents.

The President mentioned that an authoritative document had been prepared and was available for any practitioner who wanted advice on being approached by a patient on the subject of artificial insemination. Counsel's opinion had also been elicited on the question of the reporting by practitioners of deaths to coroners. He went on to refer to the grave concern felt in certain quarters concerning the quality and standard of the medical certificates issued by some practitioners, and urged members to exercise scrupulous care in this matter; especially should they refuse to be importuned by their patients to issue a certificate when there were no adequate medical grounds for doing so. The Union could not hope, he said, to achieve any success in the defence of a member who had disregarded these basic principles. Finally, he reminded all concerned that even if as a result of legislation a complete or partial State Medical Service came into operation membership of the Union

would be none the less essential to ensure the necessary legal and financial aid which a practitioner sooner or later might require. The State or the local authority did not accept responsibility for the professional mistakes of its medical staff.

The annual report and statement of accounts were adopted. The accounts showed a credit balance of £7,779 on the year. Dr Fenton was re-elected president, Mr E. D. D. Davis treasurer, and Prof. Gilbert Strachin was added to the vice presidents. The retiring members of Council, Dr Elizabeth Bolton, Dr E. Lewis Lilley, and Dr Henry Robinson, were re-elected.

THE TUBERCULOSIS SERVICE

The Joint Tuberculosis Council at its meeting in Birmingham on Sept. 16 decided to publish reports on two important subjects.

Report on Reorganization

The report of the Council's Committee on the Reorganization of the Tuberculosis Service proceeds, from a survey of the progress made in the 32 years which have elapsed since the publication of the Astor report, to a definition of principles for the continued development of the fight against the disease. The experimental stage, says the report, is past. The principles of 1912 are still of basic importance, but extension of them is needed in several directions.

The individual patient must not be considered as separate from his family when the question of treatment arises: the family is the unit for treatment, whatever the manifestation of the disease, whatever the prognosis, whatever the probable future working capacity of the patient. Small authorities, the report states, should combine to form joint tuberculosis boards, and the smallest authority should not deal with a population aggregating less than 250,000. Some arrangements should be made to remove the need for interpreting fresh advances in medicine to 183 separate local authorities before improvements in the service can be brought into general effect. Better central supervision of local tuberculosis services and national minimum standards are needed. Housing authorities should be obliged to provide suitable living accommodation for families which include tuberculous persons. The necessity for full co-ordination of tuberculosis services with other public health units and the unwisdom of allowing tuberculosis clinicians to work in "isolation" are stressed.

Other sections of the report deal with the equipment of dispensaries and the importance of associating these with hospital out-patient departments. It is suggested that "boundary barriers" should not be allowed to obstruct the use of dispensaries by patients living near them. Special sessions for children are advocated. The tuberculosis officer should be provided with hospital beds for the observation of cases, and these beds should be under his own care. Waiting lists must be abolished, not merely for the cases of pulmonary tuberculosis but for all varieties of the disease.

Medical education in tuberculosis (undergraduate and post-graduate) is discussed, and the lack of official encouragement for research and statistical study criticized. It is pointed out that tuberculosis nursing is still not recognized as a specialized branch of the nursing profession. Revised qualifications for tuberculosis officers are proposed, and these include, for the junior entrant, certificates of having held residential posts in general hospitals (with, if possible, experience in children's wards) and a certificate of training in social medicine as part of a reformed DPH. The tuberculosis officer must stand in professional relationship to the general practitioner as an expert and specialist in chest diseases of all kinds, must devote the whole of his time to tuberculosis and other lung diseases, and must not be asked to combine other public health appointments with his tuberculosis work. Salaries must be such as to attract highly qualified men and to compare favourably with the salaries of administrative medical officers. The tuberculosis service must be brought more into the current of general medicine than hitherto.

The report suggests that two forms of notification be employed instead of the present single form. "Notification" would be reserved for infectious or progressive types of tuberculosis, and a new procedure of "intimation," or provisional notification, would be introduced for cases of infection in which the activity of the lesion was in doubt. Transfer from the "intimation" category to the "notification" category would be at the discretion of the tuberculosis officer. "Intimation" should also apply in cases of pharyngeal conjunctivitis and erythema nodosum.

It is strongly emphasized that no tuberculosis scheme is complete without a comprehensive scheme of after-care, rehabilitation, and resettlement.

Wartime Diet for the Tuberculous

The report of the Council's Committee on Nutrition deals with the subject of wartime diet. It sets out to assess whether the diet available to tuberculous persons during the present war is sufficient (a) to help the infected person to avoid developing active disease, (b) to treat the active case during stay in an institution, and (c) to

aid the discharged patient to avoid relapse after leaving the institution.

In investigations such as these, questions of calories and vitamins obviously exist side by side with questions of finance. It is calculated that from rationed and "points" foods about 1,000 calories a day can be obtained, and that the additional 1,600 calories necessary to keep above the "danger line" can be obtained from unrationed foods such as offal, fish, sausages, potatoes, bread, flour, fruit, and vegetables. The wartime diet of rationed foods supplemented by unrationed foods provides, according to the report, the requisite vitamin intake. But 8s 6d or 9s a week must be spent to provide these calories and vitamins, whereas the maintenance allowances for the dependent children of a tuberculous person, permitted by Ministry of Health Memorandum 266/T, range from 5s to 8s a week, according to age. Moreover, although the J.T.C. considers 8s 6d a week per person the minimum sum to be spent on food alone to help infected persons to escape active disease, it observes that this does not necessarily mean that the patient is receiving food in satisfactory quantity.

With regard to institution diets in wartime, the J.T.C. quotes approvingly from the recent report of the King Edward's Hospital Fund on hospital diets, and adds some riders about "priority" milk, the addition of vitamin C to tuberculosis diets, and the preparation and presentation of institution meals. On the question of diet for the discharged patient, it points out that, with the "priority" allowance of 2 pints of milk a day, the patient has exactly the same amount of food available to him as he had in the sanatorium, and, in addition, he can obtain meals in canteens and restaurants. As he will often be doing more work "outside" than he did in the sanatorium, he probably needs these extra meals to combat any tendency to relapse. With regard to children, the report says that for those under 5 years old the optimum daily quantity of milk is 1 pint, and for those between 5 and 12 years the optimum daily quantity is $1\frac{1}{2}$ to $1\frac{3}{4}$ pints, therefore, instead of 2 pints daily, tuberculous children should be allowed 1 pint and extra butter, cheese, or eggs.

The report on wartime diet concludes with a strong plea for more general and more efficient pasteurization of milk, and urges the Government to facilitate the manufacture of pasteurizing plant, to pool pasteurization facilities in areas where this is practicable and desirable, and to inform the public officially that when pasteurized milk is not available boiling is the only satisfactory alternative.

Copies of both reports may be obtained on application to Dr Norman England, Hon. Secretary, Joint Tuberculosis Council, 1 Becket Street, Oxford.

Nova et Vetera

BOLOGNA AND THE BEGINNINGS OF ANATOMY

Of the ancient Italian medical schools the most interesting are those at Salerno, at Bologna, and at Padua. After the landing at Salerno we published some notes on the history of its school (*Journal* Sept. 25, 1943, p. 402). Now that our armies are closing in on Bologna, we direct attention to certain important incidents in the history of its venerable university. We hope that circumstances will soon call for a similar note on Padua.

Bologna is an important railway junction and manufacturing centre, with a peacetime population of about 200,000. It also contains many highly interesting antiquities, notably its famous towers and its unique collection of Etruscan remains. In ancient times it was an Etruscan stronghold and sided with Hannibal in the Punic War. In 189 B.C. it became a Roman colony. Legend tells that the university was established by Theodosius the Great in A.D. 425, and certainly it was a renowned law school very early in the Middle Ages. Other departments accumulated around that of law, and it thus became the first institution in Europe to which the term "university" can rightly be applied. An organized medical school can be traced back as far as 1156.

At first the teaching of medicine at Bologna, as elsewhere, consisted entirely in readings and commentaries of Latin translations of Arabic, Greek, and Hebrew works. The Medical Faculty was so dependent on the jurists that until 1306 it was not permitted to elect its own head. This is of importance in view of the manner in which dissection of the human body began at Bologna.

An Early Post-mortem Report

Post-mortem examination is heard of earlier than dissection. It is quite natural that we should have early news of this process at the greatest of law schools, but the very first frank

account of a necropsy comes to us from Cremona, some 150 miles to the west. The Franciscan Salimbene of Parma, in his chronicle of 1288, tells that, during a pestilence two years before, a physician of Cremona opened a corpse to see if he could find the cause of death. The first formal account of post-mortem examination does, however, come from Bologna. In February, 1302, a certain Azzolino died there under suspicious circumstances. Poison was suspected; a judicial inquiry was held, and a post-mortem actually ordered by the court. It was conducted by two physicians and three surgeons, with Bartolomeo da Varignana at their head. Their report exists, and terminates with the formal statement, "We have assured ourselves of the condition by the evidence of our senses and by the anatomization of the parts." There is no remark that the proceeding was unusual. Bartolomeo was professor of medicine at Bologna, an office in which he was succeeded by his son and two of his grandsons.

A fellow student of Bartolomeo at Bologna was the Norman, Henri de Mondeville. About 1300 he settled at the famous and ancient medical school of Montpellier. There, some years later, he wrote a book on surgery, which was decorated with figures displaying dissections. These, unfortunately, have disappeared, but some small and inferior copies of them have survived, so that we know their general character.

Taddeo and his School

Now, towards the end of the fourteenth century the medical faculty at Bologna included among its members a most remarkable man, Taddeo Alderotti (1223-1303). Under the cloak of extreme scholastic conservatism he succeeded in introducing many changes in the intellectual climate of the University. He understood well the importance of access to Greek sources, and encouraged the preparation of good Latin versions. He himself translated an Aristotelian treatise into Italian and impressed Dante with his powers and knowledge. He stamped his personality on the whole development of medicine at his university. He is bound up with the beginning of dissection in a peculiar way. Not only are many hints of post-mortem examinations scattered through his *Consilia* but all the first generation of writers who discuss dissection—Bartolomeo da Varignana (died 1318), Henri de Mondeville (died 1320), and Mondino de Luzzi (died 1326)—were his pupils. The evidence is that the process was initiated by Taddeo himself. As the revival of medicine in North Italy is investigated the lines seem always to converge on him.

One of the most famous of the pupils of Taddeo is Mondino. He was born near Bologna, graduated in medicine there, and joined the teaching staff soon after Taddeo's death. He is the first known to have dissected the human body systematically in public, and his book on anatomy is the first based on direct knowledge of human dissection. He thus introduced practical anatomy as an academic subject. His *Anothomia*, written in 1316, rapidly became a standard work. It retained its position for nearly three centuries. It was the most widely read text when Vesalius began to teach at Padua towards the middle of the sixteenth century, and was still studied when Harvey was a student there at the end of that century. Anatomy had by then passed from Bologna to Padua, but Bologna was its cradle and Taddeo and Mondino were its two godparents.

BEQUEST TO AN APOTHECARY'S WIDOW IN THE FOURTEENTH CENTURY

The will of John Foot (alias Maryns), apothecary, was proved in the Hustings' Court, London, in 1384-5. It had been signed in 1381. At such an early date it is unusual to find so long a period of time as three years intervening between the signing and probate of a will. He willed his body to be buried in the "Pardounchirchawe," and among other bequests left to Cristine atte Bowe, widow of Thomas atte Bowe, citizen and apothecary of London, a "calyxcoppe" standing upon lions silver-gilt with silver covercle and 100 shillings. When the widow died at the end of March, 1403, her will was proved both in the Hustings' Court and in the Commissary Court of London. Her son, John, inherited "my silver cup standing upon lions gilt, with cover." This lady also desired to be buried in the Pardounchirchawe, which was situated on the north side of the cathedral. It is not often that one can trace a piece of plate through two wills at so early a date as this.

Correspondence

Rate of Artificial Respiration

SIR,—The article by Dr. P. R. Tingley (*Journal*, Sept.-16 p. 366) calls for prompt criticism.

Quite logically he recommends (from his breath-holding experiments) that the rate of artificial respiration should be as fast as possible consistent with efficiency—i.e., Schäfer's method 30 to 60 times a minute, Silvester's up to 45, and my rocking method at double the usual rate or faster. He also "states confidently that an increased rate can do no harm in any case, and must in many cases do much good." This sentence alone shows that he is unaware of the dangers of acapnia, and is therefore hardly qualified to revolutionize resuscitation.

His arguments are the more dangerous because they are plausible (especially when cyanosis is present). Indeed, they are unanswerable if one falls into the old error of assuming that the state of a drowned person and his needs are similar to those of a conscious subject. They are quite different. Thus, in the normal subjects of Dr. Tingley's breath-holding experiments combustion (turning O_2 into CO_2) is active—especially in the muscles resisting respiration—and CO_2 is accumulating in the blood until it stimulates the respiratory centre beyond resistance by the will. Respiration has then to be violent to make up for arrears. But in the cold and toneless drownedee combustion is in abeyance, the consumption of O_2 is minimal, and very little CO_2 is being formed. Hence, when cyanosis and errors of CO_2 and O_2 have been adjusted by the first few minutes of artificial respiration, overventilation may then easily wash out too much CO_2 and produce a deficiency of it in the blood (acapnia).

Very briefly, the dangers of acapnia are: (1) The respiratory centre is deprived of its normal stimulus (CO_2); this causes apnoea, which may be fatal to the centre if prolonged. (2) Lack of CO_2 makes oxyhaemoglobin reluctant to part with its oxygen to the tissues. (3) The capillaries of the brain (and intestine) have been shown to constrict. (4) Acapnia causes atonia in the muscles, so that the unsupported veins dilate and the left heart is unfilled. Atonia of the diaphragm allows the lungs to collapse.

So acapnia has very ugly possibilities, though perhaps we are apt to magnify them. In fact, Prof. R. R. Macintosh of Oxford kindly wrote me (Dec., 1943) that in some operations apnoea is maintained by hyperpnoea for 20 or 30 minutes without apparent injury from acapnia. Recovery occurs without using CO_2 (avoided as being toxic to nerve cells in extremis).

Different rates of artificial respiration by rocking have already been investigated by Eve and Killick (*Lancet*, Sept. 30, 1933), who found that the adequate ventilation of 6 litres was produced in a minute by 10 double rocks through a total angle of 100 degrees without reducing the CO_2 in the expired air below normal. Increasing the rate up to 20-22 per minute increased the ventilation but reduced the CO_2 too much. As to the important aid given to the circulation by the rocking method (presumably by the weight of long columns of blood acting alternately in arteries and veins, reflux being prevented by valves), it is evident that in rapid rocking this hydrostatic effect would not have time to act. Prof. Hemingway advises 4 seconds head-down and 3 seconds feet-down for the circulation.

A year ago the Home Security Department of the Australian Government cabled me that their medical advisers considered 12 rocks a minute excessive and likely to cause hyperventilation: they suggested half this rate, or 12 rocks dropping to 6 after the first 5 minutes. I replied with the above evidence, but obviously these experts feared acapnia. For all these reasons I trust that the present recommended rate of 9 double rocks per minute through 90 degrees will not be exceeded. It would be a serious step to increase the standard rate (12 per minute) of Schäfer's and Silvester's methods. Possibly an expert in acapnia might like to do so in the early stage of cyanosis, but the first-aider must be given a definite rule.—I am, etc.,

HULL.

FRANK C. EVE.

Intravenous Anaesthesia

SIR.—In recent years several devices for the administration of continuous or intermittent pentothal have been produced. The latest are those described by Major W. W. Mafdlow (Sept. 30, p. 432) and Major Wallace M. Dennison (Sept. 30, p. 437). All such devices suffer from the disadvantage that they require cumbersome apparatus. The following method, for which no originality is claimed, is just as effective, more controllable, and involves a minimum of equipment—a 20-c.cm. eccentric nozzle syringe, needle, sand-bag, tourniquet, Spencer-Wells forceps, and arm-board or anaesthetic trolley. Pentothal in 5% solution is used throughout. The average patient is induced with 0.5 g., transferred to the operating table, and put on nitrous-oxide-oxygen. An arm-board is placed in position, or the arm stretched out over a trolley, a small sand-bag being used as support. A tourniquet is applied, and a needle, with the 20-c.cm. syringe attached, is inserted into the vein. The tourniquet is loosened and is used, secured by Spencer-Wells forceps, for keeping the syringe in position on the arm. Injection is made as required. Clotting will not occur if a sufficiently coarse needle (size 12 or larger) is used, and if minimal amounts of solution are injected every few minutes.

All operations for which pentothal is a suitable anaesthetic agent can be performed with this technique. An arm-board is preferable to the trolley for supporting the arm, as then the table can be moved either bodily or into a Trendelenburg tilt with no risk of displacing the syringe. In those cases in which the patient is already on a saline drip the pentothal may be introduced directly through the rubber tubing after this has been pinched up distal to the needle-puncture. I have found this method simple and satisfactory.—I am, etc.,

London, N.W.3.

HELEN BOWER ALCOCK.

Apparatus for Fractured Femur

SIR.—In the third edition of his *Fractures and Joint Injuries* Mr. Watson-Jones goes to some pains to discuss and to condemn the method of treating fractures of the shaft of the femur by the Hamilton Russell traction apparatus. As the great weight of Mr. Watson-Jones's authority may lead to the disuse of this excellent apparatus I would like to say something in its defence. In the first place, this apparatus is easily the most comfortable of all that can be used for fractures of the femur. In the second, it is very easy to put on and requires no special piece of apparatus that cannot quickly be obtained. The Thomas-splint method, by way of contrast, requires a Thomas splint that fits the patient well. This is a matter of small moment in a big city hospital, but it is of some importance to a practitioner in a remote area who is unlikely to have more than one Thomas splint in stock. In the third place, if the surgeon uses the apparatus correctly he can expect to get a result either where there is no shortening at all or where there is not more than half an inch of shortening. This apparatus has been in routine use in this hospital since 1926. There are a number of patients in the neighbourhood who have one femur half an inch shorter than the other. If they have any disability they certainly don't complain of it.

If the method is to be used properly, however, there are certain points that should be noted. It is impossible to put the splint up properly without first studying thoroughly Hamilton Russell's own description.² If this is not done it is almost certain that the apparatus will be so put up that the necessary forces are pulling in wrong directions. The diagram shown by Mr. Watson-Jones is correct. In putting up the apparatus there is one very important point—and that is that extension should be applied to both legs. This was first done, so far as is known, in this hospital in 1926. When Mr. Hamilton Russell saw this method in action during a postgraduate tour late in 1926 he expressed his strong approval of it, and until his death both used and advocated the two-leg method. The advantage thus gained is that it obviates trouble arising from the pulling down of the pelvis on one side. Although easily put up, the apparatus is certainly not self-regulating, and requires constant attention. This is to be regarded as a virtue and not a fault. The three main difficulties are: (1) a tendency to exertion—this can be overcome by making the sling under the knee pull from the outer side; (2) the tendency of the patient to slip down in the bed and thus to alter the parallelogram of forces—this is helped by taking away the patient's pillow or by gaining his co-operation; (3) the tendency of the fragments to sag backwards at the site of

fracture. Mr. Russell used to place under the site of fracture a small pillow, which had to be constantly adjusted. Possibly a better method is to make a plaster gutter for the back of the thigh and to put the pillow under this. If the surgeon is prepared to give the attention that is required he can be quite certain of getting a good result.

A description of its practical application should not conclude a discussion on the Hamilton Russell extension apparatus. It is usually forgotten that the apparatus represents the practical application of a great principle. This principle has to do with the action of muscles on bone fragments. For generations it has been taught that, if a fracture separates one muscle group from another, the whole limb must be postured so that the distal fragment corresponds to the position into which the proximal fragment has been drawn by unbalanced muscle action. Hamilton Russell taught the exact opposite. He taught that if the fractured limb were placed in a position of physiological rest the unbalanced muscle action would soon cease to have effect, and that all muscles would do their best to return to their ordinary position. In two articles^{1,2} I critically examined his contention in the light of acknowledged physiological research. On re-reading these articles I see that I have since learned a good deal about fractures, particularly in regard to the time necessary for union. With regard to the action of muscles on fragments, however, every year of experience confirms me in the belief that Mr. Hamilton Russell enunciated a master principle when he wrote the following words: "Muscles are the creatures of habit and the slaves of custom. In a broken limb every muscle and muscle fibre will co-operate in the endeavour to preserve the position to which it has been habituated, and the last thing a muscle will do will be to abuse its liberty by displacing a fragment into an unnatural and unaccustomed position."³

There is one thing more that can be said about Hamilton Russell's contribution to the study of fractures, and that is that he was one of the first to insist on active as opposed to passive movement.

May I, in conclusion, pay a tribute to Mr. Watson-Jones's great work on fractures, which in this, as in many other hospitals; is the bible of the fracture room.—I am, etc.,

C. CRAIG,

General Hospital, Launceston, Tasmania.

Surgeon-superintendent.

Episiotomy

SIR,—My conclusions on episiotomy (Aug. 26, p. 291) having been objected to by Drs. O'Meara (Sept. 9, p. 353) and Banks (Sept. 16, p. 385), I to-day tried the latter's tip of fully extending the primipara's legs at the hips when the head was stretching the perineum ("Trousers don't tear when you are standing, but when you are bending down"). The result was a perineal tear to within 1/2 inch of the anus, and I wished I had done an episiotomy.

Regarding my remark that I frequently give pitocin in uterine inertia when the head is well down and the os fully dilated, Dr. O'Meara says, "I don't like it, won't do it, and won't allow it to be done, even in hospital." This peremptory interdiction would carry more weight if he gave some reason for it. He has had great experience of midwifery, and arguments against the practice would be of great interest to people like myself who have consistently given pitocin before the birth of the child for many years with nothing but beneficial results. As it is, his mere negation cuts no ice whatever. Dr. O'Meara disbelieves my contention that the injection of ergometrine has banished the boggy of post-partum haemorrhage. Possibly his experience of this procedure is not so happy as mine. If so, he does not say so, nor does he adduce any instances of failure. These again would be interesting and instructive. I only give my own experience of ergometrine, not anything I have read or heard, and still retain vivid recollections of occasional awful moments, in pre-ergometrine days, of intimidating torrents of blood, frantic bimanual grabbings of uteri, and intra-uterine douches of water at 118° F. I still carry my intra-uterine douche, but only as a talisman. Dr. O'Meara "strongly disagrees with the practice of giving ergometrine before the placenta is expelled." So do I; as a practice. Why? Because years ago, in ignorance or without thinking, when ergometrine was first put on the market, I thus gave it on one occasion, with the result that the uterus snapped down on the placenta like a vice and it took a large part of the staff of a gynaecological

ward in hospital two days to get it out. But circumstances alter cases, and a few weeks ago, after chloroform delivery and before expulsion of the placenta, I had a powerful hunch that I was going to get a bad p.p.h., and knowing that ergometrine injected intramuscularly takes 4 minutes to act, I risked it just before squeezing out the placenta. My hunch proved correct, as even then the patient lost a little more blood than normal, and I agreed with the nurse when she said, "We should have had some trouble with her if you had not given that."—I am, etc.,

Stowmarket, Suffolk.

H. S. GASKELL.

Nystagmus in Anxiety States

SIR,—It is not generally realized that lateral nystagmus may be a prominent feature in some of the patients who suffer from acute anxiety states. Nearly 17% of a group of patients who broke down under the stress of intense enemy action developed varying degrees of nystagmus, which, in the majority, disappeared quickly under rest and sedation. In a few patients, however, it persisted for several weeks. Nystagmus in these patients appears to be part of a process of temporary disintegration, similar to that responsible for producing generalized tremor of the limbs or stutter or temporary loss of bladder control. This is worth emphasizing in order to avoid prolonged investigation and unnecessary hospitalization of these patients. —I am, etc.,

London, N.W.7.

M. N. PAI.

Débridement

SIR,—With reference to the letter on débridement (Sept. 16, p. 387), may I add a brief note.

The word was frequently used (and not infrequently misused) in the earlier years of the present war. In a review by Mr. (now, I believe, Major-Gen.) W. H. Ogilvie of "War Primer" in the *Bulletin of War Medicine* (1941, 1, 138), dealing largely with gas gangrene, he states: "... débridement, a term used to describe the excision of the whole wound track and of damaged or devitalized structures around it, the removal of blood clot, dirt, and foreign material, and the complete arrest of haemorrhage."

Also, in an earlier issue of the same *Bulletin* (1941, 1, 3), Mr. Reginald Payne, reviewing an article by Hoche in *Med. Klin.*, speaks of "surgical revision" of wounds, and adds the following note: "The term 'surgical revision' is one which has recently been introduced and includes the following:

(1) examination of a serious wound under anaesthesia; (2) determination of its extent; (3) removal of dead tissue and foreign bodies; (4) arrest of haemorrhage; (5) provision of drainage, if required. It will be seen that 'revision' includes considerably more than the French term 'débridement.'"—I am, etc.,

Braintree, Essex.

H. HAROLD SCOTT.

Prevention of Industrial Dermatitis

SIR,—I am grateful to Dr. Mummery for his further letter (Sept. 16, p. 387). If he publishes figures he takes the risk of having them read and having the reader draw his own conclusions. My quotation of 203 cases in 3,850 workers is still the total in Dr. Mummery's cases.

The fact that Dr. Mummery failed to protect his workers against paraffin and oil with barrier creams is suggestive that he did not use the correct protection. There is no one satisfactory barrier cream. Specific hazards must be protected by specific barriers.

I have recently investigated the risk of dermatitis in the photographic industry, and I learn that the common solutions in which photographers put their hands vary from pH 4.2 to pH 11, and it is the habit of these workers to put their hands into one solution and then another many times in the course of their work, and it is impossible to wash except at the end of a batch of printing and developing. It requires no imagination to see that far more than cleansing is necessary here. As a sufferer myself from sensitization and dermatitis due to so-called metal poisoning I have found that I now can pursue my hobby without risk if the correct barrier cream is used.

In Dr. Mummery's own field it is evident that the workers in America take far more recognition of the sensitizing dermatoses. Fletcher Hall,¹ in a recent article of great importance to this industry, stated that oil folliculitis and chloracne were the only industrial dermatoses of major importance to the aircraft industry on which adequate studies have been published, and reference is made in the article to Schwartz and Russell, "Skin Hazards in Airplane Manufacture." He found after an investigation of 580 cases of dermatitis (210 industrial) in 65,000 employees in an aircraft company that sensitivity is a major factor. Schwartz² in the same issue of the *Journal of the American Medical Association* dealt with dermatitis from explosives, and makes the alarming statement that 30% of tetryl workers had dermatitis in the first six months. He recommends a protective. Peck, in the same issue,³ "Dermatitis from Cutting Oils, Solvents, etc.," states: "... exposed parts such as the face should be covered with protective ointments of the invisible glove type reinforced with inert powders." He also advocates adequate washing facilities and the use of the aliphatic alcohol sulphates or alkylated argylsulphonate, which removed dirt more easily than soap. Schwartz, the eminent American industrial dermatologist, in the article previously quoted,² goes through the whole of airplane manufacture—anodizing, degreasing, dope, hydrofluoric acid, machine shop, paint, plaster, welding, zinc chromate, etc.—and in his summary, which was the result of an inspection of aircraft factories employing over 100,000 men he came to the following conclusions: "Preventive measure consisting of wearing of impervious clothing, the use of protective ointments, and the use of non-irritating skin cleansers in addition to proper general and local ventilation, etc."

My own experience is such that I am not satisfied with any one method of protection, and as this is in line with the recommendation of Dr. Schwartz I shall continue to recommend protection in every possible way.—I am, etc.,

Infantile Gastro-enteritis

SIR,—In your leading article (Sept. 30) you say Drs. Alexander and Eiser "stress the aetiological role of parenteral, particularly, upper respiratory, infection in gastro-enteritis." At a post-mortem on a three-months-old child whose death was due to gastro-enteritis I found a spheno-ethmoiditis with yellow pus (illustrated at p. 5, *Sinusitis and Mental Disorder*, 1939), the whole gastro-intestinal tract appearing almost normal, thus confirming the association and suggesting an aetiological relationship of the conditions.—I am, etc.,

Birmingham.

F. A. PICKWORTH.

Artificial Insemination

SIR,—May I ask that the *Journal* will use its influence to obtain for the rank and file of the medical profession an authoritative pronouncement regarding the ethics of artificial insemination.

A patient of mine, while attending a birth control clinic, was recently asked if her husband would be willing to act as a donor for an artificial insemination panel. The lady was shocked and asked my advice about the whole question, being quite bewildered that such a request could be made to her on such an occasion. The question is one in which the public confidence in the medical profession is likely to be involved. If, without the knowledge of her husband, and without legal formalities of any description, a woman visiting a doctor's consulting-room can ethically be inseminated with the genes of an unknown male parent, the confidence of the general public in the profession may be impaired.

The Church, having for years condemned lust without procreation, may find difficulty in pronouncing upon the question of procreation without lust. The medical profession undoubtedly must take a leading part in guiding the general public on this

most difficult subject. Could we not have a considered pronouncement from a high authority on medical ethics, such as the General Medical Council, to guide the members of our profession, whose privilege it will be to educate the public in his most difficult problem of human relations? Should we fail in this respect we may find that the present veterinary approach to this problem may persist and discredit our humanitarian traditions—I am, etc.,

Barnstable

RICHARD HARPER

Bequests to Anatomy Schools

SIR—There appeared in the *Daily Telegraph* of May 9 this year a short appeal from Dr Neville Goodman, H M Inspector of Anatomy, to the medical profession to give a lead to the public by bequeathing their remains to the schools of anatomy. There must be many like myself who are willing and prepared to do this, all the more so when it is realized what is happening to so many young bodies on the various fronts.

I suggest that arrangements could be made to form an association affiliated to the Cremation Society (of which I am a member). The society could estimate the cost of collecting from the medical schools the remains allocated to any particular individual. These could then be cremated and the ashes disposed of according to the wishes of the deceased or nearest relative, the charge for doing this to be taken from the entrance fee to such an association—I am, etc.,

"DELTA"

Service Medicine

SIR—There seems to me to be some confusion of thought on this subject. There is a considerable difference between "Services 'medicine'" and 'medical services'.

When a doctor is commissioned as a regular medical officer he is assumed—for the moment—to know all about medicine, surgery, and midwifery by virtue of his registrable qualification, so his training in administration begins. He has to learn that for every clinical act there is a corresponding administrative act, even though it only be filling in the "Disposal" column and signing a sick report. In addition to this he has to render certain necessary returns, some daily, some weekly, others monthly, quarterly, or even perhaps half-yearly. To omit rendering these to the proper authority is to delay the rendering of returns on the part of those whose duty it is to consolidate the returns received from lower formations. Moreover, by his signature of these returns the medical officer accepts responsibility for their accuracy. Delay and inaccuracy are two of the unpardonable sins.

He has to learn the system of store accounting, including the preparation and forwarding of indents and receipts for medical stores. When they arrive he as a medical officer, must "take them on charge" in his medical store account, which keeps a record of all receipts and expenditure. He must report deficiencies and breakages on the appropriate form and attribute blame to individuals responsible. He must keep a record of the patients he sees, with his provisional diagnosis of each, and state the disposal of the cases.

As he becomes more senior in rank he learns about the procedure with regard to medical boards, invaliding, etc., as well as the method of dealing with claims for payment from civil practitioners for attendance on Service personnel, and many other administrative details too numerous to mention here. At the same time he does actual medical work in dealing with the sick. Some he treats, others he may refer for treatment to hospitals or specialists. Then he has to act as the medical adviser to his commanding officer, and as such is responsible for camp or other sanitation and keeping a sanitary diary, as well as making application for urgent repairs to anything needing such which may come to his notice, whether they be blocked drains, leaky taps, or broken windows. But these are mostly items of administration.

In time of war the great reserve of all the medical services is the civil medical profession. The regular officer will probably be promoted to acting rank one or two or more steps higher, and, unless he be a surgical, medical, or other specialist, he will find himself in a more senior administrative post, because he has been properly trained in medical administration.

The called up civilian is more likely to be engaged in clinical work of some kind, and only such administrative activities as the nature of his employment demands—e.g., recording the patients seen and their treatment or disposal.

So far as Service medicine is concerned, it may be like general practice on a small scale (including families), or it may be actual hospital practice if he be in a military hospital, and it is his duty to maintain the high level of efficiency which is in peacetime the rule in all Service hospitals. He has to realize—getting down to 'brass tacks'—that he is employed by the State as a 'money saver,' in that he should aim so far as possible to prevent sickness and other casualties partly by advising his commanding officer, or, when these occur, that invalids must be restored to the active list with the loss of as few man hours as possible. To do this he must be an efficient doctor—whether as physician or surgeon. The principles of surgery and medicine in the Services do not differ one whit from those in civil life—which is to say that 'Service medicine' in its principles and practice does not differ from "civil medicine." I will go further, and say that in peacetime there are opportunities for doing good work in Service hospitals such as will probably not be found outside teaching hospitals. Grumbling about "Service medicine" by temporary officers serving in wartime has not been unknown in previous wars. Everything depends on the man himself, and the first thing he should learn is not to confuse Medicine with Administration—I am, etc.,

"UNCLE HARRY"

SIR—Whatever mistakes the Government may commit in the years of transition from war to peace, it is not likely to repeat the disastrous blunder of 1919, when our defences were so recklessly shorn away. Compulsory training in the Navy, Army, or Air Force has, in fact, already been announced for all boys and youths after the war, so that Service medicine will for many years cover a wider field than it did in the 1920s and 1930s. Directly or indirectly, whether we realize it or not, all of us are vitally concerned in the impending reform of Service medicine, whose existing faults I emphasize with constructive, not recriminatory, intent.

The hospital secretary and his lay staff hold an honoured position in the world of civilian medicine, and the appointment of medical men as hospital secretaries would mean a waste of medical training—to say nothing of the objection that medical men would fill such posts less efficiently than their present occupants. Yet the Services persist in using qualified medical men to do work requiring less knowledge of medicine than is possessed by the average hospital secretary, and such people must, according to Major C H Pauli (Sept 23, p 417), 'be given sufficient rank in order that medical policy may be fully stressed and enforced.' That is pure bunkum. If Major Pauli were ill with pneumonia he would doubtless desire treatment from the supposedly best doctor available, irrespective of rank. Similarly, a layman of any intelligence hearing an opinion with regard to medical policy would be impressed rather by the sponsor's professional status than by his gold oak leaves or coloured tabs.

Major Pauli's faith in the gods of administration is touching. He coolly ascribes to medical administrators the success of the Army transfusion arrangements. So far as medical men are concerned surely the chief credit belongs to (a) those pathologists who established blood transfusion depots under the auspices of the Medical Research Council before the war (see Sir E Mellanby's paper on 'Medical Research in Wartime,' *Journal*, 1943, 2, 351), and (b) the clinicians who decided which cases were in need of transfusion and those who performed it with the requisite dexterity. Questions of transport and distribution are admittedly vital, but their detailed solution is within the capacity of laymen so long as doctors give the necessary general guidance. Furthermore, Major Pauli is pleased to taunt me with ignorance of administration. As well might he reproach me for knowing little or instrument-making, radiological processes, hospital finance, central heating equipment, massage, and a host of other important matters in which the whole time clinician necessarily relies upon expert auxiliaries.

Several correspondents have sought to bolster up Service medicine by reason of the skilled diagnosis and successful treat-

ment from which they have themselves benefited in the Forces. I submit, Sir, that such instances of professional skill do not constitute a valid argument in favour of Service medicine as such. Of course no one will deny that the Services now contain a large proportion of the finest clinicians and pathologists in the Empire. Many of your readers must have shared my delight in the tale of the Eighth Army mobile field surgical teams as vividly told by Brig. C. Donald (*Journal*, 1944, 1, 709, 743). Nor will the most irreconcilable opponent of Service medicine as such seek to minimize the triumphs of Service plastic and orthopaedic surgery, and the less spectacular but equally valuable work of the general practitioner, medical officer to a unit, or M.O. in charge of a hospital medical division. Nevertheless we must remember, in apportioning the praise, that the clinical achievements of Service medicine in this war are founded mainly on pre-war training and experience outside the Services, and that many clinicians are handicapped by subordination to a professionally insignificant minority of high-ranking regular maladministrators who have forgotten when they last handled a patient.

Until the war stops we temporary serving officers will help to work this defective machine; but, in the interests of truth, efficiency, and the welfare of our patients we shall protest against the continuance of present abuses in time of peace. Although we are now condemned to silence or anonymity we shall not always remain under the censorship of "brass hats." Much will be said later.—I am, etc.,

"TEMPORARY SERVING OFFICER."

The Young Married Doctor

SIR,—With regard to recent correspondence on medical education, both pre- and post-graduate, I think there is one point which is often overlooked: that is, the influence of marriage upon a newly qualified doctor's choice of career.

After a very long undergraduate course the young doctor, apart from financial considerations, which are often weighty in view of current residency salaries, has a choice to make. If he wishes to specialize he must deliberate the old truism about marital refrigeration. In other words, he is asked to spend another lengthy period wholly unnaturally to attain that goal. As we as a class show no variation from the general public biologically, an initial loss of recruits occurs shortly after qualification. How many know only too well the fatal effect of an honest answer to the question, "Married or single?" upon an application for a hospital post. I have personally found this to be true, even in these days of shortage and being rejected for the R.A.M.C.

Could not, therefore, this simple reform be considered amid all the welter of projected contemporary schemes—namely, more provision for married men in senior hospital resident posts after twelve or eighteen months' postgraduate experience? It is not asking for a great deal when balanced with what sacrifice has already been made in comparison with most professions. It seems to me that unless this is done an even greater loss will occur after the war. Can anybody reasonably expect a Service M.O. (many of whom are married) away from his family for perhaps years to be willing to continue even part-time separation for a number of years after the conclusion of hostilities? If this be true of wartime, how many in peacetime sacrifice keenness for domesticity when both can be combined without loss of efficiency.—I am, etc.,

"Y.M.D."

A Bouquet

SIR,—May I be permitted to express my admiration for, and thanks to, the Editor and staff for the magnificent way in which the high standard of the *Journal* has been maintained throughout the past five years of war?—I am, etc.,

London, S.W.5

R. E. PALMER FIELD.

* * We thank Dr. Palmer Field and the many correspondents who have written to the same effect in private letters.—Ed., B.M.J.

D. Polowe (*J. Amer. med. Ass.*, 1944, 124, 771) records a case of splenectomy in the eighth month of pregnancy complicated by thrombocytopenic purpura haemorrhagica in a 2-para aged 29. A large splenoma was found. The patient was delivered of a normal infant about two weeks before the estimated term.

Obituary

SIR JOHN LEDINGHAM, C.M.G., F.R.S.,
LL.D., D.Sc., M.B., F.R.C.P.

With the death of Sir John Ledingham on October 4 pathology and bacteriology lose a most distinguished figure, whose whole life was devoted to the prosecution of research and the encouragement of fellow workers. He served the Lister Institute of Preventive Medicine for 38 years in all, becoming Director in January, 1931, after a long period as head of the department of bacteriology, serology, and experimental pathology.

John Charles Grant Ledingham was born at Boyndie, Banffshire, in 1875, son of the Rev. James Ledingham, minister of the parish, and from the local public school went to Banff Academy and thence to the University of Aberdeen, where he graduated M.A. in 1895, with first-class honours in mathematics and physics, and won the Simpson and Arnott Prizes. His career in the Faculty of Medicine was no less brilliant; after winning two gold medals he took the B.Sc. degree (with distinction) in 1900 and the M.B. (with honours) in 1902, and then held the Anderson scholarship. Post-graduate study at Leipzig University and at the London Hospital led to his appointment to the staff of the Lister Institute in 1905, and after a few months in the serum department at Elstree he was transferred to the main Institute on Chelsea Embankment as assistant bacteriologist; he became chief bacteriologist in 1908 and succeeded Sir Charles Martin as Director from 1931 to 1943. In 1920 the University of London granted him the title of Professor of Bacteriology, and as head of the bacteriological department of the Lister Institute he helped in every way the investigations of members of his own staff and of all research scholars or voluntary workers, native or foreign, attached to the department, including graduates conducting research with a view to the higher scientific degrees of the university. During his tenure of one of the most responsible posts in preventive medicine he proved himself a capable administrator, while inspiring those who worked under him and pursuing his own experimental studies on viruses and virus diseases and a wide range of other subjects. The establishment of the National Collection of Type Cultures was one of the many projects that gained his warm support.

The Governing Body of the Lister Institute took pride in the outstanding contributions to scientific knowledge for which Ledingham had been responsible through his own researches and through the many investigations carried out under his friendly guidance and stimulus by members of the staff and others enjoying its scientific hospitality. His wide knowledge, sound judgment, and personal distinction as an investigator in the fields of pathology, bacteriology, and immunity enabled him to render to the Government and the nation services of great importance, which were recognized by the public honours he received, including the C.M.G. in 1918 for his work in the last war, election as F.R.S. in 1921, his knighthood in 1937, the honorary LL.D. of his own university (Aberdeen), the Sc.D. of Dublin and D.Sc. of Leeds, and the title of Professor Emeritus of Bacteriology conferred on him this year by London University. He was a member of many expert scientific committees and chairman of the Tropical Disease Committees of the Medical Research Council and the Royal Society. He presided over the second International Congress for Microbiology held in London in 1936, and was honorary president of the third Congress held in New York in 1939. Some thirty papers were published under his name or in collaboration with

[Lafayette, Ltd.]

others during the period 1920-43, and a book written jointly with his colleague Sir Joseph Arkwright, *Carrier Problem in Infectious Diseases* came out in 1912. He delivered the Jarvis Lectures on 'Some Problems of Natural Immunity' in London in 1924, and ten years later the Hefter Lectures in Baltimore, describing his studies on viruses up to that time in the work that led to the publication in 1933 by the M.R.C. of the *Treatise on Diphtheria* and the publication in 1930-1 of the encyclopaedic *System of Bacteriology* in nine volumes. Prof. Ledingham took a full share as contributor and associate editor.

He was elected a Fellow of the Royal College of Physicians of London under the special by-law, had been examiner for the College, and also served as a member of its Council. During the last war he held the rank of lieutenant colonel, R.A.M.C., took charge of the bacteriological department of the King George Hospital for a year, was a member of the Medical Advisory Committee in the Mediterranean and became consulting bacteriologist to the Forces in Mesopotamia. In the British Medical Association, which he joined 40 years ago, he was secretary to the Section of Bacteriology at the Annual Meeting of 1910, vice president of the Section of Pathology and Bacteriology in 1912 and again in 1914, and presided over that Section in 1925.

ALFRED C. COLES, M.D., F.R.S.E.D.

Dr. Alfred Charles Coles died on Sept. 26 at his home in Bournemouth, aged 78. He was a very expert medical microscopist and made this his hobby after retiring from active work. He had studied medicine in Edinburgh, graduating M.B. Ch.B. in 1889, B.Sc. in 1890, M.D. in 1893, and D.Sc. in Public Health in 1903. He took the M.R.C.P. Lond. in 1907. Before settling in practice as a physician Dr. Coles had been house-surgeon for a year at the East Suffolk and Ipswich Hospital, and for three years at the County Hospital, York, later serving as R.M.O. at Queen Charlotte's Hospital. He was elected physician to the Royal National Sanatorium in 1914 and to the Royal Victoria Hospital, Bournemouth in 1919, having served during the last war as medical officer in charge of the bacteriological laboratory of the Military Hospital at Mont Dore. He joined the B.M.A. in 1891, and had been president of the Bournemouth Medical Society. He wrote three books: *Clinical Diagnostic Bacteriology* (1904), *The Blood: How to Examine and Diagnose its Diseases* (1905), which went into a third edition, and *Critical Microscopy* (1921). His last published writing appeared in these columns on Oct. 11, 1941, under the title 'The Size and Visibility of the Filterable or Virus Bodies'.

Dr. MERVYN H. GORDON, F.R.S., writes

Coles was a master of the microscope, the range of which he showed to be far higher than others realize. He concentrated on diseases of unknown aetiology, and succeeded in finding in many of them bodies that may or may not prove ultimately of causal significance. He acquired a superb technique, and when in Hodgkin's disease, after other agents had been excluded, elementary bodies were found, Coles, at first sceptical, was not satisfied merely with confirming it. He sent me wonderful photographs of these bodies—stained and unstained—side by side with similar virus bodies, the established organism of vaccination. A great investigator.

The following well-known medical men have died abroad: Dr. YANDELL HENDERSON, eminent professor of physiology, Yale University, aged 70; Dr. CHARLES HENRY MAY, a prominent ophthalmologist whose *Manual of Diseases of the Eye* went through 18 editions, aged 83; Dr. WARREN TAYLOR VAUGHAN, editor of the *Journal of Laboratory and Clinical Medicine* and an authority on allergy, aged 51; Dr. JOSE GUTIERREZ, extraordinary professor of radiology and physiotherapy at Buenos Aires, Dr. CARL KOLLER, an eminent ophthalmologist of New York, formerly of Vienna, celebrated for his work on cocaine as a local anaesthetic, aged 86; Dr. CHARLES WULFS BURY, eminent professor of mental disease at the University of Pennsylvania department of medicine, aged 82; Prof. PIERRE NOBÉCOURT, the eminent Paris paediatrician, aged 72; Dr. ARTHUR MONCORVO FILHO, a pioneer in paediatrics and infant hygiene in Brazil, aged 73; and Dr. FRANZ CHOWSTEK, jun., formerly professor of internal medicine and director of the Third University Clinic in Vienna, aged 79.

LEWIS SMITH, M.D., F.R.C.P.

Consulting Physician to the London Hospital

Dr. Lewis Albert Smith, who died in retirement on Sept. 17 at Cricketh aged 75, served the London Hospital as assistant physician and physician from 1902 to 1927, when he was elected to the consulting staff.

He was born at Chelmsford on May 8, 1869, third son of Joseph Alfred Smith of that town, and entering the London Hospital Medical College in 1889 won the Letheby scholarship in chemistry and graduated M.B. Lond., with honours in

forensic medicine and obstetric medicine after qualifying in 1895. He took the M.R.C.P. in 1901, and in the following year qualified for the gold medal at the M.D. examination. His teaching career at the London Hospital began as medical tutor, and before he was appointed to the visiting staff there he had been physician to the Eastern Dispensary in Whitechapel and to the Poplar Hospital. He was elected F.R.C.P. in 1910, and represented the College as examiner

in medicine on the Conjoint Board in 1923-6. Recognized by his house physicians and clerks as a sound teacher of clinical medicine, Lewis Smith built up a large consulting practice. He inspired warm feelings in his juniors, and had the gift of keeping up old friendships. He contributed articles to Allchin's *System of Medicine* and to Hutchison's *Index of Treatment* and was the author of a little waistcoat pocket book, *'Golden Rules of Medical Practice'*, which epitomized common sense and knowledge of human nature in the form of dry aphorisms. Lewis Smith abstained from public occasions and medical politics; he joined the B.M.A. in 1906, but after acting as secretary of the Section of Medicine at the Annual Meeting of 1909 he took no further part in its business.

SIR FREDERICK MENZIES writes

The news of the death of Dr. Lewis Smith, or "L.A.," as he was affectionately called by many of his friends, will have been received with deep regret by a large circle of his old colleagues, students, and friends, particularly of the London Hospital. For the last four years he had been living in peaceful retirement at Cricketh, North Wales, and although it had become necessary for him to live a semi-invalid life for the greater part of this period, he always continued to take a remarkably keen interest in all the developments of war-time, at home and abroad. In addition, he kept closely in touch with a large number of his old friends in all parts of the world by means of an extensive correspondence, and by the periodical issue of brief brochures, in the course of which he related various interesting experiences of his favourite pastime of fishing. Despite his severe physical disabilities, which made movement very difficult for him in recent years, he was marvellously cheerful, alert-minded, and loved a good long talk about all kind of problems—medical, political, economic, literary, etc. He possessed a powerful personality and expressed himself clearly, concisely, and strongly upon any subject in which he was interested, so that there was never any doubt about his views. Nevertheless, he did not arrive at his opinions without considerable and careful thought, and there was never a more warm-hearted, generous friend than "L.A." and not only to his friend but to many lame dogs whom he helped over a difficult stile. The sudden and unexpected death of his brother-in-law, Sir Hugh Rigg, with whom he had been very closely associated all through professional life and to whom he was extremely devoted, came terrible shock and deep sorrow to "L.A.," and was greatly accentuated by the almost simultaneous deaths of two other very friends—Hurry Fenwick and Wilfred Hadley. I cannot co-vent without paying humble tribute also to the devotion and love bestowed upon him ceaselessly by his wife. It was my privilege to be with them on the day, quite recently, when they celebrated their fortieth anniversary of their wedding day and to witness the happiness when congratulatory telegrams and letters pour in from relatives and friends at home and abroad. Like many of my friends I shall sadly miss "L.A."—with whom I have happy hours.

The death took place at his residence in Sunderland on Sept. 1 of Dr. RICHARD HENRY DIX, aged 68, after a long illness. He was born in Sunderland and studied medicine at Durham and Dublin Universities. He graduated M.B., B.S. Durham with honours in 1900 and took the M.D. in 1902. In 1914 he obtained the M.R.C.S. Eng. and L.R.C.P. Lond. diplomas. After holding appointments as assistant demonstrator of pathology, anatomy, and physiology at Durham University he settled in Sunderland, where in an extensive private practice his patients were fortunate in having the benefit of his unusual skill and clinical judgment. His reputation as a family doctor in the best tradition was well recognized among his colleagues. In his early days Dr. Dix was somewhat of a local pioneer in radiology, which he carried out with apparatus installed in his surgery. His enthusiastic work in connexion with local medical organizations was well known, but by many of the public he will be gratefully remembered as honorary surgeon to the Sunderland Children's Hospital. It was there that for many years he gave much of his time and interest to work to which he was particularly devoted. Until the time of his illness he had been hon. secretary of the Sunderland Medical War Committee.

A veteran member of the B.M.A.—Dr. JOHN HUTTON BALFOUR—who joined it in 1887, died at Gullane on Sept. 15, aged 84. He graduated M.B., C.M. Ed. in 1881, and after serving as resident surgeon at the Royal Infirmary, Edinburgh, practised for more than 57 years in the Portobello and Niddrie districts. At the close of 1931 he received a presentation at a public meeting at Newcraighall, Midlothian, when the chairman said that Dr. Balfour had succeeded his father and brother, so that his family had then practised medicine in the neighbourhood for 78 years. Before the introduction of the National Health Insurance scheme "Dr. John," as he was widely and affectionately known, was, in addition to his ordinary work, medical officer to a number of collieries. He retired from practice seven years ago. He had taken a large part in the social and athletic life of the district and was himself a keen rugby football player and golfer in his younger days, and greatly interested in rowing and bowling. He was proud of having brought into the world almost 6,000 babies, and in doing this had lost only six mothers, one of them a woman at the point of death whom he was called in to on passing the house.

Dr. HENRY ALFRED LEEBODY, who died on Sept. 19, was the second son of Prof. Leebody of MacGee College, Londonderry, and, through his mother, was a direct descendant of John Knox. After a B.A. course in Ireland he went on to study medicine in Edinburgh, where he graduated M.B., C.M. in 1895. For a quarter of a century he was in general practice in the village of Corstorphine, now a suburb of Edinburgh, and he found an outlet for his inborn love of soldiering in service with the Queen's Edinburgh Rifle Volunteer Brigade, and later, on the formation of the Territorial Army, with the 3rd Lowland Field Ambulance. Shortly after mobilization on the outbreak of war in 1914 he was posted to the Scottish Command as D.A.D.M.S., where he became before the end of the war A.D.M.S., with the substantive rank of colonel. Disappointed in his hopes of further military service by the descent in 1920 of the "Geddes axe," he was fortunate in obtaining congenial work on the tribunals of the Ministry of Pensions until 1927. For the next 10 years he served as ship surgeon with the P. & O. line, which afforded him a welcome opportunity of travel and provided him with leisure to develop his remarkable gifts as an artist both in black-and-white and in colour. Dr. Leebody was a typical Irishman, keenly observant, humorous, kind-hearted, and generous. He was tall and strongly built and apparently incapable of fatigue. Throughout his life he was, to everyone with whom he came in contact, a true guide, philosopher, and friend, and an unfailing source of strength and inspiration. His son, Dr. John Leebody, is the medical superintendent of St. George-in-the-East Hospital, Wapping.

We regret to announce the death in retirement at Redlynch, near Salisbury, of Dr. THOMAS GILLESPIE, late honorary physician to the Southampton Children's Hospital, who represented his Division at the Annual Meeting of the B.M.A. in 1922. He began the study of medicine at Cambridge, taking his B.A. in the Natural Sciences Tripos of 1897, and after qualifying in 1900 became H.P. at Bart's and assistant H.P. at the Metropolitan Hospital. He took his M.A., M.B., B.Ch. degrees at Cambridge in 1901, and served during the last war as temporary captain, R.A.M.C. Dr. Gillespie was a co-founder of the Children's Hospital at Southampton and a member of the Board of Management from 1908 until he retired in 1938: a inward is now called after him. He was also an original

member of the Itchen, Romsey, and District Local Medical Service—one of the first in this country (1921)—and its chairman for over 20 years. His charm was the most typical feature of an all-round rare personality. A medical colleague writes: So Tom Gillespie has gone, and with him something of sweetness and light has passed forever from the earth. For Tom, as he was universally called, had above everything the great gift of friendship. Few men can have had more friends, and no one was ever less likely to have an enemy. Coming to Southampton some 40 years ago after a noteworthy hospital career, he very quickly gained the affection and trust of his patients and the high regard of his professional colleagues for his skill. His best-known work was probably his connexion with the Children's Hospital, the fortunes of which he helped to guide with great wisdom for many years. For Gillespie was a man of a very matured and sane judgment; every committee of which he was a member—and they were numerous—came to rely more and more on his opinion. Few can have been called on more often by all sorts and conditions of men for advice and help in personal troubles, for he saw life steadily, and he saw it whole. It was a great blow to his professional friends and to his many patients, when an increasing lameness, borne, as would be expected of him, with courage and patience, led to his retirement shortly before the war; but we all hoped he would enjoy many years of happiness, for with his great intelligence and his varied interests, life still held much for him.

Universities and Colleges

UNIVERSITY OF LEEDS

The inaugural lecture in the Faculty of Medicine of the University of Leeds will be given by Sir Joseph Barcroft, C.B.E., F.R.S., in the Riley Smith Hall of the University Union at 3 p.m. on Thursday Oct. 26. Subject: Problems in Foetal Life. Members of the medical profession are cordially invited to be present.

Medical Notes in Parliament

Hospital Accommodation in London

On Sept. 26 Sir E. GRAHAM-LITTLE asked the Minister of Health whether he was aware that through recent requisitioning of another 50% of beds in the London hospitals, occasioned by the opening of the second front, the admission of civilian patients to the London hospitals had become almost impossible; and whether he would release for civilian use a proportion of the empty beds reserved for military casualties. Mr. WILLINK: As part of the plans for receiving casualties from Western Europe hospitals throughout the country were asked to restrict the admission of civilian patients, the aim being to reduce occupancy on the average to about 50% of the beds. In some hospitals this step was necessary in order to secure more beds for the casualties, and in others, notably in London, to set free staff for the hospitals specially designated to receive the casualties on arrival in this country. At the same time it was made clear that the restrictions were not to be applied to patients in immediate need of treatment in hospital. In view of recent developments of the war situation, my officers are now arranging for the restrictions to be relaxed, bearing in mind the varying needs at each hospital of civilian and Service patients respectively.

Mass Radiography in Liberated Countries

On Sept. 26 Mr. PARKER asked the Minister of Health whether he would consider supplying a limited number of mass radiography sets, from the stock of apparatus ordered by the Ministry from British manufacturers, to the Allied Governments that they might be able to estimate the extent of the tuberculosis problem in their countries after liberation; whether training would be provided through the Ministry's special training course to such Allied mass radiography teams as required it; and whether the co-operation of British tuberculosis experts would be available to assist and advise the Allied Governments in their antituberculosis work. Mr. WILLINK said that the question of making mass radiography apparatus available to the liberated countries was outside his responsibility, but it was under consideration by UNRRA. In regard to the last two parts of the question he would be glad to render all the assistance in his power.

Production of Penicillin

In reply on Oct 4 to Col Lyons Sir ANDREW DUNCAN said that seven plants, six of which were pilot plants, were producing penicillin in this country. Nine large-scale plants were expected to come into operation within the next six months. Two of them were about to start production. The Government was in the closest touch with organizations in America and Canada and had the active assistance of one of the American firms in one of the plants it was putting up.

Local Authority Hospitals

Answering Sir Ernest Graham-Little on Oct 5 Mr. WILLIAMS said that apart from specialized institutions, such as mental hospitals, maternity hospitals, infectious diseases hospitals, and sanatoria, the number of beds contributed by institutions and hospitals under the control of local authorities in England and Wales was 131,440. Of these 73,921 were in 154 general hospitals and 57,519 in 376 institutions for the sick, infirm, and mental cases. About 390 of the hospitals and institutions were administered under the Poor Law.

D.D.T. against Flies and Lice—On Sept. 26 Viscount CASTLE-REAGH asked the Minister of Production if, in view of the large increase in the number of flies and other germ-carrying insects and the danger of a corresponding increase in disease, he would make available to the public the disinfectant, dichlorodiphenyl-trichloroethane. Mr. LYTLETON said that the total production of D.D.T. available to the United Nations was at present required for military use, and it was not possible to release any for general civilian use. A small quantity had, however, recently been allocated to the Ministry of Health for use in air raid shelters. Raw materials for effective fly sprays had been available to manufacturers during 1944.

Notes in Brief

Provision of homes for the chronic sick and the permanently incapacitated is one of the aspects of the National Health Service which are engaging the attention of the Minister of Health.

It is estimated that the balance in the approved societies' current account under the National Health Acts at June 30, 1944, was £13,300,000 and the cost price of investments at that date £104,400,000.

The Government of Nigeria is educating the public in the dangers of fraudulent drugs and considering whether legislation should be introduced controlling advertisements of them.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales notifications of measles were 354 higher than last week, scarlet fever 105 higher, and diphtheria 25 higher. Notifications of acute pneumonia rose by 144 after being practically constant for seven weeks.

Measles is prevalent in the north. Lancashire reported 191 more cases than last week, and Cheshire 43. Lancashire also had 43 more cases of scarlet fever, and Glamorganshire 27. There were 24 fewer cases of whooping-cough in the whole country, although in Lancashire the total rose by 54.

No new outbreaks of dysentery were reported but there was a rise in incidence in most of the existing outbreaks, the total cases, 365, being 14 higher than last week. The largest returns were Essex 36, Glamorganshire 35, London 34, Surrey 27, Dorsetshire 26, Hertfordshire 26, Sussex 26, Lancashire 24 Kent 17. Only 1 case was reported from the outbreak in Staffordshire and 4 from Derbyshire, where 21 and 23 cases respectively were notified last week.

In Scotland notifications of acute primary pneumonia went up by 51, of scarlet fever by 69, of dysentery by 30, and of measles by 28, but there were 31 fewer cases of diphtheria and 27 of whooping-cough. The rise in dysentery was due mainly to increases in the 47 cases notified in Edinburgh and the 55 in Glasgow.

In Eire 117 fewer cases of diarrhoea and enteritis were reported, but the incidence is still high, 68 notifications.

In Northern Ireland the notifications of diphtheria rose by 21, while those from measles and scarlet fever fell by 5 each.

Week Ending September 30

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,828, whooping-cough 982, diphtheria 545, measles 2,015, acute pneumonia 479, cerebrospinal fever 39, dysentery 351, paratyphoid 11, typhoid 11, poliomyelitis 20, polio-encephalitis 2, encephalitis lethargica 2.

INFECTIOUS DISEASES AND VITAL STATISTICS

No 38

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 23.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Paratyphoid A, B, 1.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

a dilution of 1:16 of the patient's serum. Agglutination, if present, can be reversed by placing the tubes in a water-bath or incubator at 37° C.

The Paul-Bunnell test is carried out with a suspension (0.5-2%) of sheep R.B.C.'s, the mixture of serum and cells is incubated at 37° C. for 1 to 2 hours, and the results read immediately or after standing at room temperature overnight. (The tubes should not be put in the cold as is sometimes recommended.) The diagnostic titre depends on the particular technique used; it usually lies between 1:50 and 1:100. Thus there is little likelihood of confusion between the two tests, and a significantly positive Paul-Bunnell reaction will not occur with the infections—e.g., virus pneumonia and trypanosomiasis—that give rise to cold agglutinins provided the tests are correctly performed. A false positive Paul-Bunnell reaction may occur in serum sickness, but these agglutinins may be removed by absorption of the serum with an emulsion of guinea-pig kidney.

The rationale of the Paul-Bunnell test was described in the reply printed in the *Journal* of Dec. 11, 1943, p. 771: and cold agglutinins in the *Journal* of April 1, 1944, p. 481.

Flea Bites

Q.—*A woman of clean habits has always been susceptible to insect-bites. With canteen work and more use of public vehicles, life has become a misery. She never comes in without a flea, which never leaves her until it is found and destroyed. Is there any liquid or powder one could spray on the body and clothes which would act as a repellent, or preferably as an insecticide? Why are some people's reactions to a flea bite so violent, sometimes resulting in urticarial spots, while with some people the reaction is hardly noticeable?*

A.—Fleas are prevalent in warm weather and seem to have been particularly bad this summer. The foci of infestation are usually in houses where fleas breed in undisturbed corners; it is most unlikely that they would breed in public conveyances if these are reasonably clean. It is, however, quite easy to acquire fleas by close contact with people from infested homes. Unfortunately no repellent can be recommended at present, most of the older remedies being as unpleasant for the human skin or nose as for the flea. It may be found that spraying the socks with strong insecticide will act as a deterrent, for fleas cannot jump upwards more than five or six inches. Unless people are exposed to special risk from fleas by reason of their occupation, an infestation at home should be suspected in case of frequent attacks. In clean homes fleas can usually be traced to pet animals; both the cat and dog fleas are liable to bite man. The sleeping place of any pet as well as its fur should be carefully examined. Some people are known to be much more sensitive to flea bites than others, which is the usual case with reaction to insect bites. It would appear that the irritation is a form of allergy. It is probably for this reason that some people are apparently immune from bites, while others complain that they seem to attract fleas.

INCOME TAX

Benefits in Kind

M. S. employs a surgery cleaner whom he supplies with dinners and teas; can he charge the cost of the meals as a professional expense?

****** Certainly. As to the amount to be charged, it is not possible to give advice other than to say that a reasonable estimate of the cost of the food should be the basis of the amount which can be charged.

Appointments: Schedule D Assessment

"A. B. C." writes: "Since the beginning of the war my earned income has come from appointments only and I have been assessed under Schedule D, just as I was assessed when in general practice." He asks whether he would have been liable for less tax if he had been assessed under Schedule E.

****** It is not possible to give a categorical answer, as the choice of schedule may have worked both ways. On the one hand the rules with regard to expenses (particularly the expense of travelling between residence and the place of work) are rather more rigorous under Schedule E, and "A. B. C." may have benefited from assessment under Schedule D in that respect. On the other hand cancellation of 7/12ths of the tax assessed for 1943-4 applies only to emoluments assessable under Schedule E, and "A. B. C." has lost that advantage. On balance "A. B. C." has probably lost, but as he is presumably not paying tax for 1944-5 under the "pay-as-you-earn" system, there is, so far as he is concerned, no overlapping of tax deductions—which, of course, is the reason for the cancellation. If the loss is material application might be made to the inspector of taxes to treat the assessment as if it had been made (as apparently it should have been made) under Schedule E, or alternatively to discharge that assessment and create another under Schedule E to which cancellation will apply.

LETTERS, NOTES, ETC.

Ingrowing Toenail

Wing Cmdr. A. RONALD (Cosford) writes: It surprised me that in the various methods of palliative treatment recommended for ingrowing toenail (Sept. 16, p. 390) the most effective and simplest method—namely, packing under the nail edge with cotton-wool or tinfoil—should be given last of four methods, and the most important point of all omitted—i.e., that the nail must be allowed to grow beyond the end of the toe. Any treatment by a cutting of the nail either in "Vs" or otherwise must result in formation of a chisel edge which on walking produces a fresh ulcer, and it is only by allowing the nail to grow in its normal way beyond the end of the toe that the condition can be really cured. So-called "radical treatment" by amputating half the phalanx from such an important weight-bearing structure as the great toe seems a terrible confession of failure on the part of surgeons as a whole. If packing under the nail edge should fail to cure the condition, which is most unlikely if the packing is persisted with over three or four months, then a very effective and rapid method of dealing with the complaint is removal of the nail and nail-bed followed at once by split skin graft.

Dr. W. F. COOPER (Kingston Hill) writes: You had a note on ingrowing toenails (Sept. 16, p. 390). A very simple method is to file the middle part of the nail almost to the bed instead of cutting a piece out; it can be repeated as often as required, is quite painless, and efficient. Some nails have debris under parts, causing irregular growth; but it is easy to file the nail down, to scrape out the debris and cut off what is necessary, so that the nail grows normally. Nails are best filed when dry and cold, but cut best when wet and as hot as possible (forming the other type of chitin). A bastard-cut file is best for toes, and smooth-cut for fingers.

"Cracked Fingers"

Col. S. HAUGHTON, I.M.S. (ret.), writes: The following treatment may help the doctor who asks this question (Sept. 9, p. 361). I suffer frequently from "cracked fingers" due mainly to gardening. This treatment has never yet failed to cure this condition with me. (1) With an ordinary nail-file, file away any hard skin. (2) Paint the cracks with friar's balsam. (3) Splint the tip of the finger with elastoplast. If the crack is at the tip of the finger one requires a piece of plaster from palmar to dorsal surface and then a second piece round the finger. If the crack is at the side then a circular piece is sufficient. I reapply after 4 days. My cracks are always healed in 7 to 10 days. It is the splinting by the "elastoplast" with the subsequent rest the finger gets that allows the cracks to heal so quickly. With me this never fails and all pain goes at once.

Lieut.-Col. M. ORR WILSON (Plymouth) writes: Another very good treatment for cracks on the finger-tips which are very painful and difficult to heal is the use of methylated ether to cleanse the skin after the removal of plasters. A finger-stall made of elastoplast soon stops the pain and heals the crack. Ordinary anaesthetic ether does not seem to have the same effect. This note is the result of painful experience and further experiments.

W.C. Equipment

"M.D." writes: I would suggest that the lack of facilities for washing after defaecating can be overcome by using absorbent cotton, which can be soaked in the water entering the pan. Scrupulous cleanliness is impossible with ordinary toilet paper. I suffered for years from pruritus ani until I had my appendix removed, and found that the only way to relieve it was by washing after defaecation and applying surgical spirit.

Cerebrospinal Fever Investigation in Scotland

Dr. J. SMITH, F.R.C.P., Director of the City Hospital Laboratory, Aberdeen, writes to correct an omission in the leading article on treatment of cerebrospinal fever (Oct. 7, p. 475). Aberdeen also participated in the investigation.

Sensitivity to Sulphonamides

The reader who asked the question under the above heading in the *Journal* of Sept. 16 (p. 390) now writes: In the case which I quoted, where the patient developed irritation of the hands, mouth, and anus on taking sulphathiazole, I tried the effect of giving nicotinic acid with the drug and was completely successful in overcoming the symptoms of irritation. I began with 0.25 g. sulphathiazole and 50 mg. nicotinic acid, and, as no irritation resulted, followed this with a similar dose in two hours, then 0.5 g. plus 50 mg. nicotinic acid in another 4 hours. After that I gave 1 g. sulphathiazole and 100 mg. nicotinic acid three times daily for several days with complete success, there only being very slight and transient irritation of the hands about one hour after each dose.

LONDON SATURDAY OCTOBER 21 1944

PLASMA VOLUME IN TRAUMATIC SHOCK

BY

A. C. CROOKE, M.D.*

C. J. O. R. MORRIS, Ph D.

*Assistant to Medical Unit**Freedom Research Fellow*

AND

R. G. BOWLER, B.Sc.

Technical Assistant

(From the London Hospital)

The estimation of plasma volume in patients with traumatic shock has been beset with difficulties. Most methods have depended upon the estimation of Evans's blue in plasma after the injection of a known quantity of the dye into the blood stream. In fasting subjects quite reliable results can be obtained by direct determination of the dye in plasma, but the turbidity of the plasma of non-fasting subjects, and especially of patients with traumatic shock, renders this method very unreliable. The technique described by Crooke and Morris (1942) has overcome this difficulty, but it has been found that a small amount of hæmolytic which cannot always be avoided in shocked patients has led to considerable errors in the estimation. A method of correction for this has now been devised (Morris, 1944), but a further serious cause of error has been traced to the effect of morphine or hyoscine given to patients before the injection of Evans's blue (Bowler, Crooke and Morris 1944). These substances may cause anomalous dye concentration curves, thus making the determination of plasma volume impossible. Normal curves are obtained however when the dye is injected a sufficient time before the morphine or hyoscine to allow it to become uniformly mixed in the circulation. In the light of these observations a number of determinations of plasma volume in shocked patients can now be regarded as valid, although many of the earlier cases have had to be discarded.

The haemoglobin (pyridine-haemochromogen method, Rimington 1942) and haematocrit were measured repeatedly in some of the cases and were found to run parallel. The determination of haemoglobin is more accurate than that of the haematocrit, and the latter has been omitted in more recent cases. Total blood volume cannot therefore be determined, but it gives little more information than plasma volume when the haemoglobin value is also known. Only the values of plasma volume and of haemoglobin will for this reason, be recorded in this paper.

A few typical cases are described briefly. Some of the patients were admitted to the London Hospital, while others were seen in outlying hospitals.

Clinical Material

Case 1—A man aged about 50 was run over by a heavy lorry at 10.30 p.m. He was admitted at 11.10 p.m., conscious but restless, and protesting against interference. His skin was cold, clammy, and cyanosed, and his blood pressure was 93/72 mm Hg. He was found to have a badly crushed pelvis. The gluteal muscles were partly torn off and the left testicle was hanging out of the torn scrotum. The extent of internal injuries could not be ascertained, but the rectum appeared to be intact. There was also a cut over the right eye and blood in the left ear. He vomited beer smelling fluid material. At 11.45 p.m. a determination of plasma volume was started, and a value of 1.75 l, or about 2.1% of body weight (about 13 st.), was obtained. His haemoglobin was 14.1 g/100 c.c.m. At 11.55 p.m. he was given morphine gr 1/4, and at 12 a.m. a

transfusion of plasma was begun. At 12.10 a.m. his blood pressure was found to be 58/38 mm Hg and pulse rate 80. At 12.30 a.m. he was given morphine gr 1/4, but he got steadily worse. At 1.10 a.m. his blood pressure had fallen to 43/30 mm Hg and his haemoglobin to 11.9 g/100 c.c.m. after a transfusion of about one bottle of plasma. He died at 2.15 a.m. He was found at necropsy to have extensive crushing injuries across the left groin and hip, with a 14 in long split from the groin through the perineum to the buttock. The left ilium was fractured, but no injury of internal organs was found.

Case 2—A woman aged 36 was kicked in the abdomen by a horse at 3 p.m. She was admitted to hospital at 5.30 p.m. complaining of severe abdominal pain. Unfortunately we did not see this patient alive but she was said to be very shocked on admission. The pulse was very weak—the rate about 130. The blood pressure was about 60/30 mm Hg. The abdominal wall was lax, especially in the left hypochondrium, where she was tender on palpation. No free fluid was detected in the abdomen and no other injury found. She was given morphine gr 1/6 and atropine gr 1/100 on admission, followed by morphine gr 1/4 at 6.55 p.m. At 9.15 p.m. her blood pressure had risen to 100/50 mm Hg, her pulse had fallen to 110, and her general condition was stated to have improved slightly. At 9.30 p.m. she was catheterized and almost pure blood was withdrawn. At 10.7 p.m. a determination of plasma volume was started, this gave a figure of 1.9 l, or about 3.3% of body weight (about 9 st.). The haemoglobin was 10 g/100 c.c.m. At this time the blood pressure had fallen again to 80/30 mm Hg, and the pulse to 90. She was given morphine gr 1/4 at 10.40 p.m. She was said to have improved slightly during the night, but at 7 a.m. she died suddenly. A coroner's post mortem examination was performed, and she was found to have a complete rupture of the left kidney with a large retroperitoneal haematoma of from one to two pints. There was a small rupture of the spleen, with fractures of the 8th, 9th, and 10th ribs near their costo vertebral joints.

Case 3—A woman aged 22 was admitted to hospital at 4.22 a.m. complaining of profuse vaginal bleeding, which began about mid night but her history was unreliable. She was conscious but collapsed and very pale with a pulse rate of 132 and a blood pressure of 95/45 mm Hg. She had extensive vaginal lacerations, apparently inflicted manually, but there was only slight bleeding when admitted. She was not pregnant. At 4.55 a.m. her condition was unchanged and a determination of plasma volume was begun which gave a value of 2.74 l, or about 4.5% of body weight (9½ st.). The haemoglobin was 10 g/100 c.c.m. The lacerations were subsequently sutured and she made an uninterrupted recovery.

Case 4—A woman aged 55 was beaten on the head and arms by a man with an iron bar at 10.30 a.m. The police reported finding a great deal of blood about. On admission at 12.10 p.m. she was conscious but apathetic and very pale and cold. The pulse was 80, regular and of small volume. The blood pressure was 70/50 mm Hg. She had multiple lacerations of the scalp, with little bleeding at this time, a fracture of the shaft of the lower third of the left ulna, and some cuts on the hands. A determination of plasma volume was started at 12.38 p.m., and a figure of 1.92 l was obtained or about 3.8% of body weight (about 8 st.). The haemoglobin was 13.8 g/100 c.c.m. The blood pressure and pulse were unchanged. At 1.25 p.m. she was becoming restless and was given omnopon gr 1/3 and scopolamine gr 1/150. At 1.55 p.m. a transfusion was started and she was given two bottles of blood. Her condition then improved steadily, and her wounds were dressed and the fracture set at 8 p.m. Ultimately she was discharged well.

* Member of the Mobile Team of the Shock Committee of the Medical Research Council under Sir James Walton.

Case 5.—At 11.15 a.m. a man aged 54 fell 30 ft. from a building he was demolishing. He was semiconscious on admission to hospital at 12 p.m. and resisted attempts to examine him. His extremities were cold. His pulse rate was 156 and blood pressure 115/90 mm. Hg. There was a deep laceration of the right cheek, and cerebrospinal fluid was escaping from the left nostril. The pupils were equal, but the right reacted to light better than the left. Slight left facial weakness and slight spastic weakness of the left arm were present. The left plantar response was equivocal, but the right was flexor. There was swelling of the right wrist and the left ankle. Subsequent x-ray examination showed a fracture of the left malar bone running back into the anterior cranial fossa, involving the floor of the left orbit. There was also a fracture of the right radial styloid process and the left internal malleolus. The plasma volume, determined at 2.6 p.m., was 2.2 l., or 3.9% of body weight (about 8 st. 12 lb.). The haemoglobin was 13.4 g./100 c.cm. The blood pressure at this time had fallen to 115/80 mm. Hg and the pulse to 130. He was given morphine gr. 1/4 at 2.15 p.m. He gradually recovered consciousness during the next three days, but was found to have complete aphasia. He continued to improve, however, and the plasma volume was estimated again two weeks after admission. It was found to have risen to 3.1 l., or 5.5% of body weight. The haemoglobin had fallen to 9.5 g./100 c.cm.

Case 6.—A boy aged 14 fell in front of a bus and sustained a head injury at 5.10 p.m. He was admitted to hospital unconscious at 5.30 p.m. His skin was grey-coloured but warm and not sweating. His blood pressure was 156/110 mm. Hg and pulse rate 100. His pupils were deviated to the left, but otherwise there were no abnormal signs in the central nervous system. There was no evidence that he had lost any blood. At 6.30 p.m. he had recovered consciousness sufficiently to take sips of tea. The pupils were still deviated to the left. The blood pressure was 130/85 mm. Hg and pulse rate 96. A determination of plasma volume was started at 6.36 p.m., and was found to be 3.45 l., or 6.2% of body weight (8 st. 11 lb.). His haemoglobin was 11.6 g./100 c.cm. He continued to improve steadily, the deviation of the pupils disappeared, and he was finally discharged well.

Discussion

A reduction of plasma volume is accepted as being characteristic of traumatic shock, the amount of the fall being proportional to the severity of the shock. In general this has been confirmed in the present series of cases, but the reduction is greatest when examined early, as shown by the first two patients, both of whom died of their injuries. In Case 1 the plasma volume had fallen from the normal level of between 4.5 and 5.5% of body weight to about 2.1% in 1½ hours. This patient died 3½ hours after a severe crushing injury of the pelvis. In Case 2 the plasma volume was about 3.3% of body weight 7½ hours after the patient sustained a ruptured kidney and spleen. She died 16 hours after the injury. In less severe cases the reduction of plasma volume may be slight, especially if not examined until some hours after the injury. This is demonstrated by Case 3, in which the plasma volume was about 4.5% of body weight some five hours after traumatic vaginal haemorrhage, from which the patient made an uninterrupted recovery.

Head injuries may also be accompanied by a reduction of plasma volume, but only when haemorrhage has occurred. In Case 4 the plasma volume was about 3.8% of body weight some two hours after the patient received severe lacerating wounds of the scalp, cuts on the hands, and a fractured ulna. It was not known if she had temporarily lost consciousness. She made an uninterrupted recovery. In Case 5 the plasma volume was about 3.9% of body weight some three hours after the patient sustained a fractured skull with cerebral contusion, deep lacerations of the face, and minor injuries of the wrist and ankle. In both these patients there had been obvious haemorrhage associated with the head injuries. In contrast to them, no haemorrhage occurred in Case 6, a patient who received severe cerebral concussion which was associated with a transient hypertension. The plasma volume was about 6.2% of body weight about 1½ hours after the accident.

Haemoglobin concentration falls following traumatic shock, but the fall is minimal immediately after the injury, and may not become marked until several hours later. In Case 1, the most severe example, it was normal—14.1 g./100 c.cm. at the time of estimation of the plasma volume 1½ hours after the accident. In Case 4 it was 13.8 g./100 c.cm. and in Case 5 13.4 g./100 c.cm. at the time of estimation of the plasma volume about two hours and three hours respectively

after the patients were injured. In both Case 3 and Case 2 it was 10 g./100 c.cm. some 5 hours and 7½ hours respectively after the injury. This series shows a progressive fall in haemoglobin concentration as the time since the injury increases. The fall must be due to dilution of the blood with extravascular fluids, so that the determination of plasma volume at a later time may give a figure which is appreciably higher than would have been found one or two hours after the injury. Thus in Case 5 the haemoglobin was 13.4 g./100 c.cm. and the plasma volume 3.9% of body weight some three hours after the accident. Subsequently the haemoglobin fell to 9.5 g./100 c.cm. when a second determination of plasma volume showed that this had risen to normal—5.5%.

The reduction of plasma volume in all the cases which we have examined could be explained by haemorrhage alone, but many workers have claimed that shock is a toxic condition associated with haemoconcentration (see Moon, 1944). Haemoconcentration as judged by increased concentration of haemoglobin or a haematocrit value above normal has not been observed in any of the cases in our series except when associated with burns or with the crush syndrome (Bywaters, Crooke, and Morris, 1943). Haemoconcentration in these cases is due to loss of serum into the damaged tissues without a corresponding loss of corpuscles. The conception that haemoconcentration occurs in traumatic shock in man is probably due to the cyanosed, viscid character of the blood in severe cases. We have found, however, that in contrast to this increased viscosity of whole blood the viscosity of plasma is below normal. In one instance a man aged 70 sustained multiple injuries. He had a fractured spine, pelvis, ribs, humerus, tibia, and fibula and a ruptured aorta and pericardium. A little blood was obtained for examination at the time when a transfusion was started some 45 minutes after the accident. It welled slowly from a vein in the leg when this was cut down upon. It was very cyanosed and viscid. The plasma viscosity was 1.62 at 20°C., which is significantly less than the normal—2.0 at 20°C.

Dr. E. R. Holliday kindly examined this plasma, and reported as follows: The plasma was examined in the Tiselius electrophoresis apparatus at pH 7.5 in 0.05 ionic diethyl barbiturate buffer at a dilution of 1 part of plasma to 3 parts of buffer. The migration diagram obtained by the Philpot modification of the "Schlieren" method was not entirely satisfactory. The ascending and descending diagrams showed considerable differences. The main abnormality of both diagrams is a deficiency in a component.

The increased viscosity of the blood with a decreased clotting time and a normal haemoglobin suggests a state of incipient clotting. The fibrinogen content of the plasma was, however, found to be normal by electrophoresis. The increased viscosity of the whole blood may therefore be due to an abnormal state of dispersion of the α component, since it is known that both α and β components readily form gels under certain abnormal conditions. This gel would be removed in the centrifugal separation of cells and plasma, and such plasma would have a decreased viscosity, a deficiency in a component, and a normal fibrinogen content. A further study of this problem is, however, necessary.

Summary

Difficulties in the estimation of plasma volume in shocked patients and the methods employed in overcoming them are described.

The plasma volume may be reduced to about 2% of body weight in the most severe cases.

The haemoglobin concentration is generally reduced, except in some cases of burn shock and crush syndrome.

The reduction in haemoglobin concentration does not run parallel to the reduction in plasma volume. It is least pronounced immediately after the injury, but subsequently progresses as water is restored to the circulation from surrounding tissues. It is most pronounced after the plasma volume has been restored to normal.

The theory that haemoconcentration occurs in shock is discussed.

EUSTACHIAN OBSTRUCTION AND OTITIC BAROTRAUMA IN AIR-CREWS OF HEAVY BOMBERS

BY

R. M. S. MATTHEWS, M.B., B.Chir., M.R.C.S.

Flight Lieut. R.A.F.V.R.

The following report is presented from the academically meagre but administratively important viewpoint of the medical officer because of the subject's interest and as possible guidance to civilian practitioners in the medical ministrations of aerial transport in the post-war era. The paper is based on the personal observation of 66 cases during recent 30 weeks period with a heavy bomber squadron of the Royal Air Force.

These two conditions present one of the greatest problems to beset the medical officer on a flying station. The former condition, Eustachian obstruction, is so mildly incapacitating on the ground, unless the obstruction is sufficiently severe to form a complete block, that it is difficult to imagine how much administrative trouble may result therefrom. The limitation of the flying duties of one man may mean the cancellation of a sortie by a complete air crew. But the decision to let a man fly with established Eustachian obstruction may equally well result in otitic barotrauma—which is therefore a lesion directly attributable to Service conditions—quite apart from the man's discomfort and the inefficient performance of his duties. The following figures are eloquent. During the 30-weeks period under review 56 men suffering from Eustachian obstruction were passed as unfit for full flying duty for periods of 24 hours or more, with a total loss of 145 "man nights"—an average, therefore, of approximately 2.5 nights lost per man. But for otitic barotrauma the corresponding figures are 10 men removed or a total of 204 nights, which gives an average of 20.4 "man nights" lost.

The term "Eustachian obstruction" has been used to cover all those cases presenting a reduction in the patency of the Eustachian tubes, whether partial or absolute. Strictly, the term "Eustachian obstruction" should be confined to cases of absolute "block," but terminology here is not easy. "Eustachian catarrh" is convenient but not always pathologically accurate. The term "Eustachian tube insufficiency" has been suggested, but is cumbersome, and "insufficiency" belongs more happily to the endocrine system than to an anatomical structure. "Otitic barotrauma" is a more exact and accurate descriptive term, and refers to those cases presenting persistent abnormal drum appearances and hearing changes.

Anatomy and Physiology

Some basic facts are worthy of recall. The Eustachian tube runs downwards, forwards and medially from the middle ear to the nasopharynx. There is a bony part derived from the skull and a cartilaginous portion which lies under the mucous membrane to produce an elevation, and the tube is narrowest at the junction of these two parts. It is lined with ciliated columnar epithelium continuous with the pharynx, in the lower end of the tube are some mucous glands, and around the orifice some adenoidal tissue is present. Medial to the tube is the levator palati muscle and the tensor palati lies lateral thereto. The palpingopharyngeus muscle arises from the inferior side of the cartilaginous portion and, in company with the former two muscles, is inserted into the soft palate. Consequently when these three muscles contract in swallowing the lower part of the tube receives a pull outwards in three directions and so should normally open.

The tympanic membrane consists of two layers—an outer layer derived from the skin and an inner derived from the mucous membrane of the pharynx—with an intervening sandwich layer of fibrous tissue. The drum derives a nerve supply, among others, from the auriculo temporal nerve, which also supplies the lining of the external auditory meatus, and this has an interesting practical application, as will be seen later. The drum normally appears slightly concave externally and the tubes are generally closed.

Pressure Changes

On ascent, as the atmospheric pressure falls, there is a progressive increase of pressure in the middle ear, which is eased spontaneously by the opening of the Eustachian tubes and the expulsion of a volume of air sufficient to equalize the pressure. This occurs without any discomfort, and all the subject notices is a succession of "clicks" in the ears. In none of these cases has there been any complaint of pain on the way up. On reaching and remaining at a constant altitude equilibrium between the internal and external pressure on the drum is maintained by the above mechanism. On descent the external pressure on the drum builds up, and to restore normality air must enter the middle ear. But the tubes open more readily to an increase of pressure from the aural end than to a similar increase at the pharyngeal opening, and this is where the difficulty starts.

Swallowing is the normal physiological way of opening the tubes and is therefore the first manoeuvre tried. Certain people achieve greater success by manipulating the mandible in an antero-posterior plane or by wide chewing movements. In difficulty, however, the most universally effective method is auto-inflation, by Valsalva's method, in which there are several important points. First the cheeks should not be puffed out as the extra pressure is taken up in the buccal cavity, whereas it is in the post-nasal passage that the increase is desired. Secondly, the pressure should be slowly built up, as the tubes open more comfortably to a slowly increasing pressure than to a sudden short burst. Lastly, it is helpful to incline the head forward with the chin on the chest.

A greater change of pressure takes place between 10,000 feet and ground level than between 20,000 feet and 10,000 feet, and so auto-inflation is more necessary during the later stages of a descent than during the earlier, in practice it is usual to auto-inflate about six times from 20,000 feet to 10,000 feet and every 1,000 feet thereafter. Meteorological conditions do not affect the pressure very much and the greatest change that could be produced by barometric disturbances on a horizontal flight would equal a descent of 1,000 feet from London to Edinburgh.

Clinical Findings

(1) *Eustachian Obstruction*—In the series of cases examined the Eustachian obstruction encountered has been due to naso-pharyngitis, either catarrhal or mucopurulent. The leading symptoms are monotonous in their consistency. The patient reports complaining of a cold and that his ears are "blocked" and if he has flown before reporting he states that his ears have caused him "trouble." The presence of a nasal discharge is variable. The throat is not described as sore, but there may be a tickle due to the irritation of the post-nasal discharge. On examination the throat may show injection and there may be, but not necessarily, a post-nasal discharge. The drum is always examined, and in pure Eustachian obstruction is only slightly invaginated in appearance, but if the man has discovered his condition only through flying there may be barotraumatic appearances as well. On attempting auto-inflation no movement is observed and no subsequent click is heard. An important point is that, even in normal people after prolonged attempts at auto-inflation the leath of vessels overlying the head of the malleus becomes engorged from venous-back pressure giving a spurious appearance of "injected drum head." But of course this is only a transitory phenomenon. A true injection of the drum from barotrauma persists much longer. The problem arises whether the tubes are patent when there is no movement of the drum on auto-inflation. It is doubtful if this is the case in experienced fliers, whose drums usually move with an audible click. No movement, however, may be found in less experienced air-crew and, further, a previously damaged and scarred drum will often fail to move. These last conditions render the diagnosis of Eustachian obstruction dependent in a few cases on the individual's own statements. This of course raises the awkward problem of possible psychological reactions to flying, which is beyond the scope of this report. (The following figures have since been supplied in a series of 2,000 ears examined: the tympanic membrane was visibly mobile in 91%, the tubes were audibly patent in 49.8%, and negative in 7.4%.) It is emphasized that

it is quite possible to have a "cold" and to experience no discomfort from the ears during flight owing to the Eustachian tubes remaining patent. Chronic rhinitis, mild forms of acute pharyngitis, and tracheitis do not necessarily curtail flying duties.

The pathology of the condition is conjecturally simple, although of course there has been no opportunity for verification in this series. The changes must either be a generalized catarrhal or occasionally inflammatory congestion in the epithelium—these cases give the sluggish response to auto-inflation—or there must be oedema of the adenoidal tissues at the pharyngeal orifice of the tube, giving a more substantial block. Among civilians, where the patients will not fall in the same healthy age group, the condition will be less simple. Adenoidal children will presumably present a special difficulty.

(ii) *Otitic Barotrauma*.—The symptoms are first a sensation of fullness in the ears, then increasing deafness, and lastly pain, which increases with the rate of descent and eventually becomes very severe. If no relief is obtained from opening the Eustachian tube the drum may eventually rupture. As the initial pain of a fracture may ease off in spite of persistent anatomical displacement, so may the initial pain of otitic barotrauma pass off to some degree in an hour or so after landing, giving rise to the false supposition that the Eustachian tube has opened. In mild cases many patients consider that there is wax in the external auditory meatus, and it is suggested that this is due to sensations from the auriculo-temporal nerve supply of the drum being referred to the lining of the meatus. Before proceeding further it must be admitted that, with the few cases seen, no hard-and-fast conclusions can be drawn. However, from these 10 cases certain tentative deductions can be made. Five only out of the 10 had colds before experiencing barotrauma, and so presumably there was no degree of Eustachian obstruction in the other five before flying. From the findings on examination of these 10 cases a rough classification under three headings has been made.

(a) *Slight*.—In heavy bombers this is the most common. There is slight impairment of hearing and the drum appears invaginated, injected, and indrawn. A number of the cases with Eustachian obstruction show mild degrees of barotrauma after discovering the disabling nature of their cold on short flying trips in the daytime, when there has been plenty of time for descent and repeated attempts at auto-inflation have been made. This stage is also seen in air-crew who have not had colds, but have lost the last 1,000 feet of descent rapidly. The majority of air-crew must have suffered from some trifling otitic barotrauma during their careers.

(b) *Moderate*.—The symptoms are the same, but height has been lost more rapidly and the trouble may have begun at a higher altitude and so there has been a longer strain on the drum. Hearing is more impaired than in the slight cases. An additional feature, however, is the appearance of haemorrhagic areas in the drum, usually in the postero-inferior quadrant, analogous to an ecchymosis of any other traumatized region. These haemorrhages are between the layers of the drum and may distort the drum features, or a solitary one may simulate a perforation. Recovery in these cases, as judged by the absence of symptoms on an air test, will take longer than in group a.

(c) *Severe*.—The findings are the same as above, but two complications can occur: first, a long-continued barotrauma may produce an effusion into the middle ear; and, secondly, the pressure may be so severe as to rupture the drum. The latter is very rare, and not one case has been seen in this 30-weeks period, nor, indeed, during twelve months with Bomber Command.

Treatment

Preventive.—Prevention is of the greatest importance from the Service point of view, and time spent by the medical officer in instruction in these conditions is well paid by the saving of time lost to the air-crews. It is the practice to see every air-crew on arrival at the station and to give a standard lecture on aviation medicine, including this condition. It may be argued that to dwell too much on the possible sources of a disability may be to sow the seed of a neurosis, but in this 30-weeks period this was found to be not true. With the aid of a diagram the elementary anatomy is shown and the Eustachian tube is likened to "an inch and a quarter of flabby drinking-straw" through which with a funnel it is possible to blow but not suck. This gets over the problem of why the air can get down but not up the tubes, whether it be the strict truth or not. The essential points in auto-inflation as described above are stressed along with a very practical point—namely,

that the captain must tell his crew when height is about to be lost so that they can auto-inflate before the onset of symptoms. Only three of a crew can tell the altitude from instruments, and very often, if auto-inflation has not been carried out, the ears give the first intimation to the others that the aircraft is descending. It is obvious that methods of preventing nasopharyngitis are of paramount importance on flying stations, and at the lecture mentioned the equation "Infection + impaired individual resistance = cold" is stated as a binding truth. The infective factor is considered endemic, but the virtues of unimpaired resistance or positive health are stressed and attention is directed towards the three basic physiological requirements to achieve it—viz., food, sleep, and exercise. Facilities are also available for supplementing a very adequate diet by vitamin A and D capsules, which have an undoubted psychological effect on air-crew. Lastly, ultra-violet light is available, and a full course is recommended during winter months: colds do not exist among the really conscientious attenders.

• *Curative: (a) Eustachian Obstruction*.—In the type of case most commonly seen pyrexia and systemic features are not necessarily present and in-patient treatment is not required unless there are urgent administrative reasons for intensive treatment. Eustachian obstruction arising from nasopharyngitis will disappear as soon as the congestion at the mouth and in the lumen of the tubes has resolved. To facilitate this use is made of a standard treatment given in the out-patient department, and the patient reports three times a day. A sympatheticomimetic drug causing constriction of arterioles is used, and this can be supplied either with a nasal spray or in oily drop form. Opinion in this unit seems equally divided, but the oily drop method has the better theoretical chance of reaching the orifice of the Eustachian tube if given correctly. A prescription containing 0.75% ephedrine in liquid paraffin is used. It avails nothing if the patient sits in a chair and merely throws his head back; after blowing his nose he must lie horizontal over a couch with his head unsupported, and the head must be dorsiflexed on the neck until either the tip of the chin and the ear or the tip of the nose and the eye are in the same vertical plane. In this position three drops are placed in each nostril and have no option but to slide down into the nasopharynx when the head is raised with slight rotatory movements to ensure equal distribution. When the patient reaches an upright position proof of thorough administration is furnished by the desire to expectorate some of the solution that has slid over the soft palate. The patient waits three minutes for the ephedrine to act and then tries to auto-inflate. It may be argued that persistence in auto-inflation with nasopharyngitis may lead to the spread of infection to the middle ear. There has been no such unfortunate incident in this series. The patient now receives an inhalation. The standard inhaling earthenware pot is not necessary, for a saucer under a towel provides a wide evaporating surface, but of course does not give off vapour for so long. From observations in this series it is considered that the standard tinct. benzoin. co. is too weak for this purpose though of great use in other conditions. Better results are gained from vap. menthol et eucalypt. (N.W.F.), using a teaspoonful to a pint of hot water. When stocks are short a crystal of menthol in hot water is useful, as are a few drops, similarly used, of lin. methyl. salicyl., lin. terebinth., and even liq. picis carbon. Stocks of materials from which inhalations can be made are of paramount necessity at all flying stations. After receiving this treatment all sufferers feel their heads to be clearer, and it is necessary to detain them for a period before they proceed out of doors to meet a cold rush of air causing immediate hyperaemia of the nasal mucous membrane.

The man is examined after his first treatment and an opinion formed as to his fitness for flying duty. Even if the tubes are now patent a temporary limitation is given—not for barometric reasons, as will be understood from earlier remarks, but because it will ensure that he will only be able to fly on non-operational duties, where there will be plenty of time for descent and for auto-inflation should the obstruction recur. From the operational point of view, however, he is a "man night" lost. If there is still no patency of the tubes after treatment the patient is confined to ground duties. The average

time for recovery to fitness for full flying duty has been found, as stated to be 2.5 days. Dominion personnel are notoriously prone to catch colds, and recurrence of Eustachian obstruction is therefore common. In this series there have been approximately 17% of Dominion patients. After recurrence, evidence of possible sinus infection is looked for by transillumination and x-ray examination. The proprietary "benzedrine" or "karsodrine" inhaler is most convenient for air crew, and those who have difficulty in auto inflation often derive considerable benefit by using these before and after descent. Politzerization has its place in the treatment of Eustachian obstruction, and will be discussed later.

(b) *Otitic Barotrauma*—The symptoms can be most satisfactorily relieved by immediate ascent to a height above that at which the barotrauma originally began and by subsequent slow descent with frequent auto inflation. Indeed, many cases in which this has been done never find their way to the medical officer. But for military or meteorological reasons the danger to all the crew from delay caused by this manoeuvre may outweigh the advantage to the individual, and so ascent may not have been carried out. On landing the individual must report for examination and treatment at the earliest opportunity, as the first essential is to get the Eustachian tubes patent. The regime outlined above is tried, and many cases respond within 24 hours. Valsalva's method is persisted with forcibly. If these simple measures fail and there is no purulent nasopharyngitis then recourse to politzerization is necessary. The nasal olive is too small for many nostrils, and a fellow medical officer has suggested the very useful practice of slipping over the olive a pierced rubber cap of a 10-cm TABC vaccine bottle as manufactured by the Lister Institute. This has proved most successful in securing a good airtight fit. The last stage in the therapeutic crescendo is Eustachian catheterization. In this series, however, this has only three times been necessary, and in the type of flying that will be experienced in peacetime passenger transports it should similarly be seldom needed. After the tubes have become patent it is necessary to wait until the effects of the trauma to the drum have resolved before flying is recommenced, otherwise there will be pain on change of pressure. This is the time-consuming part of the treatment which is purely "masterly inactivity," and accounts for the 20.4 days average stated above. Discoloration of the drum at the site of the haemorrhagic areas mentioned earlier may persist after freedom from symptoms, and the point can therefore only be satisfactorily decided after an air test, which is generally carried out around the 14th day.

Case Histories

Case 1—Warrant Officer D. Diagnosis: nasopharyngitis and slight otitic barotrauma. Had a cold before flying. While listening to morse on descent from 20,000 ft noticed that the signals were getting weaker. Then felt pain in both ears, increasing till 2,000 ft. Rate of descent 1,000 ft a minute. Auto inflation at 2,000 ft with only partial success. On examination after removal of cerumen both drums injected, indrawn, and immobile on Valsalva test. Received drops and inhalations t.i.d. Next day right Valsalva was positive. Left Valsalva still negative and nose catarrhal. Continued on same treatment for two days and then politzerized. Two days later left ear was very easily inflatable. Resumed full flying duty after total absence of five days.

Case 2—Flying Officer W. Diagnosis: slight otitic barotrauma. No cold prior to flying. No record of altitude changes, and landed away from this unit with symptoms of barotrauma (left). Politzerization before return, and on arrival here complained of persistent aural pain. On examination drum injected and wrinkled in appearance. Two days later ear still painful, auto inflation increased pain and caused further pain in left mastoid region. Three days later this mastoid pain was more severe, and relief was obtained only from resting on a hot water bottle and from analgesics. Eventually fit for full flying duty after 12 days' absence.

Case 3—Pilot Officer W. Diagnosis: slight otitic barotrauma. No cold before flying. Descended from 21,000 ft and experienced pain in right ear to 15,000 ft. Pilot thereafter descended more slowly, but only partial success with auto-inflation. Three hours after landing flew again to 15,000 ft with some relief. Reported four days later. Right drum injected, indrawn, and immobile. Politzerized next day by ENT surgeon, with good air entry and some immediate improvement. Continued to receive inhalations, and resumed full flying duties after 25 days' absence. When examined 20 weeks later there were no signs of impairment of hearing.

Case 4—Sergeant C. Diagnosis: severe otitic barotrauma. No cold prior to flying. No record available of altitude changes, but complained of immediate pain in right ear on descent. On examination the normal features of the tympanic membrane were obscured by "bubbles" due to a serous effusion in the middle ear. Received routine drops and inhalations, and two days later the Valsalva test became suddenly positive spontaneously, and on examination the bubbles were seen to have disappeared, to leave haemorrhage in the drum, which was mobile on auto inflation. He then proceeded on nine days' leave, and on return the haemorrhages had resolved. He proceeded on non operational flying duties, and after a satisfactory air test resumed full flying duties after a total absence of 20 days.

Case 5—Sergeant M. Diagnosis: severe otitic barotrauma. No cold before flying. Aircraft involved in fast dive from 13,000 ft, and pain developed in left ear, becoming very severe. Captain reascended to above 10,000 ft and pain eased off, but recurred again and was acute after landing. On examination the drum was intact and mobile on auto inflation. Received drops and inhalations, and pain passed off completely. Six days later flew again and experienced pain from 4,000 ft at three quarters of previous strength. Next day, when examined by the ENT surgeon, the drum was inflamed, was mobile on auto inflation, and there were the remains of a serous effusion in the middle ear. Watch-tick heard only on contact, and Weber test referred to the right ear. Six days later the inflammation of the drum had subsided, and in a further seven days the hearing had returned to normal. Thirteen days later he resumed full flying duties after a total absence of 27 days.

Case 6—Flight Sergeant T. Diagnosis: nasopharyngitis and severe otitic barotrauma. Coryza before flying. Pain in right ear on descent from 23,000 ft, increasing to a maximum at 20,000 ft and then easing off. Reported next day. On examination nose inflamed, drum inflamed and indrawn with haemorrhagic posterior patch, and could just hear watch tick against the ear. Politzerized by the ENT surgeon next day. Seven days later cold persisted and the Eustachian tubes were catheterized by the ENT surgeon. Thereafter auto inflation daily and politzerization at unit on "negative" days. Eleven days later still—i.e., 20 days after barotrauma—patch still present on drum. Four days afterwards his cold had cleared, his drum appeared normal, and his hearing had returned. Resumed flying below 5,000 ft. After a satisfactory air test resumed full flying duties after 45 days' absence.

Conclusion

Once again it is stated that this paper does not attempt to give a comprehensive picture of otitic barotrauma, but merely depicts those features that have been observed with air crews of heavy bombers by a unit medical officer. There is much more that could be discussed in the way of treatment—for instance, by those who have the opportunity of seeing more of these cases. Inhalation of helium-oxygen mixtures, drum punctures and the implantation of radon tubes into the nasopharynx around the tubal orifices of patients with recurrent nasopharyngitis are all interesting remedial measures.

On R.A.F. stations there is no difficulty in the diagnosis or disposal of cases of severe otitic barotrauma, but the handling of air crew with nasopharyngitis presents a problem that will be found in any form of aviation. It is hoped, therefore, that the remarks on prevention may be of interest and may indicate one way in which the medical branch, by applying the science of aviation medicine, can join with the other sections at R.A.F. stations in helping the air crews to carry out their task in greater comfort.

Summary

During a 30 weeks period with a heavy bomber squadron of the Royal Air Force 56 cases of Eustachian obstruction and 10 cases of otitic barotrauma have been encountered.

From this series the importance of these two conditions, their anatomy, physiology, pressure changes, clinical appearances, preventive and curative treatment, and some case histories, are described and discussed with reference to civilian aerial transport.

Cases of severe otitic barotrauma have been found to be rare, and the incidence of all cases can be lessened by instruction in auto-inflation, by the prevention of nasopharyngitis, and by curtailing the flying duties of patients with Eustachian obstruction.

Grateful acknowledgements are due to Air Cdre E. D. D. Dickson, R.A.F. Consultant in Oto-rhino-laryngology, for his helpful comments, and to both Squad Ldr W. L. James for interest and encouragement in the preparation of this paper, and Squad Ldr J. W. Cope, ENT surgeon, for reading the proofs also to the staff of Station Sick Quarters for undertaking the clerical work in their spare time.

A LABORATORY TEST FOR DIAGNOSIS OF SMALLPOX

BY

C. E. van ROOYEN, M.D., D.Sc.Ed.

Major, R.A.M.C.

AND

Major, R.A.M.C.

(From the Middle East Forces)

Experience of over 100 cases of smallpox studied in the Middle East has convinced us that a diagnosis of variola on the first and second day of the rash is often extremely difficult and that the differentiation of mild smallpox from varicella may be impossible throughout its course. The purpose of this paper is to describe the clinical application of a laboratory test which has helped us greatly in establishing the identity of variola in the first day or two. The test is based on certain points of distinction between the elementary bodies of variola and varicella found in the skin lesions of these diseases.

Historical

The viruses of variola and vaccinia were discovered in 1886-7 by Dr. Buist, of Edinburgh University Bacteriological Laboratory, who practised as a public vaccinator in the city. Unfortunately Buist failed to appreciate the nature of the tiny bodies which he found and called spores of micrococci, and it was not until 19 years later that Paschen (1906), of Hamburg, stressed their aetiological significance and named them "elementary bodies," followed by Eagles and Ledingham (1932) and others. (For historical notes see Gordon, 1937; and Mackie and van Rooyen, 1937.)

While the existence of the minute organisms has been known for many years, it is strange that few bacteriologists have attempted to utilize them for the laboratory diagnosis of smallpox, despite the fact that their biological characteristics have been extensively studied. (For review of literature see Smedel and Hoagland, 1942.)

In the past, three laboratory procedures—namely, the variola-vaccinia flocculation, the complement-fixation, and Paul's rabbit's cornea tests—have been employed for the diagnosis of human variola in the late stages of the disease. Tanaka (1902) demonstrated that if smallpox vesicle fluid was mixed with vaccinia lymph a precipitate developed; and later Gordon (1925) showed that extracts of variola scabs exhibited a specific precipitation effect when added to vaccinia antisera. The flocculation phenomenon was applied in medical practice by Burgess, Craigie, and Tulloch (1929), who used it as a confirmatory test in mild smallpox as well as a laboratory procedure for the identification of clinically atypical cases occurring in Dundee (see also Craigie and Tulloch, 1931; Tulloch, 1934; Craigie, 1932a and 1932b).

Specific complement-fixation reaction for variola has been practised for many years, and in particular by Beintker (1908), Sugai (1909), and Kolmer (1916). In recent times Gordon (1925) proved that the specific deviation of complement by the interaction of extracted variola scabs (or vesicular fluid), as antigen, with antiserum derived from convalescent smallpox patients or vaccinated rabbits could be of diagnostic help. The modern technique of the variola-vaccinia complement-fixation tests is described by Craigie and Wishart, 1934a, 1934b, 1935, 1936a, 1936b, 1936c; and Tulloch, 1940.

Paul (1919) showed that, if a rabbit's eye was scarified with variolous material, after 48 hours the animal developed acute kerato-conjunctivitis, accompanied by the formation of acidophilic intracellular Guarnieri inclusion bodies (Guarnieri, 1892) in the epithelial cells of the cornea. Paul's test has been extensively used by Scott and Simon (1923), who have recommended a technique whereby the test can be completed within three days.

The present report deals with the prompt recognition of variola by identifying the causal agent of the disease in human

skin lesions during the early stages of the malady, when the virus is easily visible.

Method of Examination

Apparatus.—A sharp-pointed scalpel and two highly polished slides cleaned with potassium bichromate and sulphuric acid solution are required for each case. **Microscope.**—The best instrument available should be employed, and should be fitted with a good substage condenser, a 1.4 N.A. apochromatic 1/12-inch oil-immersion objective; and a $\times 10$ or $\times 12$ compensating eyepiece giving a total magnification of 1,000 diameters. The ideal source of light for critical microscopy is the low-voltage high-intensity electric light bulb, used in conjunction with a light-blue ground-glass filter and condensing lens. For technical details of optical equipment suitable for virus research see van Rooyen (1937).

Staining Reagents Required.—**Löffler's flagellar mordant**, which is made up as follows: 20% aqueous solution of tannic acid, 100 c.cm.; saturated solution of ferrous sulphate, 50 c.cm.; and saturated alcoholic solution of basic fuchsin, 20 c.cm. It should be allowed to stand for three days and then be filtered before use. **Carbol Fuchsin Stain.**—Two stock solutions are stored separately; they consist of (a) 0.3 g. of basic fuchsin in 10 c.cm. of ethyl alcohol, and (b) 5 g. of phenol dissolved in 95 c.cm. of distilled water. One part of solution *a* and nine parts of *b* are mixed together and filtered before use.

Collection of Specimens.—Six early lesions are selected, preferably fresh vesicles containing clear fluid, and these are opened with forceps. The base of fully formed papules can also be scraped, and when opening these one must try to avoid drawing blood. If the lesion is a vesicle the fluid is first absorbed with cotton-wool. The base of the exposed cavity is then firmly scraped with a sharp knife or the corner of a glass slide, and the material obtained is rubbed with a rotary motion on the surface of a glass slide. Three such smears can be made on each slide. The best results are obtained by scraping the earliest papular and vesicular lesions of smallpox; consequently pustules should be avoided, as these often contain artefacts.

Paschen's Staining Method.—Slides are placed upright in distilled water for from 2 to 15 minutes, according to thickness of the smear, and then allowed to dry in air. They are treated with ether, and then with alcohol for two minutes. The alcohol is poured off and the films allowed to dry. **Filtered mordant** is added, the films are heated very gently, and the mordant is allowed to act for three minutes. They are washed repeatedly and very thoroughly with running water for two minutes. Diluted and filtered carbol fuchsin stain is poured on and gentle heat is applied until the steam rises; the films are left for seven to ten minutes, and then washed with water. (If necessary any excessive deposition of stain is removed by a rapid application of a few drops of alcohol and by washing in water.) They are dried, blotted, and mounted in neutral Canada balsam.

Bad results are attributable to failure to wash off all traces of the mordant with water before application of carbol fuchsin, or to drying of the mordant or stain by overheating and precipitation of carbol fuchsin dye so as to leave a granular background. (Such films should be discarded.)

Essential Control Preparations

Before searching a stained slide from a suspected case of smallpox for elementary bodies it is imperative to familiarize oneself with the appearance of control slides—two negative and one positive. The former should consist of: (a) a slide showing a pure culture of *Staph. aureus* or *albus* stained by Paschen's method; (b) a good film showing the elementary bodies of varicella: these are not easy to demonstrate, and it may be necessary to make several scrapings before a characteristic film of varicella elementary bodies can be obtained from a case of chicken-pox. The positive control should be a film which is made from a typical case of variola stained by Paschen's technique and which shows "myriads" of elementary bodies.

Points to be Remembered when Searching Films

In interpreting the results of stained films one should never state that elementary bodies are present unless masses of them are found. Moreover, these should be of uniform shape and of regular size and be clearly stained a deep red, identical in appearance with the positive control. Pleomorphic granules, deposited stain and isolated single or scattered elementary bodies, however suggestive in appearance, should be ignored. To diagnose variola on the presence of scanty elementary bodies in a suspected film will inevitably lead to disastrous conclusions.

In the event of doubt one must discard that particular film and examine the next preparation; hence the reason why at least six smears should be made from every suspected case. In the average case of variola at least three of the slides will show numerous elementary bodies without much searching, and their appearance is so striking as to leave no room for hesitation.

If all the slides are doubtful or completely negative then that can be interpreted as strong presumptive evidence against the diagnosis being one of smallpox. In such circumstances the laboratory examinations should be repeated the next day. An attempt can also be made to isolate the virus by rabbit inoculation, but this procedure is both uncertain and slow.

The Elementary Bodies of Varicella, Variola, and Vaccinia

When viewed under the same optical conditions the elementary bodies of variola and vaccinia are identical in size but are larger than those of varicella. Certain other subtle differences can also be detected, such as avidity for carbol fuchsin dye and relative numbers in infected tissues.

The accurate measurement of stained microscopic objects of the dimensions of elementary bodies is a difficult task. Several technical methods have been evolved for the purpose, but none of them is perfect. One principle, advocated by Coles (1929), is Nelson's (1909) method of micrometric extinction performed with a dry high power objective fitted with a graduated iris diaphragm calibrated against an apertometer. Using such a device, van Rooyen and Rhodes (1940) estimated vaccinia virus to be 0.23μ in diameter. In the present studies the elementary bodies of variola and varicella have been measured. The former were found to vary from 0.3 to 0.24μ , and thus were of approximately the same size as vaccinia virus. We have also repeatedly noticed that the elementary bodies were not only easier to demonstrate during the papular eruption of smallpox but appeared to be larger than those demonstrated later in the same case, at the stage of pustulation.

Smears showing elementary bodies of varicella were also measured and compared with those of variola, and were found to range from 0.125 to 0.175μ in diameter. This difference can easily be appreciated by the naked eye, and was first noted by Paschen (1933), who referred to the essentially smaller size of the elementary bodies of varicella, "as well as their poor staining affinity, in the following paragraph:

"Vor 15 Jahren habe ich auf der Versammlung der Vorstände der Staatlichen Impfanstalten berichtet, dass ich in Ausstrichen von ganzfrischen Varizellen Bläschen E.K. gefunden hatte die wesentlich kleiner als die bei Variolavakzine beobachteten waren und sich schlechter färben liessen."

We have confirmed Paschen's findings and have appreciated that the difference in size between these two varieties of elementary bodies is great enough to permit it to be utilized as a laboratory diagnostic principle. Subsidiary points of distinction observed by ourselves are as follows:

In variola they appear in "myriads," whereas the elementary bodies of varicella are relatively scanty, are hard to detect (stained by Paschen's method), and usually leave some doubt in the microscopist's mind whether they are real or artefacts. Moreover, only a small proportion of films made from typical vesicles in a case of varicella show elementary bodies, whereas in variola the reverse is true. In the early smallpox rash elementary bodies occur intracellularly in masses and clumps as well as in the form of clusters of extruded bodies in the proximity of ruptured epithelial cells. Another common appearance is the tendency to form long rows of

bodies stretching from ruptured infected cells across the film. These appearances are rarely observed in varicella.

Varicella cannot be diagnosed by the film method, and one must resist the temptation to try to do so. The elementary bodies of varicella are exceedingly small, are too scanty, stain with difficulty, are often hard to find in films prepared from vesicles, and are readily confused with stain deposit.

The elementary bodies of variola and varicella can also be demonstrated under the dark field-illumination microscope. Unfortunately artefacts are impossible to identify by this method, and consequently oblique illumination of unstained material should be restricted to the examination of infected tissue cultures and other special purposes. This unreliable method must never be employed in routine smallpox diagnosis, and far less for attempting to differentiate between the elementary bodies of variola and varicella (See van Rooyen and Rhodes, 1940).

Vaccinia—Since the elementary bodies of vaccinia are morphologically indistinguishable from those of variola, the direct film method is not applicable to their differential diagnosis. However, this is not a serious obstacle, because the natural disease is confined to agricultural communities, and large outbreaks of cowpox are (at least in Egypt) uncommon. Even if an occasional case were wrongly labelled as smallpox no damage would result from any preventive measures which might have been instituted at the time. As for generalized vaccinia following vaccination, the history of inoculation, together with the patient's clinical state, should be enough to exclude variola.

Correct Wording of Laboratory Reports

It is imperative to adopt a uniform phraseology in recording results, so that both the bacteriologist and the clinician may serve the best interests of the patients. Two stereotyped examples of laboratory answers are recommended: (1) Positive for variola-vaccinia group. (2) Nothing found. If the case remains in doubt scrapings are repeated next day. Repeated negative results are suggestive of varicella—if the clinical diagnosis justifies it.

The Test in Varicella

Egypt

(a) During March-April, 1943, approximately 2,000 cases of chicken pox and 3 cases of smallpox occurred in an isolated group of West African troops during sea transit from the Belgian Congo to Egypt. The R.M.O. in charge, Capt. Loge Bain, R.A.M.C., informed us that the whole unit had been well vaccinated within a year and that, except for the three typical instances of smallpox mentioned, the cases were in every way characteristic of varicella. Skin scrapings were duly obtained from 60 typical cases of varicella by Major Hartston, R.A.M.C., D.A.D.H. to the camp, as well as from the 3 cases of variola. The results showed that whereas in the cases of smallpox elementary bodies were easily demonstrable, they were usually absent or difficult to find in the patients suffering from chicken pox.

(b) A group of 6 cases with a vesicular rash not due to smallpox were investigated in another military hospital. Four of these had chicken pox, one a vesicular rash of unknown cause unlike smallpox, and one a fine pemphigoid rash very closely resembling smallpox. The test was of great value in these cases. In this area smallpox is ten times as common as chicken pox, and a diagnosis of chicken pox had to be made with great caution in view of the prevalence of mild modified smallpox in vaccinated personnel. One of the cases of chicken pox had a prodromal scarlatiniform rash and three vesicular lesions on the sole of one foot, but these lesions were not hard and shotty as those of smallpox, and the subsequent fully developed distribution of the rash showed that the case was one of chicken pox. The absence of elementary bodies of smallpox in the scrapings was a help in diagnosis. Another case of chicken pox had an unusual number of lesions on the forearm, giving rise to doubt about the diagnosis, but the absence of elementary bodies in the scrapings helped the diagnosis, which was confirmed by the distribution of the rash when it was fully developed. The pemphigoid rash was at first thought to be smallpox, but repeated scrapings from

lesions failed to reveal the elementary bodies of smallpox, and the subsequent course of the rash showed that it was septic in nature. The negative laboratory finding was therefore of as much value in these cases as were the positive findings in some of the cases of small pox.

England

Although the cases affecting West African and Belgian Congo soldiers were unquestionable examples of adult varicella, studied before epidemic smallpox had begun in Egypt, to be doubly assured of our facts we decided to obtain a second series of control scrapings from genuine chicken-pox cases from independent reliable sources in Great Britain, where all chance of possible contact with variola could be excluded. This was done in June and July, 1944, when Great Britain was free from smallpox according to published information on infectious diseases and vital statistics. Major (Miss) Janet Niven, R.A.M.C., and Dr. E. M. Young provided us with skin scrapings from a total of 16 different typical cases of adult and juvenile chicken-pox contracted in Wiltshire and the S.E. London area. All these were carefully stained and examined under identical conditions with similar scrapings obtained from cases of variola acquired by British troops in Egypt. The results showed that the morphological picture presented in stained skin scrapings from cases of varicella, whether acquired in Egypt or England, were the same. Of a total of 88 well-prepared smears from 16 patients, typical exceedingly minute varicella elementary bodies were found in 12 smears from 4 cases. The latter were compared with typical Paschen bodies of early smallpox, and the difference was immediately recognized.

The Film Test in 80 Cases of Variola

Results in 50 Test Cases affecting British and Other Soldiers

Scrapings from lesions were taken in 50 out of 100 cases of smallpox seen by one of us (R. S. I.) at a military hospital in the Middle East. The cases chosen for the test were of all degrees of severity. Eight of the 50 were extremely mild throughout, while 10 were of the very severe type, of which seven were haemorrhagic. In 10 of the 50 cases the rash was in the papular stage at the time when scrapings were taken, in 39 the rash was vesicular, and in 1 it was in the early pustular stage. In 47 (94%) the scrapings showed the elementary bodies of smallpox, and in 3 (6%) they did not. Every positive laboratory diagnosis was subsequently confirmed clinically. In 21 of the 50 cases the diagnosis of smallpox was obvious at the time when the scrapings were made. Scrapings were taken from these cases, which were early ones in the series, in order to check the validity of the method. In 23 of the cases the diagnosis was not obvious at the time when the scrapings were taken, but became so later. Thus the laboratory diagnosis was made before the clinical diagnosis was possible. In 6 cases the clinical diagnosis was not clear when the scrapings were taken, and from the appearance of the rash did not become so later, but the laboratory result was confirmed by other means—notably by the history of close exposure to infection at the appropriate interval before the development of the disease. Three of these six cases figured in an interesting local outbreak in which the laboratory test was of real value in diagnosis.

A Jamaican was admitted with a very sparse vesicular rash of about 20 to 30 spots, none of them on the palms or soles, which had been preceded by three days of fever. He had scratched almost all the spots, but an attempt was made to obtain scrapings from the remaining one or two unscratched lesions. The scrapings did not show the elementary bodies of smallpox, and it was not possible to repeat them as there were no remaining lesions suitable for the test. No new lesions developed, and it was never possible to distinguish the rash from chicken-pox, but the three-day prodromal fever made the diagnosis of smallpox likely. He was kept in an observation tent separate from known cases of smallpox, vaccinated, and notified as having smallpox so that unit precautions could be instituted. Twelve days after his admission two more Jamaicans were admitted with a still more sparse rash, which had appeared 1 to 2 days after the onset of fever. Chicken-pox was diagnosed, but scrapings showed the elementary bodies of smallpox. Neither developed further lesions, and it was never possible to distinguish them from chicken-pox by their appearance. But two days later three others were admitted—natives of Jamaica and British Guiana—

all with a vesicular rash, two of them characteristic of mild smallpox, with lesions on palms and soles, and the other indistinguishable from chicken-pox. All had developed the rash on the same day as the fever. Scrapings were taken from one of these cases, and they showed the elementary bodies of smallpox. It was then found that all these six cases had come from the same hut in the same unit. Twelve days later three others were admitted from the same hut, all with obvious mild smallpox, and the scrapings from all three showed elementary bodies of the disease. One of these three had the classical three-day prodromal fever before the rash developed. All the 9 cases had been very recently "vaccinated," and the clinical diagnosis was difficult at first in all and impossible throughout in four. The laboratory test was here of great value in establishing the nature of the outbreak.

The test was of great service in the early diagnosis of many of our cases. In 22 of them the scrapings were taken on the first day of the rash, at a time when a clinical diagnosis was usually difficult or impossible, and all these scrapings showed the elementary bodies of smallpox. In 4 of these 22 cases the laboratory diagnosis was actually made on the first day of the disease, because the rash had developed on the same day as the fever. One of our early cases which developed the rash—not a prodromal one—on the same day as the fever while in this hospital presented great difficulties in diagnosis. This patient developed a very severe form of the disease, which was fatal, and the laboratory report was a great help in the diagnosis, which was subsequently obvious.

In many of the cases the rash was extremely sparse when the scrapings were taken, there being 12 to 24 lesions in all. In a Cingalese boy there were only 12 vesicles when the test was made, the rash having appeared on that day. In another case 12 to 15 papules were found on the back of a man who had had fever for three days. They were non-specific in character, but, by carefully opening the papules without drawing blood, scrapings were obtained which showed the elementary bodies of smallpox. It was not possible to make a clinical diagnosis in this case until 36 hours after the scrapings had been taken, and he was therefore kept in an observation-room until the diagnosis became clinically obvious.

In 3 of the 50 cases elementary bodies of the disease were not found in the scrapings. Only one series of scrapings was taken in each of these cases, and it is likely that if the series had been repeated a positive result would have been obtained. One was the Jamaican patient mentioned above in whom there was a scarcity of lesions suitable for the test. The other two were typical mild cases of smallpox.

Independent Observations in a Further 10 Selected Cases

At another military hospital the film method of diagnosis was put to a critical trial by Lieut.-Col. H. L. Wallace and Major R. W. Eason in 12 patients who had been admitted to the general wards of the unit, labelled pyrexia of unknown origin, and who subsequently developed a rash in hospital. Skin scrapings were made at the first signs of the appearance of the rash, usually on the second or third day of illness. Ten were reported as positive, and all ten cases subsequently proved to be typical smallpox. One patient had been admitted to hospital at the height of the typhus season, and the rash was strongly suggestive of epidemic typhus, but the diagnosis was changed to variola on the findings of the film test. The man later proved to be a case of haemorrhagic smallpox, and died. Another case was of particular interest. The illness was exceedingly mild, and the patient, who had been under treatment for another complaint, had fully recovered and, while waiting to be discharged as cured, was working as a voluntary helper in the wards distributing bedding and linen to other patients when it was noted that he had developed a few red spots on the arms and trunk. A film scraping proved to be positive, and seven days later the diagnosis became apparent. In the two remaining cases the film test was repeatedly negative; both ultimately proved to be septic skin conditions, and no secondary cases developed from them.

Results in 20 Civilian Cases of Late Smallpox

Twenty late fully developed severe cases of pustular semi-confluent smallpox affecting Egyptians were investigated. Film

were prepared from these subjects, duly stained and examined. The results showed that, although elementary bodies were present in considerable numbers, they are difficult to detect after pustulation and secondary infection has occurred. Prolonged immersion in distilled water is required to rid the film of excess serofibrinous pus, and the film tends to over-stain. Nevertheless even in late cases, by scraping the base of the pock, it is possible to obtain excellent stained preparations showing elementary bodies.

Discussion

To perform either the complement-fixation test or the variola-vaccinia flocculation test vesicular fluid or dried scabs are required, or the serum of patients 7 to 10 days after infection. In consequence their use is restricted to cases in the stage of pustulation or desquamation. Moreover, both tests demand a high standard of serological technique with proper controls, and about 24 hours must elapse before results can be read. Paul's test likewise suffers from the disadvantage of the time taken to obtain an answer. Moreover, our experiences with Paul's test in true smallpox have been disappointing, and it is not as easy to do as the literature indicates it to be. The slide method provides a quick and easy test for recognition of smallpox from the first day of the rash, when it is in the papular stage before vesiculation. A smear preparation can be made from a suspected case of smallpox, stained, examined, and a reply handed to the physician in half an hour. To assess the relative merits and percentage of experimental error in different laboratory tests would be unfair without comparative trials over a large series of cases. However, we believe that if all the laboratory diagnostic methods for variola were put to a rigid trial and judged according to their merits the slide technique would surpass the remainder in speed and accuracy.

Summary

We have confirmed Paschen's (1933) observation that the elementary bodies of variola are larger than those of varicella, and have utilized this finding to form the basis of a laboratory test for the identification of smallpox.

In Egypt, skin scrapings from 80 cases of smallpox ranging in severity from mild to fatal haemorrhagic variola were subjected to the film test for elementary bodies.

The laboratory and clinical findings corresponded in 77 cases (i.e., 96%). A negative result was returned in three cases of smallpox.

Variola elementary bodies were demonstrated with ease in the papular and vesicular stages of the illness, but after the onset of pustulation they tended to disappear.

In 32 cases of early smallpox the laboratory answer was positive on the first day of the rash, when it was very sparse and the clinical diagnosis was difficult or impossible to establish.

In no instance did a positive laboratory verdict disagree with the final clinical diagnosis of the case.

Control skin scrapings from 64 clinical cases of varicella occurring in Egypt, together with a further 16 cases of chickenpox contracted in England, have been studied under identical conditions and compared with similar material from 80 cases of variola in Egypt.

The film test is not applicable to the diagnosis of chickenpox, because the elementary bodies of varicella are too small, are too scanty, and show feeble affinity for Paschen's stain.

The principal conclusion reached is that the film method, when used with caution and discretion, can be of great value in the early recognition of variola, especially on the first day of the rash, when the clinical picture may so closely simulate chickenpox.

We have to thank Col. H. T. Findlay, D.D.P., G.H.Q., M.E.F., for his interest in our efforts and for the supply of material from cases of varicella from England. Also for the technical assistance given by Sgt. D. Danskin, R.A.M.C., and Pte. G. R. Pollak, A.T.S., who examined and reported on many specimens submitted from units at all hours of the day and night. For permission to publish

this article our thanks are due to Major-Gen. J. A. Dowse, Director of Medical Services, Middle East Forces, Col. W. B. Stevenson, and Col. L. S. C. Roche.

AIR EMBOLISM - AS A COMPLICATION OF VAGINAL DOUCHING IN PREGNANCY

BY

GILBERT FORBES, M.D., B.Sc., F.R.F.P.S., F.R.C.S.E.

Lecturer in Forensic Medicine at the University of Sheffield;
Police Surgeon to the City of Sheffield

The potential dangers of air embolism during surgical procedures are well known, and are being constantly emphasized by all those responsible for surgical teaching. Within recent years the importance of this subject has increased proportionately to the frequency with which intravenous resuscitation therapy is employed. According to Hamilton and Rothstein (1935) the first case was reported by Beauchene in 1818, and since then many other accounts of fatal accidents due to air embolism have been placed on record.

The Causes of Air Embolism

When any large vessel containing blood under less than atmospheric pressure is opened and cannot collapse owing to rigidity of its walls, partial severance, or external fixation, the entry of air is possible and the mechanism easily understood. This may happen during operations in the region of the great vessels of the neck, as a sequel to their traumatic severance, and through opening the dural sinuses during operations on or within the skull. A somewhat similar situation exists when air enters the uterine venous sinuses during or after delivery. This may happen in normal healthy women during labour when the sinuses are open after detachment of the placenta (Osborn and Dawson, 1938), or up to 11 days post partum where retained membranes, clot, or placental fragments have kept the sinuses open and the entry of air into the uterine cavity has been facilitated by the adoption of the knee-chest position (Gough, 1924; Quigley and Gáspár, 1936; Stroh and Olinger, 1938; Redfield and Bodine, 1939). In these circumstances the air is sucked into the open vessel. Criminal abortions are often attempted by the injection of fluid into the uterus. If the fluid passes the cervix its force detaches the membranes or placenta and air may be driven into the open uterine sinuses, as precautions are seldom taken to ensure that the syringe is completely filled with fluid before use (Gonzales, Vance, and Helsen, 1937; Gough, 1924; Hamilton, 1936).

The fact that even quite small veins may, if damaged, serve as a point of entry for air is perhaps not so widely known.

This is particularly liable to happen if the air is under pressure. This mechanism operates when air embolism occurs during antral lavage (Gording, 1920; McGovern, 1941); during the distension of the bladder or urethra with air (Mathé, 1929; Rettig, 1930; Jeck, 1933; Dible *et al.*, 1938), while testing the patency of the Fallopian tubes by insufflation (Moench, 1927; Mansfield and Dudits, 1934), during therapeutic vaginal insufflation (Latham Brown, 1943; Peirce, 1936; Partridge, 1943), and as a result of perineal insufflation for diagnostic purposes (Weyrauch, 1940). In these circumstances the vessels may be either diseased from inflammation or tumour growth, or damaged before or during the operation. Finally, the injection of air into the peritoneal cavity or the administration of fluids intravenously may result in air embolism.

When air embolism arises under the conditions outlined above the gas accumulates in the right side of the heart and the emboli lodge in the lungs, except in those exceptional cases in which a patent foramen ovale or interventricular septal defect exists, when a proportion of the air may reach the main circulation. Cerebral and coronary air embolism are common sequelae of penetrating wounds of, and operations on, the lungs, and of the induction of artificial pneumothorax in the treatment of pulmonary tuberculosis (Chase, 1934; Hamilton and Rothstein, 1935). Many authors suggest that a proportion of the cases previously regarded as fatalities due to pleural shock have in fact been unrecognized cases of air embolism.

The Mechanism of Death in Air Embolism

The effects depend on whether the pulmonary or systemic circulation is invaded. In the former case the air accumulates in the right auricle and ventricle, and emboli are impacted in the pulmonary arterioles. If the volume of air is large and it enters the circulation quickly death takes place rapidly. It is still apparently not settled whether death is due to mechanical interference with heart function, to blockage of the pulmonary artery by froth with arrest of the circulation in the lungs, or to multiple emboli choking the finer arterioles in the lungs. If the volume of air admitted is smaller or its entry slower and life is prolonged, the air blocking the pulmonary arterioles may be absorbed in part. The remainder may escape through the capillaries and veins, thus finding its way to the left side of the heart and into the systemic circulation, to produce cerebral and coronary infarction. In the ordinary case of pulmonary air embolism this is rare, and the experiments of Jung and Pierre (1935) confirm that opinion. The work of E. and A. Curtillet (1939) and of Chase (1934) tends to show that the actual obstruction occurs in the arterioles, and that while there impacted the air bubbles become smaller owing to absorption. After a time the bubble, now reduced in size, escapes into the capillaries and so to the veins. In the average case, however, life is not prolonged sufficiently for this to happen. When the systemic circulation is invaded from the vessels of the lung, either primarily or as a sequel to pulmonary air embolism, the mechanism of death and the symptoms are different. The air blocks the vessels of the brain, interfering with the nutrition of the vital centres, and/or it lodges in the coronary vessels, producing cardiac infarction.

The Volume of Air

There seems to be no measure of agreement as to the volume of air required to bring about a fatal issue. Hamilton and Rothstein (1935) assert that small amounts of air can be introduced into the venous system with impunity, while Mathé (1929) believes that small volumes cause only mild transitory symptoms, which resolve when the air is absorbed. These opinions seem reasonable when one considers the numerous occasions on which intravenous therapy is administered, often by comparatively inexperienced operators, and the relative rarity of fatal air embolism during such a procedure. It seems almost incredible that in nearly all cases the operation is carried out without some small leakage of air into the vein through faults in the transfusion apparatus or directly when the vein has been opened to insert a cannula. Dible *et al.* (1938) consider that in nearly all cases of recorded fatalities considerably more than 100 c.cm. of air was introduced in a short period of time. Coles, Richardson, and Hall (1937), applying to man the results they obtained in experiments on

dogs—which may perhaps not be justifiable—conclude that a minimum of 480 c.cm. of air is required as a lethal quantity. It is probably not possible to arrive at a definite figure. According to Simpson (1942) the total volume of air that can be tolerated depends on the person's general condition and on how quickly the air is admitted. He claims that sometimes even 10 to 15 c.cm. may be fatal. In Mathé's (1929) opinion marked differences in resistance to air embolism exist in different individuals and different species.

Case Report

History.—Recently a case occurred which in several respects was unusual and which points to a danger probably not generally recognized. A woman aged 34 who had had three previous pregnancies complained of feeling in poor health on June 30, 1944, but attributed her symptoms to the onset of menstruation. She usually had dysmenorrhoea severe enough to require two or three days in bed. She began to menstruate on July 1. Next day no fresh symptoms appeared till 9.50 p.m., when she collapsed on her way to bed and died a short time later. No further details were available at the time of the necropsy, and there was nothing to suggest what the cause of death might have been.

Necropsy.—The examination began at 3 p.m. on July 3—i.e., 17 hours after death—and putrefaction had not started. There was a blood-stained sanitary towel between the legs, but the external examination revealed nothing of significance. On opening the abdomen a retroverted gravid uterus was observed which was not impacted and could easily be lifted out of the pelvis. The peritoneal surface of the genito-urinary organs was uninjured. The bladder and urethra were healthy and free from injuries, and the ureters and kidneys were also healthy. The external genitals and vagina were free from abnormalities. The cervix was soft, and an erosion was seen round the external os. The cervical canal was open, but the cervix showed no sign of injury. On opening the uterus the placenta was found low on the right lateral wall, and its lower edge was detached to a depth of one inch. The membranes were separated to a depth of two and a half inches. The uterus contained a foetus of three months' gestation in intact membranes. In the wall of the uterus there were a few small subserous fibroids. The ovaries and tubes were healthy, and in the right ovary there was a large corpus luteum of pregnancy. The trachea contained some fine froth, and the pleural cavities were dry and normal in every respect. The lungs were very oedematous. The pericardium appeared normal. The right side of the heart was dilated, and on opening it the auricle and ventricle were found to be filled with frothy blood. The pulmonary artery contained identical material. The tricuspid valve was relatively incompetent. The foramen ovale was patent, but the opening was valvular. The left side of the heart was healthy, as were the coronary vessels and the myocardium. The alimentary system presented no significant abnormality. The meninges were normal, but there was some congestion of the brain. No haemorrhages were seen on the surface or in its substance.

Histologically the brain was free from abnormalities. Sections of the lungs showed numerous small areas of infarction with normal lung tissue intervening. In the infarcted areas there was intense congestion, with abundant oedema fluid in the alveoli. Some of the alveoli were filled, partly or entirely, with packed red cells.

Discussion

In the entire absence of any history to suggest it, the possibility of air embolism was not thought of before the necropsy, and consequently the special technique usually followed in such cases was not adopted. However, the findings indicate conclusively that this was the cause of death. In the light of this discovery the obvious suspicion was that this case was one of criminal abortion, and further inquiries were instituted. These revealed that this woman had not missed a menstrual period and on June 3, 4, and 5 she was medically attended for dysmenorrhoea. So far as can be ascertained neither her husband, relations, intimate female friends, nor her doctor knew that she was pregnant. There is definite evidence also that during one of her previous pregnancies she continued to menstruate for three months after the pregnancy began. From all the circumstances of the case there seems, therefore, to be some genuine doubt whether the deceased realized she was pregnant. She was accustomed to using a Higginson's enem syringe for vaginal douching and, though no definite evidence on this point was forthcoming, it seems likely that she douched immediately before retiring at 9.50 p.m. on July 2. The fatal douching which was responsible for the air embolism must have occurred shortly before her collapse, and the above seems reasonable hypothesis. It therefore appears fairly certain that

this death was accidental, the woman being in ignorance of her condition and police inquiries having failed to reveal the possibility of interference by any third party.

It is of course accepted that air embolism may occur when an attempt is made to inject air or fluid, or both, through the cervix with the object of producing an abortion. There are three cases on record in which therapeutic vaginal insufflation during pregnancy had resulted in death from air embolism. So far as can be ascertained, however, there is no previous report of an instance in which simple vaginal douching led to air embolism from detachment of the placenta.

This case is one of pure pulmonary air embolism. The finding of the patent foramen ovale at once raised the possibility that air would be found in the cerebral vessels also. Presumably the valvular nature of the very slight septal defect prevented this.

Summary

The causes of air embolism are reviewed and the mechanism of death due to this condition is discussed.

A case of accidental death from air embolism due to vaginal douching during pregnancy is recorded.

ACTIVE CONVALESCENCE OF HERNIAL REPAIRS

BY

DERRICK J. MARTIN, F.R.C.S.E.D.

During investigations into the causes of the high incidence of post-operative respiratory complications in Service cases it was shown that the incidence and intensity of symptoms were lessened in those cases specially liable by early movement and, in particular, by getting up out of bed. The type of case with the highest incidence was the group of hernial repairs and to a lesser extent appendicectomies. It was therefore determined to get all these men up the next day after operation, and the consent of the consulting surgeon of the Command was obtained to take a course of action contrary to the usual practice and contrary to the instructions later issued in the *Army Medical Bulletin*.

At the beginning of this investigation various operations were used—viz., Bassini, simple removal of sac, fascial graft, and finally the slide repair as described by Tanner (1942). As the series went on the operation of choice became the simple removal of sac, and the value of this decision was later emphasized by the survey given by Maj.-Gen. Max Page (1943) and others at the Royal Society of Medicine, which had not been published when this step was taken.

It has generally been agreed that the results of operations are not as satisfactory when a thorough investigation is made as is the impression of many surgeons who have not kept strict figures. Various critical reports have shown a recurrence rate between 0 and 20%, but among the most valuable published figures are those of St. Thomas's Hospital of 12% (1943).

The cases described have been an unselected series in men of military age. The great majority of them have been indirect inguinal herniae. Direct herniae have been operated upon only when there is evidence of a funicular sac coming down into the scrotum. Those with only a diffuse bulge have been advised against operation, as it is felt that the likelihood of strangulation is negligible. Nevertheless, some errors of diagnosis were made earlier in this series.

Many factors are involved in producing successful results, and in all probability no one factor is paramount. Much stress has been laid on the type of operation, but probably the truth is that no one type will meet all conditions and that a certain number of recurrences are the result of a faulty choice of operation.

There are several recognized factors of importance, of which some are the care of adequate haemostasis, strict aseptic technique, and the removal of the whole sac as far back as the "corn" which marks the position of the neck of the sac. I deprecate the use of gauze dissection as a means of separating the sac, though some have argued that good results follow the formation of a firm mass of inflammatory scar tissue. This, however, will certainly stretch under strain in a way normal tissue will not.

The great value of the Tanner slide operation where the inguinal ring is much enlarged is that the action of the arcuate fibres of the internal oblique is not interfered with. If their attachment to the conjoined tendon is slackened before suture their direction of pull remains normal. The hernial ring is closed against intra-abdominal pressure by the constriction of the arcuate fibres of the internal oblique, which, in contracting between its two attachments on Poupart's ligament and the conjoined tendon, flatten the arch, approximating the top of the arch to Poupart's ligament. It is essential that this muscular mechanism should be maintained in good activity. Therefore every opportunity must be taken, by free movements of the patients, to prevent adhesions forming between the internal and the external oblique. This is a matter of great importance, seeing that the likelihood of respiratory complications is so high. The strain placed on the inguinal canal by coughing is considerable, and it is apparent that anyone who could cough and vomit after operation certainly could sit in a chair without any increased risk and with greater comfort.

There is much difference of opinion in regard to the choice of suture material, and there are responsible advocates for the use of catgut or of more permanent sutures such as silk or linen thread. In this series I have used catgut throughout. Floss silk, so enthusiastically described by Maingot (1941), has not been employed at all, for I have had through my hands three cases of prolonged sepsis and sinus formation after the use of this material. Whether thread or catgut is chosen is probably a matter of no great importance so long as strict aseptic precautions are maintained. The post-operative dressing which has been used as a routine has been a thin layer of gauze stuck on healthy skin by mastisol. This has been done to avoid the inevitable moisture from sweating which is present when both elastoplast and bulky wool and bandage dressings are employed.

In the previous article (Martin *et al.*, 1943) we demonstrated that the choice of anaesthetic is a matter of little importance. I feel that the choice of an anaesthetist is of far greater moment. The only break with convention has been in the after-care. Active convalescence has been found to be of value in many conditions, and is practicable after herniotomies and appendicectomies when a muscle-splitting operation has been done. It has been found to accelerate recovery in bronchitis, pneumonia, and even cardiac, where functional activity, carefully graduated, enhances convalescence. The scope of this form of convalescence has proved to be far more practicable than we imagined a few years ago. Hospitals with enthusiastic rehabilitation departments have demonstrated the value of this form of treatment.

The routine of activity that these men are encouraged to accept is as follows:

On the first day after operation they get out of bed and walk a few steps to a low armchair. There they find they could sit in greater comfort than in bed and that the greater flexion of the hips helps to support the inguinal canal so that they can cough with less strain. They are allowed to sit up as long as they enjoy it. On

the next day they get up for two similar periods, and are told that they may walk to the lavatory if they want to. Not many avail themselves of this permission until the third day. From that time they are told that they may do anything that they can do, and are up the greater part of the day. Many play billiards, help with light ward duties, and walk about the grounds. They are given no specific exercises until the eighth day, when they are transferred to J.W.O. Convalescent Hospital, and begin graduated physical training with a sergeant instructor. An interesting side-light has come from the nursing staff, who are able to predict with a fair degree of accuracy which patients will have post-operative respiratory complications before operation has taken place. They have noted that the anxious, miserable, worried, unhappy patients who are afraid of hurting themselves will get respiratory complications, while the happy active type will succeed in avoiding them. This point has also been noted by Lucas (1944). If it should be thought that this regime is unduly rigorous the details of the recovery of my daughter, who had a simple herniotomy done, may be of interest. She followed this routine exactly, and had been told from the outset that she might do anything that she was able to do so long as it did not hurt. She got out of bed readily after 24 hours and was walking with confidence on the third day. She left hospital on the eighth day and travelled by train across Britain. From that time she was running about with her brothers and swimming from a beach one and a half miles from home. On the fourteenth day she turned six cartwheels in succession without any hesitation or thought of having recently had an operation. She went back to school without any complaint.

It is notoriously difficult to follow up Service cases, but a questionnaire has been sent out to 200 consecutive cases one year after operation, and reports have been received from 123. Among these there have been 8 recurrences—i.e., 6.5%. Among the remainder, information is given that many of them are serving over-seas, and it may be assumed that recurrences had not occurred among these men—at any rate before they sailed. Of the rest it is fair to assume that those who have a recurrence or are in any way disabled are more likely to answer questions than those who are quite well. Answers have been received from every battlefield where British troops are engaged. It would appear that a routine of early activity has not increased the recurrence rate.

Summary of Conclusions

1. The rate of recurrence of operations for inguinal hernia is higher than is often realized.
2. Early activity is not a factor leading to recurrence.

My thanks are due to the Director-General, E.M.S., for permission to publish this report.

Medical Memoranda

A Case of Locked Twins

The following case of locked twins appears to be unusual enough to warrant publication.

The patient, a secundipara aged 30, was seen by me several times during her pregnancy for routine antenatal examination. Her last normal menstrual period was from May 24 to 28, 1943, but she had a further period of vaginal bleeding from July 18 to 22 before she consulted me. This made it difficult to estimate the correct date for the expected confinement, but according to the size of the uterus it appeared that she was due to be confined about March 15—i.e., four weeks earlier than the actual labour. At my last consultation on the expected date, March 15, I informed the patient of the possibility of twins, owing to the large size of the abdomen and the difficulty of ascertaining the foetal position.

On April 17 at 3.30 a.m. the waters broke, and at 9.30 a.m. she started getting weak pains. Towards 7 p.m. the midwife made a rectal examination and thought she felt a foot presenting through the fully dilated cervix. I confirmed this finding with a further rectal examination at 7.15 p.m., and, to the right of the foot, felt what I took to be the half-breech. The patient was bearing down strongly with good five-minute pains. On abdominal examination no definite positions could be distinguished, as foetal parts could be felt everywhere, and in the left flank there was an ovoid mass which the midwife insisted was a head, but this was subsequently disproved. One foetal heart was heard in the right flank below the umbilicus, and another in the left flank at the level of the umbilicus. The difference in rate between the two was not enough to be significant. A diagnosis of twins was made, and I anticipated no

trouble. However, after about an hour the pains became weaker and less frequent, and there was no apparent progress. The patient showed signs of exhaustion, and at about 9 p.m. I decided to make a vaginal examination to find out what was holding up the progress of labour. I found a leg lying in the vagina, and could feel along the leg as far as the mid-thigh; but, to my surprise, lying to right of the leg was a head covered by a bag of membranes, and it was apparent that the head of the one twin and the half-breech of the other had entered the pelvis together and become locked. What I had taken for the buttock, on rectal examination, was now disclosed as the second head covered by a "bag of waters." The latter bag of membranes, incidentally, was formed by a fold of membrane being caught between the two twins, as we subsequently found only one placenta and chorion.

I sent for the aid of Dr. David Gamsu, and under deep ether anaesthesia he pushed the presenting head up out of the pelvis with his vaginal hand and held it up with his external hand. We thereupon pulled the half-breech of the other twin down and delivered this twin as a breech presentation. The infant was a female weighing 5 lb. 3 oz. and, like its sister, exhibited only slight blue asphyxia. Delivery was complete at about 10.30 p.m., a single placenta being born about 30 minutes after the second foetus, and the post-partum haemorrhage was normal in amount.

The puerperium was normal, and the patient got up on the 10th day, both babies doing very well. The case appears to be interesting because of (a) the comparative rarity of locked twins—the usual incidence given being 1 in 90,000 pregnancies; (b) the unusual method of locking.

I am indebted to Dr. D. Gamsu for the delivery of a difficult case and his help with these notes.

Johannesburg, S. Africa.

B. A. BRADLOW, M.B., B.Ch.

Quinsy, complicated by Deep Pharyngeal Thrombosis, Multiple Infarcts of the Lungs, and Myocarditis

Quinsy appears to be a fairly common complaint among Service personnel, but the complications in this case are unusual and should be of interest to readers. I am unable to find a similar case in the literature.

CASE RECORD

On July 15, 1943, a W.A.A.F. was admitted to hospital as a case of diphtheria. On the previous day she was admitted to the R.A.F. sick bay complaining of nausea, vomiting, sore throat, and general malaise; temperature 101°, pulse 84. The throat was inflamed and there was exudate on both tonsils. The temperature rose to 105° despite tepid sponging.

On admission the patient was ill and extremely pale. Examination showed: no oral fetor; right cervical adenitis and right tonsillar gland acutely tender; throat very inflamed, with gross oedema of right tonsil; right anterior faucial pillar pushed well forward; left tonsil much less involved; no membrane; stream of pus down post-pharyngeal wall coming from the right tonsil. The condition was characteristic of quinsy with good drainage. Swab H.S. and K.L.B. negative; Schick test negative. Course of sulph-anilamide started. Patient developed a swinging temperature, 102°, 104°, to 97°; trismus. Pulse septicaemic in type.

July 17.—Despite the fact that the throat condition improved, the patient became much worse and developed a fine tremor of the left leg.

July 19.—Pulse septicaemic—very full and bounding. Extremely toxic; rigors. Temperature 104°, but throat condition improved and oedema well reduced. Patient's manner very strange. Resistant to examination. Quinsy still draining. W.B.C., 9,884 per c.mm. On July 20 sulph-anilamide was stopped: total 14 g.

July 21.—Condition deteriorated. Rigors; profuse sweats; quinsy almost resolved, but temperature continued to swing—102°, 104°. Tremor of left leg continued. Liver palpable 1/2 in. below costa margin. W.B.C., 29,952. A radiograph of the chest revealed some fluffy densities in the right upper zone; the right diaphragm was raised and flat, and the illumination of the right lower zone was poor. Diagnosis: thrombosis of pharyngeal plexus involving the veins close to the internal jugular vein. Sulphapyridine begun.

July 23.—Blood culture positive for non-haemolytic streptococci. Patient complained of pain in right side of neck. A tender swelling felt in the region of the right jugular vein. W.B.C., 23,000.

July 26.—Large tender mass palpable along right jugular vein just above the level of the tonsillar gland. Palatal and right tonsillar oedema; stream of pus coming from the old quinsy opening. Next day a transfusion of one pint of fresh blood was given. Sulphapyridine was stopped on July 29: total 40 g.

July 30.—Acute left-sided pleurisy. Dyspnoea well marked; very slight haemoptysis. The neck condition improved—not tender; a hard knotty mass about 3/4 in. long palpable along the jugular chain. Quinsy dry. W.B.C., 14,040. A course of sulphadiazine started on Aug. 2.

Aug. 3.—Dry unproductive cough with pain in the left chest. Crepitations ++ left lower lobe. Throat tender; some pus again leaking from quinsy. X rays showed massive density in the right upper zone laterally and densities in the right middle and lower zones. The appearances were not like a tuberculous lesion and were compatible with infarcts.

Aug. 4.—Sulphadiazine stopped: total 25 g. Sulphapyridine started. E.C.G. showed gross myocarditis. Between Aug. 23 and 30 the patient had three attacks of pleural rub.

Sept. 27.—Mild laryngitis. Streaks of pus on post-pharyngeal all. Three days later the throat condition cleared up completely. Oct. '5.—Radiographs of chest showed previous densities completely cleared up. The right diaphragm was still raised and flat, ut apart from this there was nothing abnormal.

The patient was discharged on Oct. 15 for three months' rest. The myocarditis was still present, but had improved. The total amount of sulphonamides given was 103 g. over a period of 26 days. The only toxic symptom was vomiting. These drugs were discontinued when the white count fell to 12,000.

COMMENT

In this case of quinsy, venous thrombosis resulted in suppuration in the deep pharyngeal plexus, which eventually drained back into the pharynx through the original thrombosed vessel. This was demonstrated by the fact that light pressure produced green pus via the superior tonsillar fossa. Further complications resulted in extensive relatively sterile thrombosis throughout almost the whole of the cervical portions of the internal jugular vein.

It is suggested that the rigors resulted from almost sterile pieces of clot and that the ensuing metastases produced sterile pulmonary infarcts.

My thanks are due to Dr. George Hurrell, medical superintendent, City Hospital for Infectious Diseases, Newcastle-upon-Tyne, for interpretation of the films. I am indebted to Dr. J. A. Charles, medical officer of health, Newcastle-upon-Tyne, for permission to publish this case.

Purpura Fulminans

The following account of a case of purpura fulminans is thought to be of interest because of the rarity of the condition.

CASE REPORT

The patient, a girl aged 6½, was admitted in a stuporous condition on June 25, 1944, with a diagnosis of acute purpura. Two days previously she had developed purpuric spots, but had felt perfectly well, her only complaint being a slight headache on the night before admission. She had had no recent illness. On the morning of admission her mother had suddenly found her unconscious.

On examination the patient was very restless and almost unconscious. The temperature per rectum was subnormal and the pulse was raised only during bouts of particular restlessness. There were large symmetrical purpuric ecchymoses on the arms and legs and a few on the trunk. A very few minute spots were present in the buccal cavity, which was examined with difficulty owing to a tightly clenched jaw. The pupils were then equal and the retinae showed gross haemorrhages, especially on the left side. There was an internal strabismus. Nothing abnormal was found in the chest, but the heart gave a haemic murmur. The abdominal wall was collapsed and there was guarding in all quarters, but no rigidity. The child resisted abdominal palpation, especially over the left upper quadrant. Nothing abnormal was found in the central or peripheral nervous system except a dorsiflexed plantar response. There was no neck rigidity. Lumbar puncture produced a heavily blood-stained fluid at negligible pressure, and in view of this it was decided that blood transfusion would be of no avail. The bleeding time was 8 minutes and the clotting time was normal. The capillary fragility test was positive.

The patient's condition deteriorated throughout the day and finally a generalized spasticity set in. All reflexes were very brisk, though at no time were the abdominal reflexes present. The left pupil was dilated and Cheyne-Stokes breathing began, with occasional laryngeal spasm. The temperature gradually rose to 103° just before death. The pulse was weak and very irregular, and the patient vomited once or twice, producing mucus with a few streaks of blood. She became incontinent of urine. Nephenthe, 5 minims, was given to control restlessness. At 4.15 the next morning she died.

Post-mortem Examination.—The brain seemed large for a child of her size, but it was not congested or oedematous. The ventricles were filled with blood and clot, which had burst through the brain substance in the region of the posterior horn of the left lateral ventricle. The meninges were normal. The heart was normal. The right lung was healthy, but the left was collapsed and engorged with blood. There was free blood in the left thorax. The stomach showed a patch of submucous haemorrhages, through which perforation had occurred. This was considered to be due to post-mortem digestion. The gut revealed a few haemorrhages, and one or two were present in the bladder mucosa. There was slight congestion in the liver and spleen, but apart from these organs were normal. The kidneys, adrenals, and bone marrow appeared normal. There were no joint effusions. Microscopic examination of blood and cerebrospinal fluid showed one or two lymphocytes per c.c.m. in the latter, but no other abnormalities. Death was due to spontaneous cerebral haemorrhage.

I should be grateful to glean any information from others with experience of this condition.

C. R. OYLER, M.R.C.S., L.R.C.P.,
House Physician, Worthing Hospital.

Reviews

LYMPH NODE METASTASES

Lymph Node Metastases. Incidence and Surgical Treatment in Neoplastic Disease. By G. W. Taylor, M.D., F.A.C.S., and Ira Theodore Nathanson, M.S., M.D. With foreword by S. Warren, M.D. (Pp. 498; illustrated. 42s.). London: Oxford University Press.

Metastasis to neighbouring lymph nodes is such a fundamental feature of most forms of malignant disease that one may perhaps question the wisdom of writing a book which concerns itself exclusively with the secondary lymphatic involvement divorced from the primary lesion. The primary principle in the surgical treatment of malignant disease that the growth itself, the secondary (usually lymphatic) extensions, and the intervening tissues should be removed *en masse* whenever possible still remains unchallenged. In situations where this is technically impossible the treatment of the glandular involvement has to be accomplished by a separate operative approach. Here there may be some justification for considering the glandular problem as an entity in isolation from the disease as a whole, though even so we feel that anything which tends to divide the conception of a single disease process into two compartments must be fundamentally unsound.

This criticism of the scope of *Lymph Node Metastases* by Taylor and Nathanson of the Harvard Medical School must of course not be regarded as applying to the actual matter or presentation of the subject, for which we have nothing but praise. A large amount of information has been collected in the book which would otherwise need prolonged search through the literature. Statistical tables compiled from studies of large numbers of cases are numerous and valuable, especially as they include some rather unusual aspects, such as the size of the lymph nodes in relation to metastases, and so on. The uncertainty of palpation as a guide to lymph node involvement is clearly brought out, as is the relation of pathological grading to the incidence of metastasis.

The book is divided into three parts, the first of which deals with general considerations, and gives a review of the normal lymphatic anatomy. Part II is concerned with lymph node metastasis on a regional basis, and Part III with certain of the commoner operative techniques. There are some sixty illustrations of anatomical and surgical details. A valuable volume for the surgeon's reference library.

A BOOK ON ANAESTHESIA

Practical Anaesthetics for Students, Hospital Residents and Practitioners. By J. Ross MacKenzie, M.D., D.A. (Pp. 130; illustrated. 10s. 6d.) London: Baillière, Tindall and Cox, 1944.

According to the preface this book is intended to form a foundation on which medical students, hospital residents, and occasional anaesthetists can build a "practice of anaesthesia." Yet in this book of 130 pages and with this title such readers will find a disproportionately large amount of space devoted to splanchnic anaesthesia, helium therapy, and anaesthesia for thoracic surgery—subjects of little interest to any but the experienced anaesthetist. The novice will search hard for detailed guidance on everyday practice, and it avails him little to find a description of unilateral anaesthesia for pneumonectomy, caudal anaesthesia for childbirth, and splanchnic anaesthesia by the abdominal approach. Those who want to know practical details of how to use the Boyle machine, or pass an endotracheal tube, or give a spinal anaesthetic, will be disappointed at the sketchy descriptions. One searches in vain for answers to questions which casualty anaesthetists (often junior M.O.s) ask so frequently, such as how to deal with a man with a bleeding wound in the mouth or a straightforward sucking wound in the chest. Here and there the author touches on physiological or physical points, but some of his statements are open to question. He says, for example, that the concentration of anaesthetic required for maintenance varies with the weight of the patient; that the dials of a McKesson machine measure the volume of gases flowing; that the Oxford vaporizer delivers warm ether; and that the main function of the expiratory valve of "a Boyle"

is to control rebreathing. Dr. Ayre will surely be surprised to learn that an endotracheal tube which is too small for efficient respiration becomes satisfactory when his T-piece is affixed.

It seems that the author forgot the title when he set pen to paper. Before the next edition he must make up his mind whether he really wants to guide the novice or whether the D.A. candidate is the reader he has in view. If the former, then the book must be rewritten; if the latter, it must be factually correct.

SIDELIGHTS ON WAR MEDICINE

Clinics. Volume II. February, 1944, No. 5. Edited by George Morris Piersol, M.D. (Pp. 266. Six volumes a year commencing June of each year. One volume every two months. £4 10s. per year.) London and Philadelphia: J. B. Lippincott Company.

Several interesting discussions are recorded in this volume, which is devoted to war medicine. The subjects are chemotherapy, venereal disease, fatigue, fractures, plastic and reconstructive surgery, war wounds and burns, and gastro-intestinal disorders. If there is nothing startlingly new brought forward in the discussions it is interesting to read the views of men actively engaged in dealing with the problems in the various theatres of war which are now spread over the whole world. With the rapid development of practice some of the questions raised—for example, those relating to the very early use of penicillin—seem almost out of date already; and the most valuable part of the discussion deals with the experience of more or less well-established methods not all of which have stood up to the test of extended trial. Unfortunately a large part of the section on fatigue, especially relating to desert warfare, has had to be cut by the censor; but the remainder, dealing with the nutritional value of American field rations and the advantages of the physical training of operational flying personnel, is highly interesting. The gastro-intestinal section deals with the dysenteries, epidemic jaundice, and peptic ulcers in relation to the neuroses.

On the whole the American experiences seem to have been very much on a par with those of the British Medical Services and will be of interest to everyone concerned with war medicine, which will obviously not end with the cessation of hostilities. Six original contributions are included in the volume: on diagnostic cardio-roentgenography in Army examinees, on a walking cast, on burns, on the management of purpura (a useful review of the subject), on the effect of shock upon intramuscular pressures, and on ochronosis.

Notes on Books

Handbook of the R.N. Sick-Berth Staff (H.M. Stationery Office; 7s. 6d.) is a guide book for the sick-berth attendant both when training and after he has qualified. It has been evolved from the earlier *Manual of Instruction* (1930) and in some respects is more formative. For one thing it contains more padding, some of which is, however, quite attractive—e.g., a brief history of the sick-berth staff and a page on "the nursing code," which may be said to propound the golden rule from the aspect of the sick-bay man. In other respects, however, it is less comprehensive. The previous manual of instruction contained matter which is omitted from the handbook and now found in another volume, *First Aid in the Royal Navy* (noticed in these columns in 1943). This separation of what the sick-bay man should know into two volumes has given rise to duplication; bandaging, for example, is dealt with in both books. The methods of performing artificial respiration are not mentioned in the handbook, and he is referred for these to the first-aid book, but the treatment of fractured clavicle or fractured ribs, for example, is again dealt with in both books. While there may be something said for a nursing manual apart from a first-aid book, this division and elaboration has its disadvantages in loading the potential male nurse with two volumes instead of one and making his task appear more difficult merely by the amount of the reading matter. Both books, however, are admirable so far as each goes, though classification is not always very happy—e.g., fractures of the skull appear under orthopaedic surgery. The section on anatomy and physiology is worthy of special note as an admirable exposition to the uninitiated. The book is clear, concise, easy to read, and well bound, having in these respects a distinct advantage over its precursor, the manual of 1930.

Mr. McNEIL LOVE has produced a second edition of his book on *Minor Surgery* (H. K. Lewis; 15s.). In the preface (there is only the one for the new edition) he disarms criticism as to what constitutes minor and what major surgery, but it will be generally agreed that at least the field of so-called minor surgery is well covered in this attractive little handbook. Special chapters are contributed on minor surgical operations, genito-urinary surgery, and fractures and dislocations, by Messrs. R. E. Norrish and A. W. Bone, A. W. Badenoch, and F. P. Fitzgerald respectively, while the chapter on anaesthetics previously written by Donald Blatchley has been revised by H. Woodfield-Davies. Revision has been thorough, and the book can be recommended as a sound guide to residents and others who are called upon to practise minor surgical procedures.

The literature on medical mycology is widely scattered and often difficult to consult. For twenty years and more the *Review of Applied Mycology* has abstracted papers mainly on the systematic aspect, while the *Tropical Diseases Bulletin* and the *Bulletin of Hygiene* have reviewed selected papers from the medical point of view. An *Annotated Bibliography of Medical Mycology, 1943*, issued by the Imperial Mycological Institute, Kew, Surrey (price 5s. post free) lists all papers on the subject which were either published or noted by abstracting journals in 1943. This first experimental issue is edited by Dr. S. P. Wiltshire, Director of the Institute, in collaboration with Dr. Charles Wilcocks and Mr. J. T. Duncan, F.R.C.S.

Preparations and Appliances

MODIFIED SOUTHEY'S TUBE

Dr. PROTHEROE SMITH writes from Redditch:

I have found this modification of a Southey's tube of practical value when tapping oedema of legs resistant to other forms of treatment. It consists of a 17 B.W.G. short-pointed stainless-steel hypodermic needle with a rather long mount and two oval

lateral apertures in the 1-inch-long shaft. The needle, inserted in the rubber drainage tube and then sterilized, can be introduced sucutaneously without handling. No trocar is necessary and so no hole is made in the rubber tube and no leakage or air-locks occur. Drainage is quick. A piece of strapping across the junction keeps the needle in place parallel to the skin and harmless to the deeper tissues.

These needles have been made for me and can be obtained from Philip Harris, Ltd., of Birmingham.

ADJUSTABLE INSULIN SYRINGE

Dr. C. T. ANDREWS, F.R.C.P., honorary physician to the Royal Cornwall Infirmary, Truro, writes:

The accompanying illustration shows an insulin syringe which has been made for me by Messrs. Down Bros. It is intended chiefly for diabetics on a single or two equal doses of insulin daily and who are liable to make mistakes in the measurement of their dose—for example, those with failing vision, early

cerebrovascular degeneration, and senile patients who find it impossible to arrange for someone else to give them their injection of insulin.

The illustration explains itself. The stop on the piston is adjustable to 5-unit intervals for ordinary strength insulin and can be easily adjusted by the doctor. When the case is balanced and the dose of insulin determined the patient is then handed the syringe suitably adjusted and instructed to fill it for each dose.

"OUR NAVAL FORCES HAVE BEEN IN ACTION"

In the heat of the engagement the 'Monoject' Ampoule Syringe proves its worth. By its means casualties are quickly and efficiently given relief from pain. It gives medical personnel a convenient means of administering an accurate dose of morphine to the injured during action. Present output is absorbed by orders of high priority, but when peace comes again the 'Monoject' Ampoule Syringe will be available to industrial and public utility undertakings and in civil medical practice.

The most potent synthetic oestrogen

● Dienoestrol is the most potent and least toxic of the synthetic oestrogens.

The nausea and sickness commonly experienced with stilboestrol are conspicuously absent with dienoestrol. This is of particular importance in the treatment of carcinoma of the prostate.

It is completely effective by mouth; the indications for its use are all those conditions requiring oestrogenic therapy.

It is effective in doses of about one third to one quarter of those used in stilboestrol therapy, and is available in tablets of 0.1 and 0.3 mg. A 5 mg. tablet is available on application, for special use in prostatic carcinoma.

PRODUCT OF THE
GLAXO LABORATORIES

DIENOESTROL Glaxo

Tablets of 0.1 mg. in bottles of 25, 100 and *1,000
Tablets of 0.3 mg. in bottles of 25, 100 and *1,000
*Dispensing size only.

PHENIODOL B.D.H.

A Cholecystographic Agent for Oral Use

Pheniodol, when given orally, is concentrated in the gall-bladder as effectively as is iodophthalein (T.I.P.) when given intravenously. A most convenient method of administering Pheniodol is in the form of Pheniodol Meal B.D.H., a specially-prepared powder readily miscible with water to form a smooth suspension which is easily taken by the patient.

By the use of Pheniodol Meal B.D.H. the incidence of nausea, vomiting and diarrhoea is reduced to a minimum.

Details of dosage and other relevant information will be gladly supplied on request.

HEPARIN-BOOTS

ANTICOAGULANT

Clinical results have fully confirmed the value of Heparin as a potent, non-toxic anti-coagulant in the prevention of thrombosis and it is specifically indicated in operations on blood vessels, or if suture repair or graft of blood vessel is necessary. The only contra-indication is when there is active bleeding from an open vessel.

Recently the addition of Heparin to intravenous infusions has been recommended to prevent thrombosis in the recipient's vein. Over fifty cases received infusions of blood and solutions of crystalloids containing the equivalent of one Toronto Unit of Heparin per c.c. and there was no thrombosis and no bruising or hæmorrhage in operation cases. (*Brit med. J.*, 1944, 2, 308)

DRUGS AND THE DOCTOR

One of the most noticeable hiatuses in the White Paper is the failure to consider the bearing of a National Health Service on the supply of drugs and apparatus. It is true that it suggests that pharmacy may be represented on the Central Health Services Council and that the Council may appoint small groups or subcommittees for special purposes. It also indicates that the existing system under National Health Insurance, under which panels of chemists are formed in each area, is likely to continue. Nevertheless, the White Paper does not consider the general problems that will arise if medical care is provided free by the State but at the same time the supply of drugs is left to private enterprise. It is a little difficult to see how doctors are "to encourage a new attitude to health" if the patent medicine industry continues to spend £3 million a year on advertisements suggesting to people that they are ill and that they can only be cured by proprietary remedies.¹ As a result of this campaign, apparently, three out of four people in this country are taking drugs without medical advice and in many cases to the detriment of their health.² The use of proprietary remedies has increased since the introduction of National Health Insurance, and sales are much more closely correlated with factors such as the level of wages, the expansion of the popular press, and the development of mass advertising, than with the standard of medical care. The proprietary medicine industry employs a capital estimated at more than £100 million and the annual turnover is thought to reach the figure of £20 million.³ By and large its effects on personal and social health are harmful, but no Government has ever had the strength or courage to control it. The Pharmacy and Medicines Act, 1941, was merely a cartel agreement between the pharmaceutical profession and the proprietary medicine industry, which divided the retail market for drugs. It was better than many cartel agreements in so far as it was signed publicly in Parliament and not behind closed doors. The net result, however, was that proprietary remedies can now be sold without licence or duty over the counter of any shop in the country.

A second problem that arises is whether a National Health Service is compatible with the advertisement of pharmacopoeial drugs such as soluble barbitone or sulphanilamide under proprietary names. It is true that under the Pharmacy and Medicines Act such drugs cannot be sold by retail unless the label also bears the B.P. or B.P.C. description, and that a medical prescription is required for their supply to the public if they come

within the Poisons Rules, but there is nothing to prevent concentrating publicity on the brand name. As a result of this practice sulphanilamide was being offered in this country under fifty-odd names at the last time of recording. Most of the firms engaged in this trade were buying sulphanilamide from a common source and merely labelling and packing it independently. The object was to make a profit, and not to supply a consumer need, for when a drug is sold under a proprietary name it costs on the average three times as much as when sold under the official name. A third problem arises out of the change in prescribing habits which has occurred during the war. A generation of doctors has grown up which is completely unfamiliar with many of the galenic preparations such as gentian, ipecacuanha, and the vegetable diuretics. Quinine has been banned except for malaria, and even in malaria it has been declared inferior to mepacrine (atebrin) in a recent official American pronouncement.⁴ Bismuth salts have been forbidden here for dyspepsia and replaced by magnesium trisilicate and aluminium hydroxide. Sulphonamides and penicillin have ousted other antiseptics and chemotherapeutic agents in local, general, and urinary infections. During the war the Therapeutic Requirements Committee of the Medical Research Council has dealt out rough justice in this field, and permission to import or to manufacture has largely depended on the assessment of drugs in M.R.C. War Memorandum No. 3. "Economy in Drugs in Wartime" What is to happen when controls are relaxed after the war? No medical service is likely to be a success unless it leaves the individual practitioner considerable freedom in prescribing. Is the doctor to become the unsuspecting victim of pressure groups interested in restoring the sales of iodine, bismuth, quinine, or borax? Is his post-box to be crammed with expensive advertising matter, and will he need to set aside a whole morning a week when he will be at home to the travellers? Or is the supply of drugs to depend on a judicial appraisalment of the best interests of the consumer as well as the producer?

The difficulty is that no one has a vested interest in sane pharmacotherapeutics, and therefore active steps must be taken by the profession or the community to redress the balance. The individual doctor or patient must be supplied with unbiased information. The Americans manage these things better than we do, and a recent account of the Council on Pharmacy and Chemistry of the American Medical Association deserves serious study in this country.⁵ The Council has no legal powers, but most readers will agree with the claim that no single body in modern times has brought about so much change in the practice of therapeutics. The Council derives its influence largely from the important group of medical journals published by the American Medical Association, whose pages are closed to advertisements or names of preparations which are not approved by the Council. Its success has been such that it has become a model for the Council on Physical Therapy, the Council on Foods and Nutrition, and the Council on Dental Therapeutics.

¹ Thompson, D. *Voice of Civilisation*, London, 1943.² Davies, J. N. P., *British Medical Journal*, 1944, 2, 87.³ Chapman, H. E., *The Law Relating to the Marketing and Sale of Medicines*, Bedford, 1942.⁴ Report by Board for the Co-ordination of Malarial Studies, National Research Council, *J. Amer. med. Ass.*, 1944, 125, 977.⁵ Smith, A. E., *Ibid.*, 1944, 124, 433.

It consists of 17 members, chiefly professors of medicine and pharmacology in the American medical schools, who work without remuneration but with a whole-time medical secretary. The Council does not initiate clinical trials, and as a general rule the manufacturer must submit the evidence for therapeutic or other claims, which is then reviewed by the members of the Council, together with advertising material and other pertinent data. All the Council's actions, whether of acceptance, rejection, or omission, are published in the *Journal of the American Medical Association*, and later in the book *New and Non-official Remedies* or in the annual reprints of the reports of the Council. The Council's work has been of immense educative value to the members of the American Medical Association, for, however keen an observer the individual clinician may be, he cannot research on all the diseases all the time. It has overcome the kind of difficulty which occurs when new and potentially dangerous drugs, such as thiouracil, are introduced to the profession. We agree with a recent letter in our own columns to the effect that once these drugs are put on the market there can be no arbitrary selection of those doctors who use them.⁶ At the same time there is need for a mechanism for supplying information about them and for seeing that they are properly labelled. It is above all in the practice of correct nomenclature that the Council on Pharmacy and Chemistry has done most good, and it must be confessed that the advertising pages of medical journals and the demonstration stands at medical exhibitions in Great Britain compare unfavourably with their American counterparts.

Another step which might be taken to redress the balance against tendentious advertising is to improve the official teaching of pharmacology. In most medical schools, in the words of the Goodenough Committee, inadequate staffing provision has been made for the proper teaching of pharmacology. In improving this staffing it must be remembered that continuous postgraduate education is necessary in a subject which changes so rapidly as therapeutics. The universities must strengthen their pharmacology departments both with a view to research in a field here we have hitherto lagged behind the Germans and Americans, and with a view to what might be called the adult education of the profession. Few papers are so well received by a medical society as a good presentation of recent advances in therapeutics, and university pharmacologists should be provided with the time and the encouragement for frequent lectures of this kind.

PARTIALLY SIGHTED CHILDREN

It is now accepted as axiomatic that special provision has to be made for the care and education of "problem children." Schools for deaf-mutes and blind children were evolved during the last century, but such schools only touched the fringe of a much wider problem. No provision was made for the handicapped as distinct from the grossly crippled child. In these days of child guidance clinics it is difficult to visualize an educational system without special provision for children suffering

from defects which prevent them from benefiting fully from the ordinary school curriculum. Yet that was substantially the position at the beginning of the century, as is well shown by the history of the educational service in London. In 1907 Mr. Bishop Harman recorded at the Second International Congress of School Hygiene that his investigation in schools for blind children in London had shown that many were not blind but had been placed in these schools for high myopia. With the active support of the then Medical Officer (Education), the late Dr. James Kerr, who died three years ago, and of Miss Nettie Adler, a member of the Education Committee of the London County Council, special schools were established for these myopic children. These myope schools aimed not only at the education of the partially sighted child—as distinct from the blind child—but also at preventing the further development of myopia from misuse of the eyes. It is questionable how far this second objective is valid, but there can be no doubt about the validity of the first aim. In fact the London myope schools have since become designated as schools for partially sighted children; names like "preservation of sight classes" and "sight-saving classes" are falling into disuse.

While the pioneer work was being done in London Edmond Redslob of Strasbourg was responsible for similar developments on the Continent, and the movement rapidly spread to the United States. Mrs. Winifred Hathaway has been associated with American developments from their inception, and in her *Education and Health of the Partially Seeing Child*¹ she gives a balanced survey of the whole problem as seen by an educationist. Even now it is a formidable problem both in dimension and in its wealth of conflicting tendencies. She finds that in the United States there are still some 50,000 children who require special educational provision because of defective sight, and this in spite of the fact that there are some 630 special classes in 31 States. Early in the history of this movement two types of special classes appeared. In some places the partially sighted children were segregated so that full attention could be given to their special needs. Elsewhere such children were taught as much as possible in ordinary classes so that they should not lose the advantage of mixing with more normal children and participate in their activities. The first course made the organization of special facilities easier, but the second course is more in keeping with present-day tendencies to study the personality and problems of the child. Mrs. Hathaway's treatise covers fully both these aspects. The type of classroom, the equipment, the lighting, the curriculum—in short what may be called the mechanical aspects—are fully discussed, even to the inclusion of dictaphones and fluorescent lighting. All this is competently done, but what is of special interest to the ophthalmologist is the clear statement of the point of view of the educationist. If the school for the partially sighted child is not to function as a sort of educational waste-paper basket, Mrs. Hathaway's stress on the potentialities of the handicapped child and his need for sympathetic and individual handling will have to be heeded. This is a timely plea, for not to overdrive a

⁶ See, e.g., *Dr. Kerr's Medical Journal*, 1944, 2, 92.

¹ Published for the National Society for the Prevention of Blindness by Columbia University Press (\$2.50); London: Oxford University Press (17s).

handicapped child is hardly synonymous with a charter of rights for such children.

This finely conceived and well-written treatise leaves one conscious of a gap in ophthalmic literature. An authoritative account of the technical requirements and potentialities of the school for the partially sighted as seen by the ophthalmologist has still to come. Perhaps Mr. Bishop Harman might be persuaded to produce the necessary complementary volume to Mrs. Hathaway's study.

OVULATION AND FERTILIZATION

Ovulation in woman usually occurs about 14 ± 1 days before the onset of the ensuing menstrual period. Although it is a spontaneous process, brought about by a hormonal stimulus from the pituitary, its timing is probably subject to considerable variations, and on occasion ovulation may apparently be precipitated by coitus and other forms of local stimulation—the usual mechanism in such animals as the cat and rabbit. In assessing the time of ovulation no fewer than fifteen methods, with major differences in principle, have been employed. When we last commented on this subject¹ methods based on changes in electric potential and the excretion levels of various hormones were in vogue. Since then there has been a return to methods involving careful macroscopic and microscopical study of the ovary, the ova themselves, and the uterus. Recovery of ova by reverse flushing of Fallopian tubes, employed in animals by Allen and Corner some twenty years ago, has been attempted in the human being, and altogether ten free human ova have now been found, studied, and reported on in detail. The latest report on work of this kind comes from W. J. Hamilton, Josephine Barnes, and Gladys H. Dodds,² who describe, with beautiful illustrations, two ova, one of which had been recently fertilized. The recovery of ova from the tube has not only in every case so far confirmed the accepted view as to the time of ovulation but has provided information on associated phenomena. Thus it is confirmed that the ovum does not survive longer than 24 hours after ovulation unless it is fertilized. Again, there have long been differences of opinion as to whether maturation of the oocyte occurs before or after it leaves the ovary. Rock and Hertig³ report the finding of two, out of several hundred ova removed from ovaries, undergoing the first maturation division. Hamilton and others² now demonstrate one of their tubal ova at the stage of the second maturation spindle. In fact, of the ten tubal ova so far described this process has been found in three. It would appear, therefore, that the first division occurs while the ovum is still in the ovary, and the second when it is in the tube. But it is undecided whether fertilization is necessary before it undergoes the second maturation division.

Coincident with the study of tubal ova there has been a renewed search for early human embryos in the uterus. Whereas in the past the discovery of such specimens as the Bryce Teacher ovum was accidental and rare, the present-day search has become systematic and deliberate, operations for pathological conditions of the genitalia being timed in relation to ovulation and possible conception. And so Rock and Hertig,³ working in association with the Department of Embryology in the Carnegie Institution of Washington, were able in 1942 to describe 12 human embryos, varying in age from $7\frac{1}{2}$ to $16\frac{1}{2}$ days. Moreover, many single specimens have been reported in recent years,

and Hamilton and others,² along with their two tubal ova, describe a uterine pregnancy of 10–11 days' development. The study of such early embryos confirms previously held beliefs based on the changes seen in animal ova, and adds to our knowledge concerning implantation and early development. The time taken for the fertilized ovum to reach the uterus has been generally regarded as being about 7 days. Rock and Hertig³ now conclude that the time is variable and may be from 5 to 8 days. The occurrence of "implantation haemorrhage," long recognized by the clinician, has been seen in microscopical sections. Moreover, Studdiford⁴ found haemorrhagic degeneration in the decidua capsularis in a $26\frac{1}{2}$ -day ovum—a process which probably accounts for the haemorrhage sometimes seen in the early weeks of pregnancy, and also possibly explains some cases of early abortion.

It is possible to mention here only a few aspects of the fascinating story of ovum ripening, ovulation, maturation, fertilization, and implantation, but understanding of these phenomena grows apace. So far as direct observation is concerned there remains at least one gap—no one has yet seen a fertilized human ovum undergoing early segmentation or during the morula and free blastocyst stages, when it is still in the tube. But with the continued search of tubal washings there can be little doubt that specimens of 2 to 7 days' development will be found and reported in detail in the not-too-distant future.

OPERATIVE REDUCTION OF GASTRIC SECRETION

There is much evidence that the immediate cause of peptic ulcer is excessive and continuous secretion of gastric juice both during digestion and, more important, during the interdigestive period. A copious secretion at night when the gastric glands are normally quiescent is especially dangerous, since the buffering effect of food is absent. Medical treatment is largely designed to neutralize this acid by diet and alkalis, or in persistent cases by a continuous drip of milk or alkalis into the stomach. The operations of gastro-enterostomy and gastrectomy also act mainly by neutralization. After gastro-enterostomy there is no significant change in the ability of the gastric glands to secrete hydrochloric acid, and after gastrectomy it is rarely much reduced.⁵ The results of these operations are on the whole not unsatisfactory, and, however desirable the complete resection of the acid-bearing area might be in theory, it is rarely attempted in practice owing to the technical difficulties. Attempts have, however, been made to reduce the secretion of acid by disturbing the hormonal control of the stomach. The ordinary gastrectomy profoundly modifies the mechanism of gastric secretion by removing the pyloric area which produces the hormone responsible for the chemical secretion; at the same time the surgeon divides branches of the vagus nerve which carry impulses for nervous secretion. The importance of the hormonal activity of the antrum was shown some years ago when Ogilvie⁶ devised an operation in which the antrum was preserved, though it was widely separated from the fundus, and much of the acid-secreting mucosa was resected. The results were unfortunate: a high proportion of the patients did badly, and those who were reinvestigated all had a high acid curve. It seems as if the antrum still secretes its hormone, although it is excluded from contact with the acid chyme.

An entirely different principle is proposed by Andrus, Lord, and Stefcio.⁷ These workers implanted pedicle grafts

of the jejunum into the wall of the stomach of dogs and found that thereafter there was a reduction in the amount of acid secreted by the stomach in response to histamine and alcohol. Similar grafts from the duodenum were much less effective, and grafts from the colon or ileum had no action. The effect of the pedicle jejunal grafts was lost in the presence of a gastro-enterostomy or pyloroplasty, and it was not produced by an ordinary gastro-jejunosomy. If the latter was converted into a pedicle graft, and the normal continuity of the gastro-intestinal tract re-established, the secretion was promptly altered. Later it was observed that three dogs with pedicle grafts were immune to injections of a histamine-beeswax mixture, which had caused duodenal erosions and ulcerations in nine control animals. Finally, a jejunal pedicle graft was performed on two animals with duodenal erosions. One died within 24 hours of the operation. The other was killed three weeks later and was found post mortem to have a normal duodenum, despite the fact that injections of the histamine-beeswax mixture had been continued till the day it was killed. After these experiments a pedicle jejunal graft was performed on four patients with duodenal ulcer. A symptomatic cure was obtained in every instance, and in one case there was a reduction in the amount of acid secreted in response to histamine five weeks after operation. A physician reviewing these cases would say that in none of them was there an incontrovertible indication for operation, while the surgeon would stress that it may require years to evaluate a new operation. The procedure is obviously a bizarre one, and it is difficult to see its rationale. The results of further observations of the patients will therefore be awaited with interest.

DUST IN STEEL FOUNDRIES

Men employed on some of the processes in steel foundries are exposed to the risk of silicosis, and with the rapid extension of the manufacture of steel castings during the war there has been a substantial increase in the number of cases of this disease among steel-foundry workers. This rise in the incidence induced the Chief Inspector of Factories to call together a committee of employers and workers, a technical adviser, and members of the Factory Inspectorate to advise on preventive measures. Solutions to some parts of the problem remain to be found, but the committee has already reached certain conclusions, which are set out in the report now issued.¹

Dust arises in many of the operations in steel foundries, but the main dust-producing processes are those connected with the removal of the moulds and cores and the subsequent cleaning and dressing of the castings. The principal methods of combating the risk in these processes are: (1) by substituting other materials for those containing free silica where that can be done; (2) by reducing dust production to a minimum; and (3) by preventing the inhalation of dust. The report discusses in detail the possibility of applying these various methods, and special attention is paid to the first one mentioned. The chief constituent of the foundry moulds is sand, which is a form of free silica, and for the body of the moulds it is at present impossible to recommend any practicable substitute containing no free silica. Some parts of moulds for the larger castings are often made from special moulding compositions which contain free silica. Satisfactory "compo" can be made from calcined aluminous fire-clay instead of from siliceous material; and it is therefore recommended that, as soon as sufficient supplies of the non-siliceous materials become

available, no material containing free silica should be used as a constituent of steel-moulding compositions. Silica in very finely divided state is present in some sands employed for core-making, and experiments are now in progress to determine whether this silica flour can be replaced by non-siliceous material. Separation of parts of the mould is made easier by dusting the joints with parting powder, some of which have a high percentage of silica. It is not practicable, efficient, and economic to employ parting powders which have no free silica; and the use of the former, containing free silica, should therefore be prohibited. The internal surfaces of moulds and cores are often coated with paints containing free silica, so as to prevent fusing of the moulding material to the casting. Experiments confirm that paints containing no free silica can be successfully substituted, and this step is recommended as soon as enough non-siliceous materials are available. Another recommendation is that sand or other substance containing free silica should no longer be used as an abrasive in any blasting apparatus. Normally, the linings of acid steel converters are rich in free silica, so that workers employed in repairing and renewing the linings are exposed to the danger of inhaling dust in a confined space: the possibility of using non-siliceous lining is under consideration.

Besides these substitutions of harmless materials for siliceous ones, other protective measures are advocated. For instance, the existing regulations on "sand-blasting" operations should be tightened up, and a set of precautions is presented which, it is urged, should form the basis of statutory regulations—prevention of escape of dust from blasting apparatus into occupied rooms; exhaust ventilation and the disposal of the collected dust; provision of protective helmets and gauntlets; prohibition of the employment of persons under 18 years of age on blasting operations. It is further recommended that persons engaged in the fettling and dressing of steel castings should be provided with suitable respirators.

If the precepts of this report are put into practice silicosis risks in steel foundries should be much reduced.

PLANS FOR CANCER SERVICES

The annual report for 1943 of the Christie Hospital and Holt Radium Institute, Manchester, records a remarkable increase in the number of new patients, which has almost doubled since 1938. This organization has built up a very efficient cancer service covering a large and thickly populated area; and other hospitals and authorities, when formulating plans and schemes, are increasingly availing themselves of its accumulated experience. The Director of the Holt Radium Institute has visited Sydney at the invitation of the New South Wales Government to advise on the planning and organization of a Cancer Institute for the State. Other Australian States extended similar invitations. The new plans for New South Wales and Victoria would provide for the building of single institutes in Sydney and Melbourne with ample clinical accommodation, departments for radium and x-ray treatment, and extensive facilities for research. In Queensland, where the geographical position of the capital is less central and the population is small, the provision of a special wing at the Brisbane General Hospital is contemplated. In view of the vast area of Australia a clinic service based on air transport will be a post-war necessity. Small special skin treatment centres will also be required, for cancer of the skin, especially in the Northern regions of Australia, is far more prevalent than it is in England.

¹ *Dust in Steel Foundries*. Final report of a committee appointed to consider methods of preventing the production or the inhalation of dust and the possibility of reducing the use of materials containing free silica in steel foundries. H.M. Stat. Off. (1944).

PREVENTIVE MEDICINE IN THE AIR FORCE

AIR MARSHAL WHITTINGHAM'S ADDRESS

The president (Sir Stanley Woodwork) and the council of the Royal Institute of Public Health and Hygiene held a reception on September 21, the guests including representatives of the medical and public health services of the Allies and other nations and of the *Dominions and Colonies*. Air Marshal Sir Harold E. Whittingham, D.G., R.A.F., M.S., gave an address, which was illustrated, on aviation's contribution to preventive medicine. It embraced a far wider range than his paper given before the Medical Society of London earlier in the year (*Journal*, March 11, p. 369). Outside the Institute's building in Portland Place a mobile ophthalmological unit and a mobile dental unit as used in the Royal Air Force were available for inspection.

Sir Harold Whittingham described the work done on nutrition in relation to flying aptitude. In 1941 a special physician was employed for the detection of states of pre-malnutrition, and there were biochemists to assay materials and determine in what respect food was defective. Thus faulty diets had been very quickly rectified. It was particularly important to see that people engaged in flying did not suffer from night blindness, and a useful lead was obtained from experience in the siege of Malta, when those suffering from night visual defects recovered on being given oranges. There was also a certain amount of evidence that deprivation of vitamin B was connected with fatigue. If any group of men—not single individuals—was found with a high incidence of vascularization of the cornea it could be said that the diet was deficient in some respect, but beyond that he did not think it possible to go.

He went on to describe the precautions taken against malaria. In mosquito-infested parts screening was carried out, not only of dormitories but of ablution rooms, and this had proved well worth while. He pointed out what a dangerous vehicle the aeroplane might be, in view of the rapidity of travel from one country to another, in spreading various severe infections, including those with the shortest incubation periods. Effective measures were taken for disinfecting aeroplanes by spraying with insecticides.

Predisposition to Air-sickness

Turning to air-sickness, Sir Harold Whittingham said that about 7% of those who suffered regularly had a definite neurosis, but in general the psychological make-up of the individual played no great part. Air sickness he thought was due mainly to hypersensitivity and overstimulation of the utricle by variations of pressure at right angle to its floor. Air-sickness on the part of the navigator had been diminished by the tilting of the bench at which he worked, so that he was looking straight forward and not down. During a first flight about 17% of people would be air sick or very near it, on a second flight only 4%, and after two flights about 0.5%.

Discussing accident proneness he said that this was due most frequently to temperament unfortunately only those most seriously predisposed (3%) could be detected by psychiatric interview. However, about 20% of aviation candidates were accident prone because they were heavy of hand and foot; such types could be detected by a sensori motor test and so eliminated. Others were prone because of visual defects, such as ocular muscle imbalance. Notwithstanding instrumental flying, night vision remained important to the aviator, because he had to take off and to make his final landing by vision, and avoid "taxiing" accidents and collisions over the target. The night-vision standard had been lowered as much as practicable because, after all, it was only one attribute of night-flying.

Another study had been that of "crash" positions. The idea was that everyone concerned should know his "crash" position. Service members were trained in this respect, and posters put up for the information of others. On the subject of burns he emphasized the protective effect of clothing. Even a small amount of clothing, if not soaked with petrol, would protect the skin from a flash burn. Gloves should be worn, or rather gauntlets protecting the wrist, and on the risk of a crash the face should be covered.

Finally, he described the "Mae West" jacket and how it would save from drowning even unconscious individuals and various other items of protective clothing. Frost-bite had ceased to be a problem in the R A F, during the last two years. Only 0.05% of the people concerned got frost-bite even under the worst conditions. Some interesting experiments on "black out" and oxygen requirements had been carried out in a flying laboratory. At as low an altitude as 4,000 ft., if no oxygen was taken, night visual acuity was reduced by 5%, at 6,000 ft. by 10%, and at 8,000 ft. by 15%. He added that all this work was carried out by a team of doctors, physiologists, chemists, physicists, textile experts, and others. It was also an Allied enterprise, people from the Allied and Dominion Services having co-operated most heartily, and he ended with a tribute to some medical officers who had lost their lives in their zeal for experiment.

Nova et Vetera

JOHN DALTON, 1766-1844

Every medical student has heard the name of John Dalton, indeed all educated persons know it as that of the founder of a rational atomic doctrine based on measurements, and most medical men associate the name with colour blindness. Few, however, know what kind of man the bearer of the name was, and many will read with pleasure Dr E. M. Brockbank's pleasant biography¹ and pay the biographer a compliment not many biographers earn—viz., a wish that the book had been longer.

John Dalton (1766-1844), the son of a Cumberland weaver, owed nothing to academic instruction, his father taught him the elements of mathematics, and he was also taught by a Mr. Elihu Robinson, but, as he began to earn his living by teaching younger children at the age of 12 and at 15 became a regular school teacher, we may fairly class him as self-educated in the strict sense of the word. In 1785 he joined his elder brother in school teaching in Kendal, where he remained until 1792, when he became a teacher of mathematics in the Manchester New College—the ancestor of Manchester College, Oxford. One wonders—it is only a matter of speculation—whether during his residence in Kendal Dalton made the acquaintance of another self-taught mathematician, John Dawson of Gardale (1734-1820), the Sedburgh doctor who took private pupils and numbered among these eight who became senior wranglers. Although Dalton remained in straitened circumstances most of his life his genius was recognized fairly soon, and he was elected a corresponding member of the French Academy of Sciences in 1816, 14 years later, on the death of Sir Humphry Davy he was chosen one of the eight foreign associates, and when his name was announced by the president all the members rose—a compliment not paid either to Napoleon or to Lord Brougham.

That science is measurement is, perhaps, an epigram rather than a satisfactory definition; but it is certainly true that interest in precise measurement was a primary quality of Dalton's mind, it can be seen in his early meteorological studies and, of course, in his classic researches. It is worth noting that Joule was once a pupil of Dalton.

As a human being Dalton was something of a character, cheerful and loving a joke amongst intimate friends but apt to be silent in a large company and by no means a brilliant lecturer. Dr Brockbank tells us that in a book on English grammar Dalton published in 1801 gender as expressed by a change of termination is illustrated by "prince, princess; poet, poetess, executor, executrix, phenomenon, phenomena, etc." One would like to think this was a little joke. We have read a story somewhere that Dalton, who was a Quaker, flatly refused to wear court dress when presented to the king, but consented to wear his D.C.L. gown, not knowing it was scarlet. The italicized words we suspect to be a facetious addition, for

¹ John Dalton. *Some Unpublished Letters of Personal and Scientific Interest, with Additional Information about his Colour-Vision and Atomic Theories.* Manchester University Press. (7s. 6d. cloth, 7s. boards.)

Dalton would certainly have known that the colour was called scarlet by other people. Dalton's reply to the king's question: "Ah! Dr. Dalton, how are you getting on at Manchester?" was: "Well, I don't know: just middlin'." Dr. Brockbank prints some hitherto unpublished letters; they are without any literary airs and graces, but the composition of a thoroughly clear-headed man and say exactly what he meant to say.

ROBERT BRIDGES, 1844-1930

Robert Bridges, physician and Poet Laureate, was born on Oct. 23, 1844. There have been many medical poets, but though they have been good doctors not many of them have been great poets. Bridges was both, and it was fitting for the History of Medicine Section of the Royal Society of Medicine to commemorate the centenary of his birth, when the outgoing president, Sir Walter Langdon-Brown, gave the address. From Eton and Oxford Bridges went to St. Bartholomew's Hospital, where he became house-physician to Dr. Patrick Black and afterwards casualty physician. In the latter capacity he wrote in the Hospital Reports for 1878 a powerful indictment of the running of the casualty department. This ensured that he was never given another post at Bart's, but also led to reforms, albeit slowly. But he was elected assistant physician to Great Ormond Street Hospital and the Great Northern Hospital. In 1881 he had pneumonia and emphysema, which led to his retirement from medical practice. He had always intended to devote himself to literature, but was convinced that he would be a better poet if he practised medicine in order to be brought into close contact with human life. He evidently wished his poetry to expound the philosophy he acquired from natural science in general and from medicine in particular.

In early life Robert Bridges was closely associated with his kinsman Digby Dolben, a poet of much promise who was drowned when only 19, and at Oxford with Gerard Manley Hopkins. He was responsible for the posthumous publication of poems of them both. It is a curious association since their approach to poetry was emotional and religious, while his was intellectual. He was fascinated by the sonorous rhythms of the great poets, but intellectually he was a Platonist. In 1900 he was elected a Fellow of the Royal College of Physicians, and in 1913 became, rather unexpectedly, Poet Laureate, thus restoring prestige to an office which had suffered from the apparently cynical appointment of Alfred Austin. Apart from poetry Bridges did much for the encouragement of pure English, and favoured a simplified spelling. But his enduring monument will be *The Testament of Beauty*, published on his 85th birthday, which summarizes his philosophy of life. That a man of his age should have written such a poem is in itself remarkable enough, but that he should have assimilated recent work on astronomy, archaeology, physiology, and psychology, and have welded them into new forms of beauty is indeed amazing.

Sir Henry Newbolt described him as one of the most remarkable figures of his age, who appeared distinguished in any company, not only because he was strikingly handsome but because his extraordinary charm lay in his transparent sincerity. There was always visible the strength of a towering and many-sided nature, at once aristocratic and unconventional, virile and affectionate.

The question of preparing for expansion in training for pharmacy after the war was dealt with by the Dean of the College of the Pharmaceutical Society, Prof. H. Berry, in reviewing the work of the past year at the opening of the College's 103rd session on Oct. 4. He said that pharmacy was continually expanding and diverging from the old channels of retail and hospital practice in order to cope with developments in medical practice. This expansion must be reflected in the training of the student if pharmacy was to keep pace and maintain its place. Pharmaceutical chemistry was developing rapidly as the study proceeded of the relation between chemical structure and therapeutic activity, the standardization and assay of medicinal substances, and the introduction of new synthetic medicinal substances. It was hoped that in the post-war era there would be a great expansion of the attention given in this country to the production of new medicinal chemicals. Firms were already training graduates in pharmacy of greater use in this field of research than those holding a pure chemistry degree.

Correspondence

"Dissident Doctors"

SIR,—Returning from a lengthy meeting of the committee entrusted by our Association with the task of running the B.M.J., I read in its pages, with some astonishment, that "is more than disquieting that, at a time when the shortage of doctors is acute, a number of them are prepared to spend time, money, and paper in fomenting political activity and indeed in directing it." I had believed that in giving my time and spending a little of my money, reading many pages of documents, and listening to many points of view on the Joint Committee, I was genuinely helping the political activities of the British Medical Association. I have rarely failed to answer the call of that Association to play my part in its work, and I did not expect to be thus criticized in the official *Journal* for so arranging my ordinary work that it leaves some time for duties within my professional association. Surely it is the duty of all of us to play our part in the management of the affairs of our country and of our profession—in short, to take part in all political activities that concern our way of life.

Let us, however, get one or two things stated accurately and the position clearly defined. The action of Dr. Sam Smith is surely the ordinary activity of any person or group who wish to influence opinion. I have in my possession a paper sent out by the B.M.A. suggesting precisely the same sort of activity as those suggested by Dr. Smith. Is not that one of the functions of the Public Relations Committee? Dr. Smith stood alone instead of being backed by many B.M.A. members his action would still be of a type carried on by the B.M.A. itself. Secondly, Dr. Smith may be fortunate enough to "belong to that small minority of doctors who fit themselves within the fold of the Socialist Medical Association," but he is certainly not "one of the drivers of the S.M.A. machine," nor is the work of which you complain part of the S.M.A. programme. Dr. Smith's group is composed entirely of members of the B.M.A., and is an attempt to crystallize that 60 or 70% of opinion within the B.M.A. which is all too unvoiced but which voted in the Questionnaire in favour of Health Centres organized as part of a complete service for 100% of the people.

Of more importance, however, is your reiteration in your annotation of the very attitude towards the M.P.A. of which Dr. Smith complains. The M.P.A. has declared its intention to capture the B.M.A., and has had some notable victories in certain reactionary Divisions. It must be attacked if the B.M.A. is to continue its work; for here we must distinguish between the legitimate work of the S.M.A., which exists to spread a knowledge of Socialism within the profession, and an organization which seeks to destroy our chief professional society. The S.M.A. and all progressive doctors will continue to attack the M.P.A., and would the more readily back the Council in so doing if the Council does not seek, as does your annotation, to excuse and justify it as a reaction to the work of the S.M.A. The crux of the question is whether we stand for true democracy or can support even in the smallest degree the curious mixture of Fascism and individualism (with more than a dash of anti-Semitism) which passes for a policy with the M.P.A.

Lastly, why the anxiety about Gordon Malet? Was not his attack on the M.P.A. one you should have welcomed? And are not your own leaders unsigned?—I am, etc.,

D. STARK MURRAY,
Richmond, Surrey. Chairman, E.C., Socialist Medical Association.

* * We have criticized Dr. Samuel Smith—we did not know there was a group until informed by Dr. Stark Murray in the above letter—for using an "individualistic" machine of his own instead of the democratic machinery of the B.M.A. through its Divisions and Branches, to one of which Dr. Smith presumably belongs. We criticized the action of the Socialist Medical Association because it "exists to spread a knowledge of Socialism in the profession." * Other small self-appointed groups of "political" doctors will soon sprout up to spread their political doctrines if this example

of misplaced enthusiasm is followed; and we shall see the existence of the "Conservative Medical Association," the "Liberal Medical Association," the "National Liberal Medical Association," the "Common Wealth Medical Association," the "I.L.P. Medical Association," and so on. There are political organizations in plenty to give medical men what political information they need, and to offer them scope for political activity. Dr. Murray obscures the issue by confusing medical politics with politics in the familiar use of that term. Finally, we should like to make it quite clear that no attack on Socialism is intended.—ED., *B.M.J.*

SIR.—I shall be grateful for an opportunity to reply to your annotation concerning me. The errors of fact and surmise in it I shall leave to be dealt with by others better qualified than I am. I wish only to draw attention to a fundamental issue—the right to hold my own views on the National Health Service and to put these views to whomsoever will listen, even as you, Sir, enjoy that privilege.

I am shortly entering H.M. Forces, and, feeling as strongly as I do, have tried, with, I hope, a certain measure of success, to persuade others who think as I do to become articulate on the subject. There are many doctors to my knowledge who for a number of reasons have not expressed themselves other than by means of the Questionary. That I am not in a "small minority" is shown by the figures of the Questionary.

It would appear that a "dissident" doctor is, according to your interpretation, one who opposes the views of the Council of the B.M.A. If that is correct, then I plead guilty to being one of a number whose ranks I believe will increase. If and when there is a clear-cut majority vote by the rank and file of the profession for a particular issue I shall accept that decision, but reserve the right, as in all democratic organizations, to attempt to reverse it by means of legitimate persuasion and not by coercion or hysterical outbursts.—I am, etc.,

London, E.9.

S. SMITH.

Antenatal Health and the Unborn Child

SIR.—In your report on schemes for medical and social research (Sept. 30, p. 444) child welfare is conspicuously prominent in "Social Adaptation" and "Infant Diets." This is all to the good, as the future of the race depends on the rising generation, and a sound foundation is essential for any enduring progress.

It seems to me that much more might be done by research into antenatal conditions which determine the perfection of the newborn child and minimize the risks of labour to the mother so that she may be at her best immediately to undertake the care of her baby. Antenatal clinics are doing a great service by giving advice and providing vitamins to expectant mothers, but much more might be done if the methods, as to statistics, of the Mellanbys with mice were observed: a close follow-up of results in recording the effects of diet and treatment on mother and child; as to deformities, physical and mental; lactation; maternal morbidity and mortality; and the effects of illnesses, especially sepsis, during the early weeks of gestation when deformities are determined.

During the past eighteen years it has been my practice to see every expectant mother each week from the time of booking, and to maintain her health at the optimum by advising her on diet, rest, exercise, external and internal cleanliness, and especially by actinotherapy from the earliest possible date. The most obvious and immediate effect of this course is the improvement in the appearance of the woman. Her skin becomes darker, of a better colour, and shines like silk. There is a better tone in her tissues generally. Her posture is more erect and she evidently enjoys life.

Sickness is either cured or much relieved and does not last so long, though there are exceptions. Good muscle tone of the uterus shortens labour and reduces loss of blood to a minimum. The teeth are preserved as the improvement of calcium and phosphorus metabolism by photosynthesis protects the skeletal calcium reservoir from depletion. Raising the immunity from infection protects her from sepsis, and one rarely sees even a slight rise of temperature and wounds

rapidly heal. After parturition most of these women feel that they could get out of bed and resume a normal life. This is only as it should be, but, of course, is not allowed in modern practice. A striking feature is early lactation, even in those who could not feed previous babies.

As a general practitioner in an industrial town material and time have been very limited, but there has been an advantage in having cases for a long time under individual attention. The development of the child after a good start has been most interesting. I am convinced that results have been better than they would otherwise have been. Ossification is well advanced, cranial bones firm, and fontanelles closing well; dentition normal and muscle tone good. Walking sometimes starts earlier than expected, and in one case was well established at 8½ months.

What is most striking is the healthy state of the mental faculties during the past few years; each child has either gained a scholarship to the Bolton School or passed the entrance examination. I have pressed the use of actinotherapy where there is mental defect in the family history of either parent, and results so far have justified this course.

The Government is making great plans on new housing schemes and preparing to spend freely on these, but the bodies we live in have the first claim on our attention, and the future citizen is of more importance than the shell he inhabits from time to time and which is not indispensable. Educational reforms are of less importance than good material.—I am, etc.,

Bolton

WM. HARVEY BENNETT.

Wound Fractures in Plaster-of-Paris

SIR.—I would like to support Prof. Willan in what he says about wound fractures in plaster-of-Paris. At the Royal Victoria Infirmary, Newcastle-upon-Tyne, we have had a large number of war casualties with compound fractures of limb bones enclosed in plaster-of-Paris. The bulk of these cases arrived in splendid condition thanks to the magnificent surgical treatment they have previously received, aided by the sulphonamides or penicillin. But a small minority are not in this category. They arrived in a rather poor toxic condition, running a temperature, and with the plaster stained and odorous. Some of these we know must have the plaster removed and the wound inspected, but in between are cases where one is really in doubt whether to interfere or not. X rays perhaps show the bones to be in good position, and one is afraid of spoiling this, although one is unhappy about the condition of the wound or wounds. This is the sort of case where Prof. Willan's suggestion would be most useful if carried out. The "blister" or "protuberance" would show one the site of the wound and the plaster over it can be easily removed, the wound inspected, and any necessary local treatment carried out without disturbing the position of the fracture. Of course one knows that in many cases the site and position of the fractured bones are drawn on the plaster, and this method is most useful, but it does not, perhaps, show the site of the wound or wounds. I think that Prof. Willan's suggestion is a very good one, and if carried out will be most helpful.—I am, etc.,

Newcastle-upon-Tyne.

J. HAMILTON BARCLAY.

Early Cancer: Difficulties of Hospital Admission

SIR.—Mr. Wilfrid Adams in his letter (Sept. 30, p. 450) rightly points out that the alert general practitioner is more likely to be responsible for the early diagnosis of cancer than is the institution of numerous cancer clinics. A further point I should like to make regarding the prognosis of cancer is that, having diagnosed it, the general practitioner has great difficulty in obtaining early treatment for his cases. The patient is seen at a local hospital and put on a waiting list for admission. According to the locality, he or she may be kept waiting a matter of weeks or even months. Meanwhile the disease progresses and may become inoperable or beyond the aid of radium.

Until cases of suspected or proved cancer are treated as urgent admissions for the purpose of investigation and treatment, the death rate and suffering from this disease will continue at its present high level.—I am, etc.,

Scarborough.

ANNE M. ROXBURGH.

London Medicine

SIR.—Dr. Rowland Hill's letter (Oct. 7, p. 479) must in general command such a measure of approval that his particular somewhat critical reference to the Institute of Child Health cannot be allowed to pass without comment. He is clearly under a misapprehension as to the prospective scope of the institute.

The conception in the minds of its originators has always been just as comprehensive as Dr. Rowland Hill suggests it should be, even to the full title of "The London University Institute of Child Health." It is true that the plan for such an institute emanated from the Hospital for Sick Children, Great Ormond Street, and that this hospital has been most active in furthering it. We are proud of the fact. But the design has always been on the broadest lines, aiming at co-operation between all concerned with the health and well-being of children.

A present collaboration between the University of London, the L.C.C., the Postgraduate Medical School, and the Hospital for Sick Children would seem to assure an adequate breadth of vision, which certainly aims at embracing in the future every paediatric activity in and around London.

All would agree with Dr. Rowland Hill that this great project must be made truly worthy of the capital city. I hope he may be convinced that the foundations are being well and truly laid, and that he may come to share the confidence in the builders, which has induced the Nuffield Trustees to subscribe £100,000 to the work.—I am, etc.,

Hospital for Sick Children, Great
Ormond Street, W.C.1.

T. TWISTINGTON HIGGINS.

Intravenous Anaesthesia

SIR.—Major Maidlow (Sept. 30, p. 432) has put forward several criticisms of our apparatus for continuous intravenous anaesthesia which we described in the *Journal* of Dec. 25, 1943 (p. 813). We should be grateful for the opportunity to answer his criticisms. We believe that his remarks can only be based on armchair critical perusal of our paper, as the majority of the faults he has to find do not occur in practice.

There is no flow of oxygen except to the patient via the flowmeter. There is merely back-pressure in the saline bottle caused by constricting the flow between the "Y" piece and flowmeter; therefore Major Maidlow's dogmatic and terse dismissal of this method with the words "besides being wasteful" is quite unjustified. If the rubber bung of the saline container does not fit well, it can happen that the pressure in the bottle is enough to blow the cork out. A

ill-fitting cork or a little intelligent use of adhesive strapping obviate this. In practice there is no need to turn off oxygen, nor any need to fit an automatic mercury manometer or blow-off valve, and therefore the complications or disadvantages which spring to Major Maidlow's mind do not exist and consequently do not need obviating.

Let us answer his enumerated list of disadvantages one by one:

1. The tubing, punctured at each injection, can be kept sterile by covering with a swab soaked in antiseptic; in any case the delay caused by wiping a piece of tubing with a swab is not worth discussing.

2. While we entirely agree with Major Maidlow on the prime importance of maintaining a clear airway, in the vast majority of cases some position of the patient's head can be found which will ensure a clear airway without the constant holding of the jaw by the anaesthetist. In his gravity-drip days, how did Major Maidlow drag his heavy metal stand to and fro without taking his hand from the patient's jaw and his attention from the patient's general condition?

3. There is usually a vein available in a limb not in the vicinity of the operation, surgeon, or assistant, and towels may be arranged so that the anaesthetist may have access without intruding on the operating field.

4. The last question in this section surely does not need an answer. The second shows the gnat-straining qualities of Major Maidlow's duplicitous technique. He cheerfully swallows his camel reluctantly in his own method by allowing a gallipot containing pentothal for intravenous injection to be open to the air.

5. We agree with this criticism, especially with wartime rubber tubing.

In return may we offer a few criticisms of Major Maidlow's method:

1. The aspiration indicator Major Maidlow admits is most useful but he makes a rule to avoid using it.

2. A three-way tap we tried and abandoned because: (a) it tends to leak from the tap and each of the four rubber-metal joints; (b) to avoid dead space of saline or pentothal it must be closed to the needle, and there it is heavy and tends to drag on the needle and dislodge it.

3. Pentothal in an open gallipot, besides being liable to dust contamination and airborne infection, dissociates much more rapidly than pentothal kept free from air in a syringe.

4. Unless the pressure in his bottle is unduly high there is no more reason why the saline level in the drip bulb should rise to high using positive pressure than when using gravity. However, I admit the possibility but see no use for the employment of side tube and clip—which, of course, give perfect control over the level under all circumstances.

5. Why bother to insert an air filter between bellows and bottle while the pentothal is left in an open gallipot?

6. Why wait 15 minutes to obtain the benefit of supplemental gas and oxygen? The patient can be "settled" much quicker with far less pentothal if supplementary gas is used immediately after induction.

In conclusion we should like to point out that all these differences of opinion are on minor points of technique, in which there must always be a considerable degree of personal preference. Generally speaking, we are in absolute accord with Major Maidlow on the indications and contraindications of continuous intravenous anaesthesia, and we should especially like to endorse his statement that for prolonged laparotomy the anaesthetic of choice is some form of regional analgesia combined with light pentothal, or pentothal, gas, and oxygen anaesthesia.—We are, etc.,

F. W. ROBERTS.

Middlesex Hospital, W.1.

Pentothal in the Shocked Case: A Warning

SIR.—I have recently returned from North Africa and Italy where for the past year I was anaesthetic specialist to one of the Services. It was my lot during that time to see a number of anaesthetics given by medical officers who were not trained anaesthetists, and two things struck me very forcibly while observing their technique. The first was that in the giving of inhalation anaesthetics many of these officers showed little indication of recognizing the importance of that first principle—the maintenance of a clear airway—and were quite content in many cases to let the patient continue with some degree of obstruction.

The second was to my mind of much greater importance and was the thing which prompts me to write this letter. It was the failure to appreciate the appropriate dosage of pentothal in cases suffering from shock. It seemed to be their attitude that "a shocked case needs a little less pentothal than a 'cold' case," with the result that if it had not been for the presence of an experienced anaesthetist overdoses and grave risk to the patient might have occurred. No criticism of these medical officers is implied, but it is suggested that teachers should stress that while technically pentothal is the easiest of all anaesthetics to administer, it is also "fatally easy to administer an overdose, and what might be considered a normal dose for the robust person might well be fatal to the same individual shocked or exsanguinated.—I am, etc.,

HOWARD BRUCE WILSON.

Urethral Lesions in Enuresis

SIR.—The interesting article by Lieut.-Col. Backus at Capt. Mansell on enuresis in the Army (Oct. 7, p. 462) refers to me as finding that congenital stricture in children is a causal factor of enuresis (p. 465). This, I am afraid, is a misrepresentation of what I have said on this subject. I certainly hold the opinion that urethral examination reveals a high percentage of urethral abnormalities, which are most chronic inflammatory in origin, and that laboratory reports on the urine generally fail to give any indication that such

is the case. I notice that in this report there is no reference to urethroscopic findings; these are important in relation to treatment. Nor is there any indication that observations were made with regard to residual urine in the bladder; the presence of the latter is important for the same reason. I have had more than one patient under my care who was discharged from one of the Services because of enuresis, and in whom posterior urethral lesions were found, the treatment of which caused a cessation of the enuresis.—I am, etc.,

London, W.1.

H. P. WINSBURY-WHITE.

Oestrogens and Cancer

SIR.—I read with interest the article on synthetic oestrogens and advanced cancer (Sept. 23, p. 393), and I note the authors' statement that the effect of giving stilboestrol provides an incentive to further investigation. The administration of stilboestrol is scientifically correct, but in the study of the genesis of cancer there has been a failure so far to give place to other important physiological considerations.

I am convinced that the cause of malignant change is inherent in the organism, and that it is an error in the metabolism of two interdependent bodies—fats and sugar. It has been truly stated that the fats are the cement which holds together the organized matter of the protoplasm, and in the pre-cancerous condition the cells and their protective oily envelopes are starved of fat and so rendered more sensitive to biochemical agents. At the same time the faulty fatty metabolic error results in an increase of non-saturated fatty acids, which combine with the alkalis of the tissues to form saponins. Incidentally, B. Moore and others have observed an increase in the alkalinity of the blood and tissues in cancer. That saponins are irritating and can cause increased mitosis has been proved by experiments which readers must study for themselves.

In pre-cancerous states there is also an excess of sugar in the system, for I have frequently found recurring glycosuria in patients some years before the growth appeared. This is not likely due to lack of insulin, which, after all, does not burn sugar but only prepares it for combustion. Rather is it due to: (1) over-activity of the anterior pituitary, and (2) imperfect preparation of the fats. Sugar and fats cannot burn one without the other, and both must be prepared for the burning by their respective enzymes.

I have an idea that if we could correct the faulty metabolism of these two substances the result of the stilboestrol treatment would be more satisfactory. And in the pancreas we have the necessary enzymes staring us in the face: they are the lipolytic enzyme and insulin. Why, then, not use them? They could be introduced by intramuscular injection of pancreatic extract (whole gland). I am no chemist and therefore cannot say whether in the course of preparation of the extract the activity of the more important ferment—the lipolytic—would be destroyed; if so, the extract would be useless. It all sounds very simple and easy, just as the solution of the cancer problem will appear to be. This will not come until we pay more attention to physiological principles. Indeed,

"Life is no crazy pathway. Every bit
Is planned beyond our human ken to fit."

—I am, etc.,

J. THOMSON SHIRLAW.

Wigan.

Familial Leukaemia

SIR.—Dr. Meikle's report (Oct. 7, p. 468) of two varieties of leukaemia in one family is extremely interesting, but familial incidence is not quite as rare as he suggests. Thus, Dameshek, Savitz, and Arbor (1929) have recorded chronic lymphatic leukaemia in twin brothers aged 56; and Jelke (1939) gives details of acute lymphatic leukaemia in identical twins. And Decastello (1939) reported six cases of chronic lymphatic leukaemia in two generations of one family.

Such familial incidence is a good deal commoner in lymphatic leukaemia than in the myeloid form (Ardnashnikov, 1937); but, so far as I am aware, there is no previous report of two varieties of leukaemia in the same family. Even so, it is just possible that Dr. Meikle's cases were both of the Naegeli type of

monocytic leukaemia—that is to say, that in Case 1 there was a monocytic increase in a primarily myeloid leukaemia, while Case 2 was continuously myeloid.

It is interesting to recall that Richter and MacDowell (1935) have shown definite influences of genetic factors in experimentally induced leukaemia in mice.—I am, etc.,

London, W.1.

SIR.—I have read with interest Dr. Meikle's article (Oct. 7, p. 468). There are, Dr. Meikle's case included, 28 incontrovertible cases of familial leukaemia reported in the literature. Last year I had the opportunity of diagnosing two cases of monocytic leukaemia in one family. A full account of them and a review of the literature will be published elsewhere. The occurrence of two cases of monocytic leukaemia in the same family has, to my knowledge, never been recorded before. Familial cases of leukaemia are probably more common than is usually supposed. To establish this more extensive genetic studies and systematically repeated blood examinations of all the relatives of leukaemic patients in different generations will be necessary.—I am, etc.,

London, E.17.

Words and Clear Thinking

SIR.—Clear thinking is largely determined by clear expression. Those who deliberately misuse words are enemies to science. Pre-eminent among these miscreants are the teachers of medicine who persist in the use of the phrase "hyperglycaemic coma." Their pupils are led: (1) to assume that sugar is a toxic substance; (2) to inform examiners that diabetic coma is due to hyperglycaemia; (3) to give insulin for this state without a corresponding quantity of sugar.

I wish to bring these facts to their notice, and to ask all such teachers to expunge the noxious phrase from their minds, their books, and their tongues.—I am, etc.,

London, W.1.

GEOFFREY BOURNE, M.D.

Functional Hypoglycaemia

SIR.—Dr. Wilfrid Oakley (Oct. 7, p. 479) has seen fit to pass judgment against the term "reactive hyperinsulinism" coined by Dr. F. T. G. Prunty (Sept. 23, p. 398) for those cases of hypoglycaemia not due to organic causes, such as islet-cell tumours. Dr. Prunty preferred the term "reactive hyperinsulinism" to that of "functional hyperinsulinism" of Conn (1940), since the word "functional" has other less well defined associations.

There is abundant evidence to show that these cases of "functional hypoglycaemia" occur in psychoneurotics, very often as the presenting feature, and for this reason they are often referred to as the nervous type of hypoglycaemia—open to the same objection given for "functional."

Since the condition is not uncommon it is important that terminology be simple as well as accurate. Dr. R. D. Lawrence, in a letter in your columns (Dec. 11, 1943, p. 760), used the term "spontaneous hypoglycaemia," and this seems preferable to those suggesting either a functional basis or hyperinsulinism.

May I suggest as an alternative "reactive hypoglycaemia."—I am, etc.,

Guy's U.S.A. Hospital.

GEORGE R. W. N. LUNTZ.

Service Medicine

SIR.—In the correspondence on this subject officers, almost invariably of high rank, have gone to great trouble to defend the Services—risking the obvious inferences. It appears that in all these letters hospital treatment has been held up as the be-all and end-all of efficiency. Surely hospital treatment is a very small fraction of the sum total of medical treatment, and it is at the greater aspect of the medical care of personnel that criticism might well be levelled.

The opinions of individual medical officers—of whatever rank—are of little value in the matter, merely expressing a personal belief or opinion. The opinions of Service patients would be of much greater value, and I venture to suggest that they would be far from flattering. This unhappy result is not solely the fault of individual medical officers, who are without doubt handicapped by veritable avalanches of regulations, instructions, amendments, and memoranda, etc., *ad nauseam*, which results in "playing safe and passing the buck."

The opinion of your correspondent Capt. Hall bears little weight—Capt. Hall would do well to remember that the war has been in progress for considerably longer than his two years of service. The point is that it has taken five years of futile struggling to produce the state of mind reflected in the letters of earlier correspondents. This point is, I think, borne out by the fact that this correspondence is recent.

The point raised by your correspondent R. G. Gordon is interesting. And it will always be a source of wonder to me why men with the most efficiency, the most expensive and most lengthy training of any branch of the Service, are required to inspect latrines, which task needs no medical knowledge whatsoever and merely entails inspection for dirt, flies, etc., which should be within the scope of any administrative officer.

I do not think that there is any real inefficiency among medical officers but rather a tragic state of disinterested resignation—tragic because of its long story of slow disillusionment, of blasted ideals and hopes, and of smothered enthusiasm and initiative. Generally speaking, the system works comparatively well, but the cost in post-war clinical inability and lack of knowledge through being out of touch has still to be reckoned, and will, I feel sure, be colossal.—I am, etc.,

India

GILBERT FRASER.

SIR,—“Service Doctor” in his letter (Sept. 30, p. 451) is, in my opinion, grossly unfair to the average Royal Air Force N.C.O. and medical orderly who work in station sick quarters. His five years’ service must have been unfortunate in this respect. The many R.A.F. medical officers, including myself, would have made many more clerical errors (of some importance), especially in our early months of apprenticeship, were it not for the medical N.C.O. Civilian secretaries can also be inefficient, and they have to be paid.

The pilot flying his plane up has to take it on his charge. Other officers in other branches of the Service are in the position of having vast quantities of stores on their charge, for which they are responsible. “Service Doctor” ought to be reminded that there is a fair-wear-and-tear ruling for his electric light bulbs!

Never have I seen in the R.A.F. Medical Service red tape obstructionism intervene when the life or future health of a patient was at stake. I can only conclude that accusations of incompetence made on this very important aspect of red tape

be due partly to lack of initiative of the M.O. concerned. Any of us who are in the Service for the duration of present hostilities will be glad to be free again to go as we please; but while the chaos of war remains and is likely to for some time, it seems only fair to serve patiently, especially in a Service with such a fine record as the R.A.F. Many others, besides the younger members of the medical profession, did not want their individual ambitions and desires frustrated by the war.

In concluding, it seems only fair to do away with anonymity, for it proves fear of reprisals, and surely fear is one of the things we are fighting—I am, etc.,

GLYN DAVIES,
Fl. Lieut., R.A.F.V.R.

SIR, I admire the succinct summary which Dr. G. M. Hodges (Sept. 23, p. 417) accords my letter of Sept. 9. I wish I could admire his logic as well. He first states there are “buts,” and then produces—but one, and that occurs after the man is discharged from the Service. Is there any fundamental reason why one should not get on as well with the officials of State as one does with the “higher ups” in Service medicine? Aren’t some of us, even at the present time, supervised? A D.M.O. is responsible to the guardians committee and/or the local M.O., a panel doctor is responsible to the local

insurance committee and to the R.M.O. Wherein lies the difference?

As to my being fortunate in my superior officers, I have in five years (not four as previously stated) as C.M.P. to the R.A.F. seen and experienced a vast number of changes in the personnel, but, without exception, I have always had a fair and polite association with them.—I am, etc.,

Norwich.

P. B. CORBETT.

Need for Reform in Clinical Teaching

SIR,—With regard to the problems of medical training and various projected reforms in the curriculum, I feel that you may be not unwilling to publish the views of a student on these somewhat controversial topics. The opinions I express are, I should stress, based on individual observation and experience; they are not intended to be representative of general opinion among medical students.

My own conviction is that clinical teaching, not pre-clinical, stands in most urgent need of reform. A pre-clinical student is taught along the lines accepted as being the most practical and coherent in nearly all science faculties of nearly all universities: a course of lectures, supported by laboratory classes and demonstrations, with optional or semi-optional “tutorials” for advanced students. Yet for a clinical student there are seldom, if ever, systematic courses of lectures on any of the basic subjects; teaching rounds in the wards provide a hopelessly inadequate substitute for the valuable methodological exactitude of the laboratory; and, worst of all, the student is expected to “pick up” knowledge by dint of individual push and initiative. In the latter process we may find that the lazy take discreet avoiding action, the shy or diffident are suppressed by belligerent house officers and sisters, while a few tenacious spirits collect odd fragments of “knowledge,” which are about as homogeneous as “liquorice all-sorts.”

The remedy for all this is, surely, the bringing into line of clinical teaching with pre-clinical. It is sometimes argued that clinical material cannot be made available in such a way that the teaching can be formal and systematic. To some extent this may be true, but not true enough, surely, to justify the present chaotic methods. The lack of readily available demonstrators in the wards is one of the most conspicuous flaws: overworked house officers cannot be expected to fulfil this function, but why should there not be young postgraduate teachers who make teaching their full-time job?

As to reform of the curriculum, what strikes one as most obvious is that a “little learning” of some highly complex subjects, notably psychiatry and dermatology, is a waste of time which could be devoted to a more searching acquaintance with casualty practice and so-called minor maladies. Not long ago I arranged for a young woman troubled by warts on her fingers to see an eminent dermatologist, who cured her without the slightest difficulty; she had been treated by an extremely competent G.P., who had, nevertheless, failed to remedy the nuisance. Would it be heresy to anticipate that, in due course, enlightened members of the general public, afflicted with psychological problems or skin troubles, will go straight to the appropriate person without the cumbrous intervention of the G.P.?

The essence of efficiency, few would surely deny, is to avoid “knowing less and less about more and more”; if the curriculum were to be much further burdened this dilemma could hardly be averted. But it would take a genius to sort out the existing confusion at a single stroke.—I am, etc.,

London, S.W.10.

J. A. FLETCHER.

Lay Psychiatry

SIR,—As a reply to the letter of Mr. D. H. Kitchin on the subject of lay psychiatry (Sept. 30, p. 450) I would like to stress the point that psychiatry must be strictly amoral, and must dispel guilt-feelings so often linked to ethical issues. It would therefore seem that a clergyman would usually be the last person desirable to practise psychological medicine, which should be reserved solely for the qualified physician, who also has recourse to such methods as intravenous narco-analysis.—I am, etc.,

T. H. HARGREAVES.

Obituary

ALEXANDER BREMNER, CBE, M.C., T.D., M.D.

Col Bremner died suddenly at his home in Sheffield on Sept 29 aged 54. He had led an adventurous and unselfish life in two spheres of action—as a physician and as a soldier in two wars.

He was educated at the Anderson Institute in Shetland and at Edinburgh University, where he graduated M.B., Ch.B. in 1913, and was a prominent member of the O.T.C. When war broke out in 1914 Bremner joined the Army as a sergeant major and as unofficial M.O. to a battalion raised in Hull by Sir Auckland Geddes. He was later transferred to the R.A.M.C. and went to France. After a few months he was invalided home with typhoid fever, and later was attached as M.O. to the Dublin Fusiliers, with whom he stayed for the remainder of the war and saw service at Suvla Bay, Salonika, Egypt, and Palestine. For valour in rescuing wounded under fire he was awarded the Military Cross and later was mentioned in dispatches for gallantry in the field.

In 1919 he married Miss Ella Elphinstone, herself a graduate in medicine of Edinburgh, and in the same year they went to live in Sheffield, where Bremner took over the practice of his uncle, Dr Inkster. In 1925 he was appointed deputy medical director of the Edgar Allen Institute and in 1926 honorary physician to the Children's Hospital, Sheffield. Later he became lecturer in diseases of children at Sheffield University. He took his M.D. and the D.T.M. & H. at Edinburgh in 1919 and the D.P.H. in 1920. The after-care and rehabilitation of rheumatic children was one of his constant preoccupations, and he was instrumental in organizing the clinic for rheumatism under the Sheffield School Medical Service. His most important work was probably in connexion with children's diseases, not only as a physician but as a committeeman and as an administrator. He had a talent for getting things done.

He joined the Territorial Army as M.O. to the 71st Field Brigade, R.A., about 1925, and continued to serve with them until the early part of 1940. He was then promoted to lieutenant-colonel and proceeded to France as O.C. of a field ambulance and acting A.D.M.S. Although his division was largely untrained he led his command from the south of France to Belgium when the Germans broke through in May, 1940. Here he became involved in heavy fighting, was again mentioned in dispatches for gallantry, and was severely wounded in the retreat to Dunkirk. Back in England Bremner spent some months in hospital, mending his fractured legs. He was promoted colonel, A.D.M.S., in charge of a general hospital, and with this unit he landed with the first British troops in North Africa. The transport containing his equipment was sunk in harbour by enemy action, but under heavy aerial bombardment he organized the salvage of enough stores to erect a hospital which was receiving casualties within a few days. He was again mentioned in dispatches for gallantry in the field and later was awarded the C.B.E. Among his other achievements in North Africa he organized the hospital medical services disinfecting station. He returned to this country in October, 1943, after his services had been asked for by his hospital and by the university. He threw himself immediately into organizing means to assist those now in the Forces when they returned to civilian life.

A correspondent writes: Bremner loved soldiering when there was something to be done, he could not find an outlet for his energies in the peacetime Army. In many ways he remained very youthful. He had a large practice in the West End of Sheffield, but probably had more non-paying patients than any other practitioner in the district. He was a first-class physician who used laboratory aids only when they were essential to the diagnosis. Apart from his skill as a physician his constant cheerfulness and his kindness helped greatly to restore many people to health. Whatever group or society he belonged to, his was always the chief driving power behind the organization.

WILLIAM A. BREND, M.D.

We regret to announce that Dr William Alfred Brend, barrister-at-law of the Inner Temple, died on Oct 5 at Charing Cross Hospital, where he had been lecturer in forensic medicine for many years.

Born in Kensington on April 29, 1873, son of William Brend, M.R.C.S., he was educated at St Paul's School, Sidney Sussex College, Cambridge, and King's College, London. He took a first in the Natural Sciences Tripos in 1895, and a year later the B.Sc. (Lond.) with honours, taking the M.B., with honours in forensic medicine, in 1903, and the M.D. in State Medicine

(with gold medal) in 1915. He received the M.R.C.P. in 1939. During the last war he served as temporary major, R.A.M.C., and was inspector of hospitals in France and Belgium for the Croix Rouge. Brend was a member of the British Psychological Society and the British Psycho-Analytic Society, and served for some time as Neurological Deputy Commissioner of Medical Services under the Ministry of Pensions; he had also had charge of the special Medical Board for Functional Nervous Disorders. Apart from his teaching post at Charing Cross Hospital he examined in forensic medicine for the Universities of London and Edinburgh, was an active member and at one time vice-president of the Medico-Legal Society, and wrote a *Handbook of Medical Jurisprudence and Toxicology* for the use of students and practitioners, which reached a seventh edition ten years ago. He also contributed to the *Nineteenth Century*, the *Edinburgh Review* and to medical journals, and published in 1915 an inquiry into the statistics of deaths from violence and unnatural causes in the United Kingdom, and in 1917 a book, *Health and the State*.

Dr Brend served at the headquarters of the B.M.A. on the Ministry of Pensions Subcommittee, and on the subcommittee on Amendment of Coroners' Laws and Death Certification, and was vice-president of the Section of Public Medicine at the Annual Meeting held at Bath in 1925.

Dr ARCHIBALD GORDON GULLAN, consulting physician to the Liverpool Stanley Hospital, died on Sept 9 at his home at Formby. He had been a member of the Liverpool City Council and was chairman of the Liverpool Division of the B.M.A. in 1928-9. He was born at Swansea on Oct 15, 1871, and from Berkhamsted School went to study medicine at University College, Liverpool, where he won the Holt Scholarship after qualifying in 1894. Two years later he graduated M.B. (Lond.) and proceeded M.D. in 1899; he obtained the F.R.C.S. diploma in 1897 and the M.R.C.P. in 1901. His early appointments in Liverpool were those of medical tutor and registrar at the Royal Infirmary, assistant physician to the Infirmary for Children, and demonstrator of anatomy and of physiology in the University. He served during the last war with the rank of lieutenant-colonel, R.A.M.C.(T), as officer commanding the 1/3 West Lancs Field Ambulance, he was later in charge of the Military Hospital at Gibraltar, and described in these columns the epidemics of cerebrospinal meningitis and of influenza on the Rock. In addition to his long service on the visiting staff of the Stanley Hospital Dr Gullan was also consulting physician to the Waterloo Hospital and lecturer on clinical medicine in the University. He represented his Division at the Annual Meetings of the B.M.A. at Oxford, Leicester, and Exeter in the early years of this century, and held office as secretary of the Section of Medical Sociology when the Association met at Liverpool in 1912.

NORAH BORE, B.A., M.R.C.S., L.R.C.P., L.R.A.M., who died on Sept 12, had had, alas, only five years of medical practice. Before that she had had a career in the musical and educational world where she showed the remarkable qualities of mind that won the admiration and love of many colleagues. It was as a teacher that her interest first turned to child psychology, for she felt the futility of an educational system which concentrated only on intellectual training while neglecting the child's emotional needs. She therefore took up the study and practice of psychology, only to become convinced that she could not make her full contribution to this work without a medical training. Hardly had she begun as a medical student when she was attacked by the disease which finally killed her. With full knowledge of the odds against her, she decided to go on. She qualified in 1939 and undertook a year's general practice in a Welsh mining district and a further year as medical officer in a mental hospital before she considered herself ready for her chosen work. She brought to it a sureness of touch and profundity of understanding that at once gained recognition. Her services were sought after in child guidance clinics all over the country. Her unstinting response probably hastened her end, but, as always, it was a deliberate choice. She preferred not to hoard her life. In these last three years she achieved what seemed to those who knew her a miraculous ascendency over pain and weakness. While she was working she was so effortless and easy that an outsider would not have known that she was ill. Her work in this time was more than can be measured in quantity or duration. Although death cut it short, her grateful patients and her at least, equally grateful colleagues feel that its value will live on.

The tragic death, on Sept. 24, of Brevet-Col. JOHN OSCAR THOMAS, M.C., T.D.—drowned whilst bathing—is a great loss to his many friends and colleagues in and around Rochester, where he had been in practice since 1923. Born in 1891, Thomas was the younger son of the late Mr. and Mrs. Walter Thomas of St. Blazey, Cornwall, and received his medical education at the Westminster Hospital, London, where he was a scholar and prizeman. Qualifying in 1914, he served throughout the last war, during which he was awarded the Military Cross, subsequently returning to the Westminster Hospital, where he held all the resident house appointments, became the first resident medical officer, and took his M.D. and M.R.C.P.Lond. Thomas settled in Rochester in 1923. Early in 1927 he was appointed honorary assistant physician to St. Bartholomew's Hospital, Rochester, and has been an active member of the medical committee for many years. In 1933 he established the department of electrocardiology. Later he was appointed honorary physician with charge of in-patients, and recently became full honorary physician. Despite the heavy calls of an extensive consulting practice Thomas kept up his close association with the Territorials, holding for some years command of the County of London 140th Field Ambulance, and on the outbreak of the present war he was called up from the Reserve of Officers and left his practice to organize a general hospital of 1,200 beds, with which he went to France in October, 1939. In the withdrawal of the B.E.F. he was one of the last to leave St. Nazaire. In September, 1940, he mobilized another medical unit, which he took to the Middle East, serving there for three years, first in command of No. 5 Convalescent Depot in Sinai Peninsula, and later commanding No. 16 General Hospital (A.M.S.). Always a keen horseman and a strong swimmer Thomas's busy life gave him little leisure for these relaxations. He leaves a widow and one daughter, and in their grievous loss may they find some consolation from the high personal regard in which he was universally held and the large number of those who gathered at the memorial service in Rochester Cathedral to pay their tribute.

Medical Notes in Parliament

E.M.S. Hospitals

Hospitals in the Emergency Hospital Scheme are administered by their normal governing authorities and not by the Ministry of Health. The scheme now includes 1,640 hospitals, of which 671 are controlled by local authorities. Medical officers attached to a local authority hospital are under the discipline of the hospital authority, which is generally exercised through the medical superintendent. The scheme as originally planned provided for the treatment of civilian casualties from enemy action and of persons transferred from one hospital to another to afford accommodation for the treatment of such casualties. The treatment of these cases is provided for under sections 50 and 53 of the Civil Defence Act, 1939. The scheme has since been extended under agency arrangements made with the Government Departments concerned and authorized by the Treasury, to include Service casualties and sick, members of the Merchant Navy, and various groups of civilian patients engaged on work of importance to the war effort in this country. This information was given by Mr. Willink on Oct. 11 in answer to an inquiry by Sir Ernest Graham-Little.

Production of Penicillin

Replying on Oct. 11 to Mr. A. Edwards, Sir ANDREW DUNCAN said the volume of penicillin production both in this country and in North America had substantially increased during the past three months. Total supplies amply covered Service needs. Increased quantities would become available for civilian use. A large-scale plant now being erected in this country would be managed by the Distillers Company for the Ministry of Supply and would begin production in the spring of next year. Inquiries about civilian supplies should be addressed to the Ministry of Health. Dr. HADEN GUEST reported that Mr. Willink had made penicillin available when required in a large number of cases, and that a circular to that effect had been issued to all medical men in the country.

Psychiatrists for Duty in Prisons

Mr. HERBERT MORRISON announced on Oct. 12 that the Prison Commissioners have appointed two consulting psychiatrists to act as part-time medical officers at Wormwood Scrubs and Holloway Prisons. Medical officers at all prisons have been instructed on the types of cases in which psychological treatment may be beneficial. These cases are transferred to Worm-

wood Scrubs or Holloway for assessment and treatment. The psychiatrist at Wormwood Scrubs, who was appointed in February, 1943, examined in that year 60 male prisoners, of whom 18 received full courses of treatment. The psychiatrist at Holloway, who began work in April, 1944, has investigated 25 cases, of whom 7 are receiving active treatment.

University Representation

The House of Commons went into committee on Oct. 11 on the Redistribution of Seats Bill. Mr. PRITT moved to omit the clause relating to university constituencies. He contended that if persons who had university education were specially represented in the House, there should also be special representation for scientists and doctors. Prof. SAVORY recalled that his predecessors in the representation of Belfast University had been Col. Sinclair, a most distinguished surgeon, and Sir William Whittall, whose *Dictionary of Treatment* forms part of the library of every doctor. Sir ERNEST GRAHAM-LITTLE said there was a strong view that political qualifications should not be considered in a member of a university. He followed that rule himself. He pointed out that Prof. A. V. Hill was a link between the Royal Society and the House. Mr. PEAKE pointed out that the Speaker's Conference on Redistribution had agreed that the representation of the universities should continue. Mr. Pritt's amendment was defeated by 152 to 16. The Bill passed through Committee and was read a third time.

Treatment of Silicosis.—On Oct. 10 Mrs. TATE asked the Minister of Fuel and Power whether he had any information about the discoveries that had been made at McGill University, Montreal, concerning the prevention and cure of silicosis. Major LLOYD GEORGE said he was aware of the experiments going on in Canada on the treatment of silicosis by the inhalation of aluminium powder, which were probably what Mrs. Tate had in mind. These experiments were being closely watched both by his Department and by the Medical Research Council, but he was advised that the results were not yet conclusive enough to justify the adoption of this method of treatment at British mines. Mrs. TATE asked if the Minister would get into touch with McGill University to see whether these were the same experiments. Major LLOYD GEORGE said he would certainly do so, but he believed that our people had been in touch. A report was recently published in South Wales dealing with the question of silicosis, and as a result of that he was satisfied that every possible research was being made.

Notes in Brief

A substantial additional tonnage of paper has now been allocated for educational books.

A free grant of £477,500 has been made under the Colonial Development and Welfare Act for the construction of a new hospital of 1,100 beds at Mulago, Uganda. The Governor proposes to increase the present accommodation to 700 beds in temporary buildings while the new hospital is under construction.

The Services

The King of Egypt has conferred the Insignia of the Third Class of the Order of the Nile on Lieut.-Col. A. G. Harsant, O.B.E., R.A.M.C., on the occasion of his retirement from the professorship of anatomy in the Faculty of Medicine at Fouad University.

Capt. (Temp. Major) D. G. C. Whyte, R.A.M.C., has been awarded the D.S.O., and Capt. R. R. Lal, I.A.M.C., the M.C., in recognition of gallant and distinguished services in Burma.

CASUALTIES IN THE MEDICAL SERVICES

Killed in action.—Capt. Matthew Donald Murrough Bergin, R.A.M.C.

Died.—Capt. William Dinwoodie Speedy, War Subs. Capt. Ian Malcolm Hill, R.A.M.C.

Previously reported missing, now reported to have died while a prisoner of war.—Capt. Percival Binnington, R.A.M.C.

Missing, presumed lost at sea, while prisoner of war in Japanese hands.—Major John Moore Officer, R.A.M.C.

Reported missing.—Capt. T. F. Redman, R.A.M.C.

Reported missing, believed prisoner of war at Arnhem.—Col. G. M. Warrack, A.D.M.S., 1st Airborne Division.

Missing at Arnhem.—Capt. J. G. Jones and B. Brownscombe, R.A.M.C.

Missing at Arnhem, believed prisoner of war.—Capt. G. B. D. Scott, R.A.M.C.

Missing from operations in N.-W. Europe.—Capt. C. A. Simmonds, R.A.M.C.

Missing in Italy.—Capt. E. Haigh, R.A.M.C.

Wounded.—Major R. L. Harward, War Subs. Capt. D. H. Swayne, I. S. Dalton, M. MacIntyre, I. F. Thompson, Lieut. W. L. Cooper and J. H. Orr, R.A.M.C.

Repatriated.—Surg. Lieut. A. P. B. Waind, R.N.V.R.

No. 39

EPIDEMIOLOGICAL NOTES

Discussion of Table

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 30.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included); (b) London (administrative county); (c) Scotland; (d) Eire; (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London); (b) London (administrative county); (c) The 16 principal towns in Scotland; (d) The 13 principal towns in Eire; (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

Stillbirths	182	14	32	—	—	205	24	36	—	—
Rate per 1,000 total births (including stillborn)	—	—	—	—	—	—	—	—	—	—

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Cerebrospinal Fever

The falling trend of the incidence of cerebrospinal fever has been checked during the last two quarters. The incidence of this disease steadily diminished after the violent outbreak in the beginning of 1940, and the successive peaks and endemic levels fell until 1943. Although the number of cases in the first quarter of this year were only three-quarters of the number in 1943, the returns for the second and third quarters showed little improvement on the totals for the corresponding quarters of last year. The number of notifications for recent years are:

	Average of 1936-9	1940	1941	1942	1943	1944
1st quarter ..	427	5,093	4,332	2,412	1,287	978
2nd " ..	333	4,190	3,415	1,859	916	873
3rd " ..	224	1,793	1,780	929	542	526

The trend for 1944 is similar to that of the pre-war years, but at over twice the level. The rates for each quarter are 2.3, 2.6, and 2.3.

Quarterly Returns for England and Wales

The birth rate for the second quarter was 19.3, and was the highest rate for a June quarter since 1925. The average birth rate for the second quarters in the five years before 1943 was 15.7. Infant mortality was 43 per 1,000 live births, 11 below the average of the ten preceding June quarters, and was the lowest rate ever recorded for a second quarter. Stillbirths formed 2.7% of the total births. The general death rate was 11.2 per 1,000, being 0.3 greater than the rate for the June quarter of 1943, but 0.8 below the average rate for the second quarters of the five years 1938-42. The natural increase—excess births over deaths—was 83,801, compared with 7,228, 50,674, and 67,802 for the second quarters of 1941-3.

Week Ending October 7

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,932, whooping-cough 860, diphtheria 509, measles 2,492, acute pneumonia 628, cerebrospinal fever 24, dysentery 390, paratyphoid 7, typhoid 7, poliomyelitis 19.

According to the U.S. Office of War Information, orthopaedic surgeons at Camp Wolters, Texas, have developed a new technique for treating "march fracture" when this occurs in the second and third metatarsal bones. A thin flat iron is built into the non-weight-bearing portion of the sole of the shoe, a felt or rubber pad sometimes being included as well. They call this device a "march bar," and claim that it produces rapid healing by protecting the bone from strain. The man is not sent to bed but kept on duty.

Medical News

At the annual general meeting of the Medical Society of London, to be held on Monday, Oct. 23, at 4.30 p.m. the presidential address on "Subjective Disorders of Sensation" will be given by the incoming President, Dr. Anthony Feiling.

Mr. R. A. Butler, Minister of Education, will address the School Medical Service Group of the Society of Medical Officers of Health at the Town Hall, High Holborn, London, W.C.1, on Friday, Nov. 3, at 2.30 p.m. He will speak on "The Place of the School Medical Service in the Education Service of the Future." The annual general meeting of the group will be held immediately after Mr. Butler's address.

The National Conference on Maternity and Child Welfare, which was postponed in July last owing to the restriction on travel, will be held on Thursday and Friday, Nov. 23 and 24, in the Big Hall of Friends House, Euston Road, N.W., with Sir George Elliston in the chair. The subject for discussion is "The Rebuilding of Family Life after the War." Mr. Henry Willink, Minister of Health, will give his presidential address on the second day at 10.30 a.m. Tickets, 3s. each for one day, 5s. each for two days, may be obtained from Miss M. R. Lovelock, secretary of the National Association of Maternity and Child Welfare Centres and for the Prevention of Infant Mortality, 117, Piccadilly, London, W.1.

A demonstration of some of their recent work will be given at the Inoculation Department of St. Mary's Hospital, W.C., by Sir Almroth Wright and Sir Alexander Fleming on Tuesday, Oct. 24, at 8 p.m. Owing to technical considerations the attendance will be limited to members of the Polish Medical Association in the United Kingdom and to members of the Paddington Division of the B.M.A.

The annual general meeting of the Middlesex County Medical Society will be held at Chase Farm Hospital, The Ridgeway, Enfield, on Thursday, Oct. 26, at 3 p.m., when an address will be given by Dr. C. Allan Birch on "Medical Emergencies." Visitors, including members of the American and Canadian Forces at present in this country, will be welcome.

At the next meeting of the Medico-Legal Society, to be held at Manson House, 26, Portland Place, W.1, on Thursday, Oct. 26, at 5 p.m., Dr. Eric Gardner will read a paper on "Death in the Bathroom." Members may introduce guests to the meeting; tea at 4.30.

The Personal Service League has consulted the British Hospitals Association in regard to the distribution of a substantial gift of dried banana. The League has accepted the suggestion that some of the dried banana should be held in reserve against its requirement for use in cases of coeliac disease or other emergency. Application may be made for supply to the Personal Service League, 41, Lowndes Square, London, S.W.1 (telephone, Sloane 6291) by day or night.

The twentieth annual report of the Nursery School Association of Great Britain for the year 1943 is a 16-page pamphlet, obtainable from the new headquarters at 1, Park Crescent, London, W.1.

Dr. James Deeny, F.R.C.P.I., has been appointed Chief Medical Adviser to the Department of Local Government and Public Health, Government of Eire.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a quarterly meeting of the Council held on Oct. 12, with Sir Alfred Webb-Johnson, President, in the chair, Dr. Rupert A. Willis, pathologist at the Alfred Hospital, Melbourne, Australia, was appointed as the first Sir William H. Collins Professor of Human and Comparative Pathology. Prof. Matthew Stewart was elected Moynihan Lecturer for 1945. Mr. P. H. Lovell was nominated as the fifty-second Jenks Scholar. Votes of thanks were given to Sir Buckston Browne for an augmentation of the endowment for the annual dinner of Fellows and Members of the College; to Mrs. Cecil Joll for a silver-gilt loving cup, once the property of William Cheselden; to Miss B. C. Crookshank for a fire-screen panel embroidered with the arms of the College; and to Mrs. King for pictures and busts of Sir William Blizard.

Diplomas of membership were granted to R. Astley, F. Batley, M. F. Bethell, P. H. Friedlander, Alison B. Hay-Bolton, Adrian Hill, J. G. Kendall, R. J. P. Pugh, Irvine B. Smith, A. McR. Walker.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* also unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publisher, B.M.A. House, Tavistock Square, W.C.1, on receipt of proof. Authors over-seas should indicate on MSS. if reprints are required, as proof are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh

ANY QUESTIONS?

Sulphonamides and Sterility

Q.—I have heard it stated that the sulphonamide group of drugs induce sterility. Is there any truth in this? If so, how long would the sterility so induced last?

A.—There are animal experiments which suggest that the sulphonamide group of drugs may reduce spermatogenesis, but the bad effect is only temporary and not likely to last more than a few months. It is difficult to give clinical evidence of this because the infections for which sulphonamides are given are themselves likely to reduce fertility.

Cockroaches and Infection

Q.—How far are cockroaches known to serve as carriers of human infection?

A.—Several experiments have shown that cockroaches can transfer germs mechanically on their legs, and it has also been reported that the following bacteria can be passed through the alimentary canal of a cockroach, quite unharmed: *B. tuberculosis*, *B. lepra*, cysts of *Entamoeba histolytica*, and *E. coli*. Transmission of human infection is liable to occur under the following conditions: (1) if the cockroaches have access to human food; (2) if they have access to sources of infection. Condition 1 must be very commonly fulfilled, as cockroaches are mainly troublesome in kitchen. The sources of infection (2) vary from one situation to another: there may be particular danger where there are cases of illness present, as in a hospital. A habit of cockroaches which makes them likely to pick up germs is their frequent searching for water, which leads them to visit sinks, drains, slops, etc.

The Psychology of "the Presser"

Q.—What is the mental process involved in the phenomenon known as "pressing" in the game of golf? Carried to its logical conclusion the emotions obtain complete sway over reason. The same psychological process is seen under different disguises in every day life. What is the remedy?

A.—"Pressing" in golf is the physical result of the longing to do superlatively well. The cure is not "Don't press," but, "Be content to go by easy stages from tee to pin." The better-class players and professionals do not "press" because they have a stab confidence in their own ability, born of aiming at the possible as not the impossible. The "presser's" muscles are taut and poor co-ordinated because he aims at an ideal and is apprehensively aware that this is pitched too high. The "pressers" in everyday life are aiming too high and refusing to face their limitations. Reason must control the emotions if the source of the anxiety to succeed can be faced and checked—e.g., where an adolescent deems it necessary to live up to a parent's ambitions. Emotions outrun reason when the source of the ambition presides in a modified "Lady Macbeth complex," to succeed in order to stamp out shame or guilt. The "pressers" in everyday life strain not so much the muscles of the upper extremities as their autonomic system, which reacts with irregular peristalsis and is registered as nervous dyspepsia or nervous colitis. The remedy is simple persuasion in the first group, more intensive psychotherapy in the second (if this is not contraindicated) and small doses of luminal to help them through special periods stress.

Erb's Paralysis

Q.—What is the treatment of Erb's paralysis in an infant—result of a very difficult confinement?

A.—Erb's paralysis is usually caused by traction of the upper part of the brachial plexus, leading to tearing of the nerve fibres and subsequent paralysis of the muscles which surround the shoulder—particularly the deltoid and the spinati, and the forearm muscles particularly biceps, brachialis anticus, and the supinator longus.

Treatment depends upon how long the paralysis has been present and upon whether it is thought that neurosurgical treatment is likely to be of benefit. It is a very difficult problem to decide whether it is going to be worth while to expose the nerves in the hope of approximating the ends in order to encourage regrowth of nerve fibres. The results are not sufficiently good to make one advise this procedure wholeheartedly. Some say that it is best when the paralysis is severe to explore as soon as possible in the hope of effecting a reasonable union; others recommend waiting for about six months to see whether any recovery is taking place. The physician should be guided in this by the severity of the paralysis. In any case the affected arm should be put up in a light splint producing abduction of the shoulder and flexion of the elbow—the so-called aeroplane splint. The condition of the muscles should be maintained by light massage and by adequate galvanism, which has been found to be effective in preserving muscle bulk. Later on, if paralysis persists, orthopaedic treatment can do much to improve the usefulness of the arm, particularly by transplanting muscles and by limiting the mobility of the shoulder-joint. Unfortunately many cases will require some such intervention.

Saline Infusion into Tibia

Q.—Could you advise me on the technique of saline infusion into the marrow of the tibia?

A.—Technique of saline infusion into the marrow of the tibia is similar to that of blood transfusion. An ordinary administering or taking needle as used in the apparatus for taking or giving blood supplied to the E.M.S. can be employed if ground to a proper length. If preferred the Salal sternal puncture needle is quite satisfactory. Splint the leg with a straight splint applied to the outer aspect of the leg and keep in position by ties from the foot to mid-tibia and from the lower to the upper thigh. The site of puncture is the antero-medial surface of the tibia at the level of the tibial tubercle, which can be easily felt even in the youngest infant. The skin is cleansed with soap and water and iodine or alcohol, and a local anaesthetic injected into the skin subcutaneous tissues and periosteum. The puncture needle is then inserted at right angles to the plane of the antero-medial surface of the tibia as nearly as possible halfway between the anterior and medial borders of the tibia. The needle should be inserted distally—i.e., away from the epiphyseal line—but a needle absolutely vertical in all planes should miss the epiphyseal line. The soft bone of an infant is punctured easily and gives the feeling of stale cheese; no marked give is noted when the marrow cavity is entered. Entry is usually attained about 1/8th to 3/16th of an inch below the periosteum and can be proved by the aspiration of marrow. The procedure is then the same as for sternal puncture. The infusion tends to be slow at first and to increase in rate spontaneously after 5 to 10 minutes. The infusion, therefore, in infants usually has to be slowed from time to time rather than quickened as in the adult. Reference may be made to the papers by Tocantins, O'Neill, and Jones, *J. Amer. med. Ass.*, 1941, 117, 1229; Hamilton Bailey, *British Medical Journal*, 1944, 1, 181; and Janet Gimson, *ibid.*, 1944, 1, 748.

Dehydration

Q.—What is the pathology and treatment of the clinical entity known as dehydration?

A.—A most readable account of dehydration with full references to the literature is given in the chapter on thirst in Macdonald Critchley's book *Shipwreck Survivors*, London, 1943. Many of the symptoms of disease which were formerly ascribed to toxæmia are now regarded as the effects of dehydration. About 70% of the body weight consists of water. If more than 10% of this water is lost—i.e., 6% of the total body weight—the patient shows signs of serious dehydration—scanty urine, dry skin and tongue, and sunken eyes. Dehydration may occur from a diminished intake of fluid, as in the shipwrecked sailor or the stuporose patient; or from increased loss, as from a high internal or external temperature, vomiting, diarrhoea, or polyuria. Dehydration is an important factor in states of acidosis and alkalosis.

Two good rules for avoiding dehydration are never to pass a febrile patient without offering him a drink and never to purge a really sick man. Treatment is the restoration of the fluid balance by large volumes of fluid by mouth or parenterally. The normal output of fluid is about 2,500 c.c.m. a day—1,500 c.c.m. of urine and 1,000 c.c.m. of water of evaporation from the skin and the lungs. In disease the output may be greatly increased, and a daily fluid balance chart should be kept of all patients who are threatened with dehydration. By the time a patient shows dehydration he has a debit of some 5 litres of water, so he will require at least 8 litres of fluid in the first 24 hours to restore him to normal. The kidney is not very efficient in dehydration, and care must therefore be taken not to wash an excess of salt out of the body or, on the other hand, to put in an excess of salt. About 5 g. a day is the optimum. Wherever possible fluid should be given by mouth, glucose orangeade made with one-fifth normal saline being suitable. If this is not possible the rectum is the next best route, and the fluid should be

one volume of normal saline to four volumes of tap water. Intravenously a mixture of one volume of normal saline with four volumes of 5% dextrose in distilled water may be used, but it is wise to examine the bases of the lungs and the blood chemistry at frequent intervals if large volumes of fluid are given parenterally. The body cannot pick and choose when fluid is given parenterally, and it is fatally easy to give an excess of fluid by this route.

Congenital Absence of Abdominal Muscles

Q.—At birth a child was found (forceps delivery) to have a large abdominal cyst which apparently was evacuated in utero, for the amniotic fluid contained hair and was therefore presumably a dermoid cyst. The ribs at birth were much everted, and the abdominal wall lay in thick folds, suggesting that the cyst was large and accounted for the delay in birth. The baby unexpectedly responded to stimulants and is now 5 weeks old. The abdominal wall is still much thickened and corrugated, but the baby is fit and developing normally. A cyst could be felt in the lower abdomen three weeks ago, and it was thought the tumour was filling up, but this has disappeared although the stool has apparently been normal and there is no discharge from the vagina or rectum. The urine is normal. Can any suggestions be made of the origin of the tumour, the prognosis, and the treatment?

A.—I think the case described is one of congenital absence of the abdominal muscles. An excellent illustration of this curious condition is to be found in the 3rd edition of *Diseases of Children*, by Garrod, Batten, Thursfield, and Paterson, on page 847. The syndrome consists of complete absence of abdominal muscles, thickening and wrinkling of the skin on the abdomen, which makes it look like elephant hide, and gross dilatation of the pelvis of the kidneys, the ureters, and the bladder. The connexion between these three factors is far from obvious. It is hard to imagine that simple stretching of the skin can produce the extraordinary thickening or that the absence of the pressure of the abdominal muscles should cause the urinary drainage system to dilate. It has been suggested that gross distension of the abdomen by the expanded bladder may have prevented the development of the abdominal muscles; but this again seems unlikely. I do not think that there is much doubt that the "cyst" felt in the abdomen was a dilated bladder. I have never before heard of hairs being found in the amniotic fluid in this condition, but if they had come from inside a dermoid cyst there would almost certainly have been a large amount of sebaceous matter as well.

As to treatment I have had a case which appeared to be distinctly benefited by a specially made elastic corset which supplied the pressure which should have been exerted by the abdominal muscles. Prognosis is, of course, poor. The dilated urinary system is liable to infection and the absence of abdominal respiration gives a bad outlook in bronchitis or pneumonia. Most cases die in the first year or two from one or other of these causes.

Enlarged Hilar Gland

Q.—A person gives a history of contact with a case of pulmonary tuberculosis. On examination the lungs are clear. Sedimentation rate and sputum are both normal. On x-ray investigation the radiologist gives the following report: "Enlarged hilar shadows," or "Hilar shadows more evident than normal." The lung field is otherwise normal. What importance am I to attach to such reports?

A.—If the patient is a child, the most probable cause of hilar gland enlargement, in the circumstances, is a primary tuberculous infection. If, however, the tuberculin skin test is negative, other causes of hilar gland enlargement such as pertussis or more rarely leukaemia or lymphosarcoma would have to be excluded. In the case of a primary tuberculous infection the absence of clinical signs of activity would indicate that no treatment is necessary. The child should be removed from contact with the infection and kept under close observation with frequent x-ray examinations. If the patient is an adult the same remarks apply except that primary tuberculosis becomes less likely and lymphadenoma would have to be excluded. Very slight enlargement of the hilar shadows is often of no significance.

Afferent Nerve Impulses and Shock

Q.—Given that "pain" is a large factor in the production of shock, both immediate and delayed, in the case of burns, is it possible that afferent impulses resulting from stimulation of temperature nerve-endings in the skin and passing up "heat tracts" in the cord are an added or associated factor? Not only might this apply in the case of heat—i.e., the immediate shock of the actual burn or scald—but also in the case of cold resulting from the inevitable baring and exposure of the burnt surface—delayed shock.

A.—The part played by afferent nervous impulses in the production of shock is far from clear. The most painful injuries—e.g., hands mangled in machinery—may be associated with no fall in blood pressure. Atkins (*Brit. J. Surg.*, 1937, 24, 717) has shown that the blocking of pain sensation by procaine in the brachial plexus is associated with a fall rather than a rise in blood pressure.

It is thus quite likely that painful sensations exert a pressor rather than a depressor influence on the circulation. The general cardiovascular reaction to heating the body (vasodilatation) has been shown by the schools of Carmichael and Lewis to result from the action of warmed blood on the vasomotor centres. Nervous impulses passing up the thermal pathways in the cord have little if any influence in producing this effect. It seems unlikely, therefore, that thermal nerve impulses as such play any part in producing shock or in modifying the clinical picture.

Reverting to the first clause of the question, pain is well recognized as a factor precipitating a fainting reaction. Barcroft and his colleagues have now shown that fainting results from a nervous mechanism which induces vasodilatation in voluntary muscles (*Lancet*, 1944, 1, 489). This so-called vaso-vagal type of shock is easily recognized by its association with bradycardia and other features. It might well be expected to occur in burn shock, but specific data on this point are lacking.

INCOME TAX

New Practice: Cash Basis

L. G. took over a practice on a death vacancy as from March 26, 1943. His predecessor (and he himself in a former practice) had previously been assessed on the basis of cash receipts. The inspector of taxes refuses to accept this basis for the first three years of the new practice.

** The inspector's action is legally correct and is in accordance with the usual custom. It is undeniable that the cash receipts of a first year do not give a true reflection of the earnings or profits of that year, and the tax is chargeable on profits, not merely on profits which have come to hand in cash. So L. G. will have to add to the amount of his cash receipts for the year to March 26, 1944, the value of the debts outstanding at that date, say £x less £7 (the estimated amount to be lost by non-payment). At the end of his second year he will deduct that amount from his cash receipts for that year and add the value of the debts outstanding at March 26, 1945, and so on. On that basis there need be no fear that the receipts will pay tax twice.

Board and Lodging

R. B. S. assisted a doctor as a locum tenens for a fortnight and arranged that the usual expenses of himself and his wife should be paid during their stay in lieu of salary. The income tax authorities are claiming tax on the amount of these expenses, less an allowance for railway fares to and from the place of employment.

** Assuming that the board and lodging were the responsibility of the principal—e.g., that R. B. S. did not incur the liability for payment to the landlady and the principal meet the liability for him—then we do not understand the action of the authorities. It is settled law that the receipt of benefits in kind which are not capable of being turned into money by sale, etc., does not create liability to tax. If, however, A owes his landlady £25 and B by arrangement pays it for him, that is equivalent to a payment of £25 by B to A.

LETTERS, NOTES, ETC.

Tetanus Immunization for Farm Workers

Dr. J. A. EDDY (Norwich) writes: I feel that the reply in "Any Questions?" (Sept. 16, p. 391) errs seriously on the side of complacency. You state that "among agricultural workers the risk is small," and give instances of two severe types of wound for which antitoxin would be required. I have had two cases of tetanus in this district as a result of apparently quite trivial wounds. One was a cut less than 1/2 in. long in the finger made while sharpening a hedging tool. I am pleased to add that I was not responsible for the original dressing of this wound. The other case was in a man who had been lifting sugar beet with his hands. There were several very superficial scratches, one of which had become infected, but so slightly that the patient did not seek any advice until he was actually suffering from clinical tetanus. Both cases recovered in hospital. The only safe answer to this question is that unless the farm worker is protected by means of tetanus toxoid a dose of antitoxin must be given after every wound, however trivial. The hands of these men are always likely to be contaminated with soil.

Telegony

Dr. K. B. PINSON (Manchester) writes: In the *Journal* of Aug. 26 (p. 296) the answer which you give to a question regarding telegony is, I think, quite wrong about Darwin. The impression I gathered from reading *The Origin of Species* was certainly not that he had any belief in it. In fact I do not think he mentions it anywhere. I have carefully read again all that he said in *The Origin* concerning Lord Morton's mare. The whole argument, which passes from the markings and blue colour apt to appear when distinct breeds of pigeons are crossed to the zebra-like striping on the legs

and shoulders and even the face, as well as on the hindquarters and spine of some breeds of horses, and particularly in the offspring of crossed species of the horse genus, is to support the contention that there is a tendency to revert for some reason in such cases to an ancestral type, which, in the pigeon, is known and in the horse presumed. The markings are associated with colour—blue in the pigeon and dun in the horse. Lord Morton's mare was crossed with a quagga (a species now rare or perhaps extinct), and the hybrid was much more striped on the legs than a pure quagga. So also, however, was the offspring of a subsequent mating of the mare with a black Arabian stallion. Darwin accounts for this not by telegony but by the above observed tendency to stripes, especially when a dun colour appears. This is not the first time I have come across an important misrepresentation or misapprehension, as I think, of Darwin's thesis. For one thing the book needs attentive reading, and when he sets out to answer a question it is not by a short cut-and-dried answer but by illustrations and inferences not always easy to follow.

Byssinosis

Dr. H. S. RUSSELL (Shipley) writes: Your reply (May 27, p. 737) concerning byssinosis suggested that it occurred in woolen mills and was connected with "mill fever." May I point out that only cotton mills are affected by the Byssinosis Order, and that mill fever is considered to be due to a mould contaminating the cotton, while byssinosis is due to the cotton fibre itself. Incidentally, the condition of chronic bronchitis and emphysema almost universally found in woolcombers is not legally an industrial disease. Why any discrimination should be made between cotton and wool operatives is very difficult to understand.

The Metric System

Dr. IAN CAMPBELL (Mexborough, Yorks) writes: The correspondence on the advantages of the metric system in prescribing prompts me to write that in the last six months three wholesale medical firms have been unable to supply a 10-c.cm. conical measure!

Pyretotherapy for Gonorrhoea

Dr. A. H. BARTLEY (London, S.W.16) writes: A colleague asked for a description of the T.A.B. vaccine shock treatment for gonorrhoea (*Journal*, Oct. 7, p. 457). May I be permitted to describe my method which I wrote about in the *Lancet* in September 1935. On admission the patient is put to bed on a milk diet and given an intravenous injection of 0.25 c.cm. T.A.B. vaccine (Arm brew) in 5 c.cm. sterile normal saline solution. In about an hour he develops a typical malarial attack, the temperature rising to 103°–105° F. The next day the patient as a rule is quite normal but some complaint of a slight headache may be made. The injections are repeated every third day, the dose of T.A.B. vaccine being increased by 0.25 c.cm. each time. By the third injection the patient is "dry." Three injections usually suffice. I gave four in one case only. In conjunction with this treatment local irrigations of weak solution of potassium permanganate, 1 in 10,000, is given night and morning in between the injection days, and an alkaline mixture is given internally thrice daily. I used this method for fresh and chronic infections and got excellent results in both, especially with the crippling type of arthritis that sometimes complicates gonorrhoea. Gonococci disappear from the smears after the second injection, and no after-effects whatever were noted. I emptied ward of 20 cases in a month. Some of these cases had been trailing on for six months or more. I had no relapses.

Concurrent Herpes Zoster and Varicella

Dr. EMILY SIMON (London, W.5) writes: It may be of interest to record the following case, which is strikingly similar to I. Manning's case (July 22, p. 115). A man aged 63, previously in good health, complained in the evening of March 21, 1943, of stiffness of the left side of the neck. The following morning there was a crop of vesicles over the back of the left shoulder and the left side of the neck. The vesicles enlarged and crusted and were typical of herpes zoster. On March 23 a few pink macules and papules appeared on the trunk, and by March 26 the patient had a well-developed varicella rash involving trunk and limbs. The zoster lesions were still present but subsiding. There was no previous history of chicken-pox or of herpes zoster, and no history of contact with either disease. I am indebted to Dr. Warden, the family physician, for asking me to see this case. I have also seen a case of well-marked varicella in a middle-aged woman preceded by herpes zoster of the right frontal region. Both rashes were present at the same time, but the herpetic eruption was a day or so in advance of the chicken-pox.

Correction

In Lieut.-Col. R. W. Fairbrother's article "The Control of Bacillary Dysentery," there was an error in the last line but one of the first column on p. 490, Oct. 14. Group (a)—as the first paragraph in the next column makes plain—should read "routine with sulphonamides."

LONDON SATURDAY OCTOBER 28 1944

THE NEED FOR ASEPSIS IN LOCAL PENICILLIN THERAPY

WYLIE McKISOCK, M.S., F.R.C.S.

BY

VALENTINE LOGUE, F.R.C.S., M.R.C.P.

AND

IAN BARTHOLOMEW, M.R.C.S., L.R.C.P.

(From a Neurosurgical Unit)

A study of the Preliminary Report to the War Office and Medical Research Council on Penicillin by Prof Florey and Brig Cairns (1943) reveals that Gram-negative organisms have been found in the discharge from penicillin-treated wounds. In some cases such organisms as *Bact coli*, *Proteus vulgaris*, and *Ps. pyocyanea* have been grown from the aspirate from wounds receiving local injections of penicillin solution, and in others they have been cultured from pus issuing from similar wounds before healing was complete. Often enough the presence of such organisms, either in aspirated fluid or in purulent discharge, appeared to cause no serious complication or to delay healing unduly: on page 99, for example, it is stated, "Penetrating Brain Wounds.—The bacteriological results (Table II) usually showed that after two days' treatment of the brain cavity with penicillin Gram-positive cocci were no longer found in the fluid sucked or discharged from the wound, organisms of the coliform group were almost invariably present. In wounds which remained completely closed this state of affairs persisted until healing was complete." A further statement, on page 104, runs as follows. "For wounds more than a week old penicillin solution was usually used for 3 to 5 days. Though the end-result was satisfactory, and there was never any exacerbation of pre-existing infection as a result of closure, yet usually a sinus formed in some part of the wound and discharged pus for some days before it finally healed." Particular emphasis is laid upon *Ps. pyocyanea* as a common infective agent in such pus or wound aspirate in a paragraph on page 39. "In many wounds Gram-negative bacilli made their appearance during treatment. This was particularly so with *B. pyocyanea*, which usually persisted until healing was complete"; and a more detailed description is given in the form of a brief case record (p. 102).

"July 27. Operation.—Free pus beneath the scalp. Brain fungus projecting through a dural opening (2 cm diameter). Five bone chips removed from the brain to a depth of 2.5 cm. The resulting brain cavity held 5 cm of penicillin solution. Scalp closed in two layers by a plastic procedure. One tube for penicillin solution, 9,000 units in six days. Bacteriological examination showed *Staphylococcus aureus* in swabs from all levels of the wound. July 29. Fluid aspirated from the wound shows in films pus cells and no organisms, on culture *B. pyocyanea*. Aug 1. Wound edges moist at one point. On aspiration, 25 cm of thin blood-stained pus (culture '*B. coli*', *B. pyocyaneus*). Aug 3. Culture of aspirated fluid—'*B. coli*', *B. pyocyaneus*, enterococci. Aug 11. Wound intact. To base."

On the other hand, more serious results could readily be anticipated, and we find on page 100 a description of a death (one of three in a series of 23) which is attributed to "an error of surgical technique."

"At operation pus (*Staphylococcus aureus*) and necrotic material were found beneath the healing scalp, and the bone chips were removed. He was treated by local and intravenous or intramuscular penicillin for five days (3,000 units locally, 485,000 units parenterally). He became increasingly drowsy, and on the 10th day after operation his frontal wound was aspirated and 5 cm of pus were obtained from beneath the skin. Films of this showed no organisms, and culture yielded only '*B. coli*'. He died on the following night."

"At necropsy, beneath the intact frontal wound was a button of firm granulation tissue 2.5 by 0.3 cm. Beneath that in the

right frontal lobe was a large thin-walled abscess 5 cm in diameter and extending backwards above the right frontal horn for a distance of 12 cm. It was filled with pink pus. The ventricular wall was intact.

"Section of the abscess wall showed numerous Gram-negative organisms, and in one place, where there had been a tiny spicule of retained bone, clumps and chains of Gram-positive cocci. The cellular components of the abscess wall showed nothing remarkable."

It is true that the overlooking of one small bony spicule may be regarded as an "error," but it is a mistake very hard to avoid on occasion. No comment, however, is made upon the growth of *Bact coli* from pus aspirated from beneath the scalp, the presence of this penicillin-resistant organism may have played no small part in the development of the abscess and the subsequent death of the patient.

A point of considerable importance arising out of the quotations given above is the time at which such Gram-negative organisms gain entry to the wound. The suggestion has been made that they are present in the wound initially but are overgrown by staphylococci and streptococci in first cultures, and only when the latter organisms have been removed or inhibited in growth by penicillin therapy can the Gram-negative organisms be obtained in culture media. This supposition may well be true and cannot be denied.

One can, however, postulate that the presence of these Gram-negative organisms is but another example of added hospital or cross-infection of wounds. In the quotation given above from page 102 of the Preliminary Report it will be seen that *Staph. aureus* was grown from swabs taken from all layers of the wound at operation. Two days later fluid aspirated from the wound grew *Ps. pyocyanea* five days afterwards the aspirate grew in addition *Bact coli*, and on the seventh post-operative day *Bact coli*, *Ps. pyocyanea*, and enterococci were cultured. In this case three different organisms appeared in the course of five days, during which time the wound was aspirated on three occasions, and, in view of the repeated aspirations the possibility of cross-infection obviously existed.

The emphasis laid upon the presence of *Ps. pyocyanea* is rather unusual, for this organism is not commonly grown, in our experience, from swabs taken pre-operatively from traumatic wounds. In a period of over three years, for example, preliminary wound swabs were taken from a series of 247 patients with traumatic lesions, and in only 2 cases was *Ps. pyocyanea* grown—once in pure culture and once associated with haemolytic streptococci and micrococci.

Bact coli, *Proteus vulgaris*, and *Ps. pyocyanea* however, are well known as infecting agents in hospital or cross infection of wounds (McKissock, Wright, and Miles, 1941) and it is more reasonable to assume, therefore, unless or until proof to the contrary is forthcoming, that the appearance of these Gram-negative organisms in a post-operative wound is due to added or hospital infection.

The opportunity for cross-infection of a wound undergoing treatment with penicillin solution is particularly good. A rubber tube runs from the outside air to the depths of the wound, and through this channel injections of the penicillin solution are made, usually twice daily, for from 3 to 5 days. Unless

* Indicates primary operation elsewhere.

unusual precautions are taken to safeguard this channel against bacterial contamination it is easy to imagine the common faecal organisms (which are penicillin-resistant) being carried into the wound at the time of injection.

The occurrence, therefore, of "Gram-negative" purulent discharge from post-operative wounds, side by side with a new portal of entry for hospital infection, is significant, and should lead us towards the conclusion that we are faced with yet

* Case of hospital infection.

another illustration of hospital infection of wounds, to add to the many already in existence.

It may be true that, in the vast majority of cases, added infection of the nature which we have been discussing leads to no more untoward result than a short-lived discharge, delaying healing only by a few days, but, in dealing with large numbers of patients, those few additional days in hospital amount to a very appreciable number over the course of a year. The inevitable result must be an unnecessary use of hospital beds, drugs and dressings, and the time of hospital personnel. Apart from such minor complications and delays, more serious sequelae will certainly occur in the neurosurgical field, even if in small numbers, for *Bact. coli*, *Proteus vulgaris*,

and *Ps. pyocyanea* are all capable of producing meningitis or localized abscess.

A Short-term Experiment

It was with such thoughts in mind that a short-term experiment was undertaken to see whether these organisms need necessarily appear in penicillin-treated wounds or whether they could be excluded by methods designed to close the supposed new portal of entry (the penicillin tube) and by the other precautions against hospital infection of wounds already in use in the department (M.R.C. War Memoranda, 1941, 1944). No details of the ward and dressing technique in use need be given, for the basic principles have already been widely disseminated (Miles *et al.*, 1940), although far from extensively adopted.

To protect the penicillin tube from possible contamination the open end was closed with the metal valve and cap of a bicycle inner tube, the valve being cut short at the level of the side opening. This appliance could be sterilized and inserted into the tube before the introduction of the latter into the wound. Injections could subsequently be made through the metal valve using a syringe and needle, removing and replacing the screw cap each time, thus preventing soiling of the open end. Later a more satisfactory instrument was designed, the end of which accurately fitted a Record syringe, thus simplifying the giving of the twice-daily injections (McKissock, 1944).

The first 20 battle casualties from the Normandy campaign to be admitted to the department and treated with penicillin solution as a local injection were bacteriologically investigated. Swabs were taken before operation, at each subsequent dressing, and from the surface of the healed wound and surrounding scalp on the fifth day, when the penicillin tube was withdrawn. This last swab was taken to see what organisms were present on the scalp and healed linear wound surface, and were thus available to cross-infect the small 3-4 mm. stab wound from which the penicillin tube was later withdrawn.

It should be noted that these 20 cases were treated in a well-established neurosurgical unit with a numerically adequate, experienced, and well-trained nursing staff. Special attention had been paid to the education of the nursing personnel in all matters relating to ward and dressing technique and to the potentialities of hospital infection of wounds.

Shortly after the completion of the experiment, with the results which are given above (Table, First Series), the medical personnel of the unit, with a staff of theatre nurses only, were transferred to a hospital in the country to continue the treatment of battle casualties. The nursing staff of this hospital had had no previous experience of neurosurgical work or specialized ward and dressing technique, nor had they been extensively educated in matters relating to hospital infection. In these new surroundings it was felt that the risks of cross-infection would inevitably be greater, more especially as cases were admitted in much larger numbers and at shorter intervals. Under such circumstances many of the finer details in the avoidance of hospital infection (all, nevertheless, of considerable importance) could not be observed. It was decided, therefore, to investigate another similar series of 20 cases (Table, Second Series).

Roughly two-thirds of the 40 cases were operated upon by one surgeon (W. McK.) and one-third by the other (V. L.), the surgical technique in all essential details being the same throughout. Each patient received a five-day course of treatment with one of the sulphonamides, as follows: (1) All wounds were powdered with sulphanilamide before closure.

The first series received intravenous sulphathiazole for the 24 hours, followed by sulphamezathine by mouth for a further four days. (3) The second series were given sulphathiazole by mouth for five days—sulphamezathine not being available—and because of the shortage of trained personnel no patient received intravenous medication.

Penicillin was administered as a sodium salt solution in a strength of 1 000 units per c.cm., given twice daily for 5 days. The average dose in the first series of 20 cases was just over 39,000 units and in the second about 31,000 units. The average lapse of time between wounding and operation was 94 hours in the first series and 67 hours in the second: healing of the wound was complete in an average of 5.25 and 3.5 days respectively in the two sets of cases. The stab wound through which the penicillin tube was invariably inserted healed in 7.75 days in the first series and 7.3 days in the second: as this tube remained *in situ* for five days healing was reasonably prompt in all cases.

Results

An analysis of the accompanying tables reveals that in three cases in the first series organisms which could not be cultured from swabs taken from the wound at the time of the pre-operative dressing were grown from the healed linear wound surface and surrounding scalp when the dressings were removed for the withdrawal of the penicillin tube, although in no case

was there any evidence of infection of the wound or stab opening. In two of these cases the organism was *Bact. coli* and in one *Staph. aureus*. Healing of these three stab wounds was complete on the seventh, eighth, and seventh day respectively from the date of operation—i.e., two, three, and two days after removal of the penicillin tube on the fifth post-operative day. These three cases can be classed as potential hospital infections, although clinically they happened to be of no significance, as the wounds were already healed. These figures give a percentage rate of potential cross-infection of 15, the clinical cross-infection rate being 0.0%.

In the second series, under the changed domiciliary and nursing conditions, with the concomitant changes and lapses in ward and dressing techniques, new organisms were recovered from the healed wound surface and adjacent scalp in 7 cases of the 20 when the penicillin tube was withdrawn, giving a potential cross-infection rate of 35%. In only one of these seven cases did clinical evidence of actual cross-infection appear, giving a clinical cross-infection rate of 5% for this series of 20 cases. In five of the seven cases *Ps. pyocyanea* was grown, one produced the *Staph. albus*, and one grew *Proteus vulgaris* and a haemolytic staphylococcus.

The total average figures for the 40 cases are thus a 25% rate of potential cross-infection and a 2.5% rate of clinical cross-infection.

In the whole series of 40 cases there were thus 10 in which new organisms were grown, of which one case became clinically cross-infected, producing a profuse growth of *Ps. pyocyanea* and indicating very well the importance of the potential rate of hospital infection (25%); for, if the wounds had not healed so early, actual clinical infection might have taken place in every one of the ten cases. In the remaining nine cases, in which new organisms were found, the operation wounds were already healed, and the only portal of entry for the organisms to the deeper tissues would have been through the stab wound from which the penicillin tube had been removed. In the case actually and clinically infected there were upwards of a dozen superficial wounds (none reaching the galea) surrounding the wound overlying the fracture, none of which could be surgically excised. The exudate from these wounds formed a perfect pabulum in which the cross-infecting *Ps. pyocyanea* could flourish. The wounds were fortunately very superficial in character and healed in 14 days from the date of operation.

Commentary

It would seem, therefore, that in a department where adequate numbers of experienced and specially trained nursing personnel and reasonable structural facilities exist, actual hospital infection of battle wounds of the head may be almost entirely eliminated, although a constant potential threat of such complications will always remain. When there was a shortage of neurosurgically experienced nurses, and cases were admitted in greater numbers and at shorter intervals, the incidence of potential cross-infection rose from 15 to 35%, and one case (2.5%), the wound conditions of which were particularly suitable, became clinically cross-infected.

From these facts alone the desirability of obtaining proper skin-healing in the first two to four days is evident: a scalp wound closed with sparsely placed through-and-through sutures, especially when exposing portions of the subcutaneous tissue, provides ideal conditions for the entry and growth of organisms which may have found their way to the wound surface. Delay in healing, even if no worse calamity befalls, means an unnecessary waste of hospital time, a delayed convalescence for the patient with its risks of post-traumatic complications (either physical or mental), and an augmentation of the already overflowing reservoir of pathogenic bacteria in the hospital. It would appear that penicillin tubes need not give rise to cross-infection if closed with an aseptic screw cap of the design mentioned above, as no such trouble ensued in this series of forty cases.

The single case in which the wound broke down some days after healing was apparently complete and produced a profuse growth of *Ps. pyocyanea* showed a pure culture of the same organism from a swab taken pre-operatively. The first definitive

surgery in this patient was performed six days after wounding, and at operation the wound was foul smelling and semi-purulent, and contained a piece of wood two inches long firmly plugging the skull defect and penetrating deeply into the brain. Many bone fragments lay deep in the brain substance, two of them were still visible in post operative radiographs, indicating that wound excision had been imperfect.

The non occurrence of a cross-infective discharge from these 40 wounds (except in one case of superficial infection) clearly suggests that when such discharge occurs it is more probably due to hospital than to initial infection.

It has been shown by Cowan (1938) that organisms occurring in the air and normally regarded as saprophytes may be the cause of serious intracranial infection, and this was later emphasized by Cairns (1939) in reporting a series of 23 deaths from infection following intracranial operations. In Cairns's cases the various organisms isolated had previously been considered non-pathogenic to man and were thought to have gained access to the cerebrospinal fluid spaces from the air during the prolonged exposure of the brain necessitated by some neuro-surgical procedures. The effect of introducing *Ps. pyocyanea* or any other pathogen, into the brain or cerebrospinal fluid spaces can well be imagined, and would be a matter for serious concern. If, therefore, penicillin is to be given by the method of local instillation the precaution of using an aseptic cap for the tube should certainly be taken.

No reflection upon the nursing staff concerned in the treatment of the second series of cases is intended. They have shown a capacity for hard work and co-operation which is admirable, and they could not have been expected to adopt and maintain a specialized system of ward asepsis and anti-sepsis which has been gradually developed over a period of four years. Nor could so small a number of nurses, even if trained and experienced in neuro-surgical work, hope to attain a high standard (i.e., a low potential rate of hospital infection) when confronted with large numbers of patients with serious head injuries, whose sole ambition appeared to be the immediate removal of their headdress.

Conclusion

We feel that attention to three main points is responsible for the very low rate of hospital or cross infection of wounds in the above series. These points are (1) The care taken in closing scalp wounds to obtain very early healing. (2) The insistence upon very careful ward and dressing technique as advocated in an earlier paper and the MRC Memoranda on hospital infection. (3) The aseptic cap used to close the penicillin tube.

Summary

Two series of cases are reported, each of 20 battle casualties, in which local penicillin therapy was employed.

The incidence of potential cross infection was three cases in 20 in the unit's original surroundings, and no clinical cross infection occurred. In the second series, under less perfect conditions, the potential rate rose to seven cases in 20 (35%), and one superficial case of clinical hospital infection resulted (5%).

Cross infection of wounds by way of the penicillin tube is an obvious possibility and, as it has not appeared in the present series (the one case described being only a superficial cutaneous infection), it is suggested that the aseptic screw cap in use is the responsible factor in prevention.

The need for proper closure of the scalp wound and very early skin healing is emphasized in view of the total average potential hospital- (or cross-) infection rate (25%).

Our thanks are due to Dr Lever and Dr Cross, who carried out the necessary bacteriological investigation of the large number of wound swabs taken during the period under review, and whose admirable co-operation could not have been bettered.

SOME MISTAKEN DIAGNOSES IN THE COMMON INFECTIOUS FEVERS

BY

D. F. JOHNSTONE, M.R.C.S., L.R.C.P., D.P.H.

Medical Superintendent, City Isolation Hospital, Plymouth

Recently I had occasion to go through the records of this hospital, and it occurred to me that it might be of general interest to sift carefully all those cases of "everyday" infectious disease in which my own diagnosis differed from that of the certifying practitioner. I have deleted all the doubtful cases, where almost anybody might be right: those to which I allude have been proved, so far as was possible, by bacteriological and pathological aids, for which I am indebted to Dr Wordley of Plymouth, who is ever helpful in the elucidation of obscure medical problems.

Most senior practitioners will be well acquainted with the contents of this paper, but perhaps those who have had little opportunity for the study of infectious disease may derive some benefit. Many of us after qualification find the diagnosis of the infectious fevers difficult, and I am not sure that it becomes any easier the more cases one sees, with the consequent larger number of possibilities that arise with each fresh problem.

This brief review covers the last five years' admissions to the City Isolation Hospital, Plymouth, and includes 3,516 cases of diphtheria, 2,102 cases of scarlet fever, and a miscellany of 700 other diseases. I have tried to stress the clinical aspect throughout in view of the fact that pathological aid may well be wanting when needed most, but, naturally, in many of these cases the only ultimate proof lay with the laboratory, so it was essential to send these patients to a hospital where pathological facilities existed for full investigation. Nor do I wish to convey the impression that I am in any way critical of the differences mentioned, for I well know the heavy responsibility that rests with a practitioner who, perhaps living at a distance, is called to see some of these cases and is expected to give an infallible diagnosis in impossible surroundings within a few minutes. Quite rightly, he removes the case to where observation and treatment can be carried out under more favourable conditions. Still, there is always some satisfaction in making a correct mental diagnosis, irrespective of the administrative aspects of the disease.

Diphtheria

Diphtheria is the commonest infectious disease sent to the fever hospital in this district. I propose to divide the cases, 3,516 in all, into two groups—the faucial, nasopharyngeal, and nasal varieties, accounting for some 3,363 cases, and laryngeal, making up the remainder, a total of 153.

As can well be imagined, the commonest, safest, and most justifiable error in the first group is a diagnosis of tonsillitis. This occurs in 347 cases, or 72% of the total 483 mistaken diagnoses. Next comes scarlet fever, accounting for 14% (67 cases), and third on the list are various forms of Vincent's angina and stomatitis. The remainder is made up of the following diseases: Anginous form of glandular fever (4 cases), streptococcal cervical adenitis (4), post-tonsillectomy sloughs (2), chicken-pox (1), purpura (1), secondary syphilis (1), alveolar abscess (1), mumps (1), thrush (1), acute lymphatic leukaemia (1), and, quite inexplicably, a toxic erythema, a tuberculous meningitis, a case of meningococcal meningitis, and an attempted suicide, but to this last case I shall allude later.

The clinical differentiation of acute tonsillitis from an early diphtheria may be extremely puzzling at the outset, and I have noticed during the last few years that it is increasingly common for diphtheria to start just like an early follicular tonsillitis, and at this stage it is almost impossible without bacteriological aid to make a sure diagnosis. The following points may be borne in mind when faced with such a case.

1. In diphtheria of this type the onset is insidious. I have had nurses with a vague uneasiness in their throats report to me with considerable follicular exudate on one or both tonsils who only thought that something might be wrong when they looked at their own throats. The constitutional disturbance, pain on swallowing,

tender glands, and pyrexia are all minimal at this stage. Frequently only one tonsil is affected, but within 12 hours the other shows signs of involvement, and within 24 hours the exudate has coalesced, leaving no doubt as to the true nature of the illness.

2. Coalescence is quite rapid in diphtheria—within 24 hours. A discrete exudate lasting two or three days is unlikely to be diphtheria. It follows, then, that a case which at first sight appears to be tonsillitis should always be inspected again on the following day, and the day after that if possible.

In *streptococcal sore throat* the onset is more sudden, the systemic disturbance more severe, and the temperature higher than in diphtheria. The cervical glands are very tender, the surface of the exudate is rough, pultaceous in consistency, and may be associated with intense congestion of the soft palate and adjacent tissues.

Quinsy is most likely to be confused with hypertoxic diphtheria, as in both diseases there is exudate on the tonsils and oedema of the fauces. Again, in diphtheria of similar severity there would be much greater glandular enlargement—probably even a bull neck—pallor, and nasal discharge. Quinsy is mostly unilateral and is often associated with great difficulty in opening the jaws, a most uncommon sign even in the severest types of diphtheria. Very occasionally diphtheria does occur with quinsy in the acute stage, but almost always it is a sequel after the throat has cleared of membrane, presumably due to the lessened resistance of the patient, both locally and generally, to secondary invading organisms.

Other kinds of sore throat are encountered occasionally, but the ones mentioned are those which commonly give rise to difficulty.

There seems to be an impression that the temperature in diphtheria is always normal or subnormal. This is by no means true, and in fact most cases show mild pyrexia of 100–101° during the first few days of the illness, particularly in children. The presence of fetor, on which again much reliance is placed, can be misleading, and septic sore throats or mixed infections with Vincent's organisms can sometimes produce an odour which to the inexperienced is a very good imitation of the diphtheritic smell.

Scarlet fever is the disease next most commonly confused with diphtheria; many of the cases are overlooked by omitting examination of the patient's skin, and so the rash is missed. Sometimes the rash may have disappeared by the time the doctor is called in, but a retrospective diagnosis is usually possible by consideration of the history of sudden onset with vomiting and sore throat, and the characteristic appearance of the throat, tongue, and skin. Sometimes undoubted scarlet fever occurs without a rash, but again the history will usually provide a

Occasionally both diseases coexist.

Vincent's angina has been especially prevalent during the last three years, but even before the war it accounted for some of the errors of diagnosis. It occurs not at all uncommonly in children, but adults are the chief sufferers. The disease mostly affects one tonsil and is readily recognized clinically by the ulceration, the broken and crumbly appearance of the exudate, the typical smell, and the tender glands, which are often enlarged out of all proportion to the extent of the angina. It should be noted that diphtheria is often associated with Vincent's angina, and swabs as well as smears should be taken to confirm the diagnosis. Vincent's disease will also attack the gums and buccal mucosa, causing much swelling of the gingival margins, ulceration of the buccal mucous membrane, and the secretion of tenacious mucus, a condition I have never observed in diphtheria.

The differential diagnosis of the remainder of the diseases mentioned above—namely, secondary syphilis, acute leukaemia, purpura, post-tonsillectomy sloughs, and non-diphtheritic rhinitis—are all fairly obvious, but there are three to which I would like to allude briefly: glandular fever, chicken-pox, and the attempted suicide.

The anginous form of glandular fever may simulate diphtheria very closely in children. There is considerable exudate on the tonsils, with faucial oedema and enlarged glands in the neck. A striking difference is to be found in the consistency of the cervical glands on gentle palpation. Instead of being enlarged and firm, they have a peculiar elastic and resilient feeling, quite

unlike those of diphtheria. Once one's suspicions have been aroused by this sign, further examination will in all probability reveal an enlarged spleen, adenopathy of other groups of lymph glands, and possibly some abdominal tenderness. A differential count will confirm the diagnosis, but, if a Paul-Bunnell test is done, blood should be taken before giving serum in doubtful cases, otherwise the result will be positive when in fact the true result might have been negative.

I have notes of several cases of chicken-pox misjudged as diphtheria. This has been due to a profuse crop of vesicles on the palate or uvula breaking down into coalescent ulcers. Again an examination of the skin would have settled the diagnosis.

Lastly, the attempted suicide, which is related merely as a matter of medical interest.

A man aged 45 was sent into this hospital certified as suffering from diphtheria. He had a curious-looking throat covered with dirty grey exudate, extending over the tonsils, faucial pillars, uvula, and soft palate. The mucous membrane of the cheek was involved, and it was quite easy to strip off this material, when a raw, sore area was left behind. I had never seen anything quite like it before. His general condition seemed good. He was not ill, but was rather confused in his manner. On further inspection I found a severe wrist wound on the left side which had evidently been self-inflicted by a sharp instrument—probably a safety-razor blade. The flexor longus pollicis had been divided but no large blood vessel injured. I taxed the man with attempted suicide, as by this time it was evident that he had swallowed some corrosive fluid and, perhaps finding this rather unpleasant, attempted a short cut, which was equally unsuccessful. He would admit nothing, but later I learned that he was heavily in debt and had been found wandering on several occasions.

Perhaps, however, laryngeal diphtheria is confused more than all the other kinds put together, with the possible exception of skin diphtheria. Out of 153 cases notified 38% proved not to be laryngeal diphtheria after investigation and observation. These difficulties are quite understandable, as the number of cases in the large fever hospitals has fallen very considerably in recent years and not many of the younger practitioners have had the opportunity of seeing these cases before qualification. In addition, a doctor called to see suspected cases of "croup" quite rightly errs on the safe side, so that a number of patients arrive at the hospital with this label who have no signs of the disease.

A bad faucial diphtheria with palatal oedema and noisy breathing due to mechanical causes in the throat will often be diagnosed as laryngeal obstruction, but the chief mistakes from the academic point of view arise in the confusion between the various forms of catarrhal laryngitis, the laryngitis present at the onset of an attack of measles, bronchopneumonia, and retropharyngeal abscess. Other occasional difficulties arise, and I have notes of odd cases of papilloma of the larynx, congenital laryngeal stridor, and whooping-cough.

Catarrhal laryngitis, or spasmodic croup, accounts for 55% of the total number of errors, and this is quite feasible when one thinks of the alarming picture presented by a child with this complaint. The chief clinical contrasts between this and laryngeal diphtheria are:

1. Its sudden onset, very often at night, in an otherwise healthy child, whose only previous history may have been that of a slight upper respiratory catarrh.
2. The attack reaches the acme of severity almost at once and the child is fairly well between each spasm. Often this type of patient is quite well by the morning.
3. The laryngeal involvement is never progressive, although occasionally it may last some days.

Compare this picture with that of a true diphtheritic laryngitis, which is insidious in its onset. Perhaps there may be a history of sore throat, in which case the presence of exudate on the tonsils will make the diagnosis easy. Often, however, the parents may have been unaware of the true state of affairs, and only when the child loses its voice, breathes noisily, or has fits of dyspnoea are their fears aroused. A large number of these cases have clean throats when examined, as the membrane has separated from this situation by the time the larynx is involved. As the attack has probably been severe and of the nasopharyngeal variety, much useful information may be gained by looking carefully at the throat for evidence of slight super-

ficial ulceration, suggesting recently separated membrane, and also the nose for evidence of nasal discharge or actual membrane, which often persists after the throat is clean. In addition, late cases also have a greyish pallor and may still show signs of subsiding cervical adenitis. The characteristic feature of all diphtheritic laryngitis is progression in the absence of treatment. Sometimes it is slow, sometimes rapid, but most cases will terminate fatally unless the true nature is recognized. Unlike other forms of laryngitis, where a child may be almost normal between attacks, in diphtheria the stridor and recession get steadily worse, restlessness increases, and the attacks of dyspnoea are more frequent. Primary laryngeal diphtheria is less common, but accounts for some 20% of those requiring tracheotomy.

Measles—The next most frequent disease (17%) sent into hospital as laryngeal diphtheria is measles. Not uncommonly before the appearance of the rash the child may show all the signs of impending laryngeal obstruction, and unless Koplik's spots are identified the diagnosis will be in doubt. As a rough guide laryngeal symptoms occurring before the rash are due to measles. Laryngeal symptoms appearing after the rash are probably diphtheritic. Laryngeal involvement with the rash may be either, for diphtheria is more often associated with measles than with any other infectious disease, with the exception perhaps of scarlet fever. The presence of laryngeal obstruction associated with measles whether due to diphtheria or not formerly had some prognostic significance, for if tracheotomy was found necessary the outcome was nearly always fatal, but I have recently recorded four successful cases whose recovery was probably due to sulphapyridine.

Retropharyngeal abscess should never be confused with true laryngeal diphtheria. The peculiar quacking cry, the noisy breathing, and the presence of a fluctuating swelling on the posterior pharyngeal wall, which can be seen and felt and of enlarged glands, usually on one side of the neck, all point to the correct diagnosis. Pneumonia, bronchitis, and whooping-cough are all misdiagnoses which can be avoided by careful assessment of the patient's history, signs, and symptoms.

In all these conditions diagnosis on clinical grounds is important, and the laboratory should be used for confirmatory evidence only after the necessary and immediate specific treatment has been given.

Considerable assistance in the elucidation of a doubtful case may be obtained from a knowledge of the patient's immunity in response to a Schick test and the typing of the organism. If the case is obviously doubtful, and there is no immediate danger in withholding serum for a few hours, the patient should be Schick tested and swabs taken from the nose and throat. Serum may then be given in 7 to 8 hours without upsetting the result of the Schick test. The following results may occur, bearing in mind that all intermedius and gravis strains of diphtheria bacilli are virulent and that mitis strains may be either virulent or non-virulent.

Schick positive, swab positive	Diphtheria
Schick positive, swab negative	Susceptible, but probably not diphtheria
Schick negative, swab positive	Immune ? carrier
Schick negative, swab negative	Not diphtheria

All swabs should be repeated as a confirmatory measure. In any suspicious case particularly in private practice, serum should be given first and confirmatory swabs taken subsequently. The technique just described is more suited to a hospital, where a close watch can be kept for possible extension of the disease and suitable treatment undertaken immediately.

Scarlet Fever

There is some doubt whether scarlet fever should be regarded as a distinct disease or merely as one variety of the response of the individual to the toxin of a particular strain of haemolytic streptococcus, but, nevertheless it is a notifiable disease which is usually segregated, and it is therefore necessary to arrive at a clinical diagnosis without considering too critically its exact mechanism.

Out of over 2,000 cases the diagnostic error is some 8%, composed of the following: toxic erythema (26% of errors), tonsillitis (20%), rubella (18%), measles (12%), diphtheria

(6%). The remaining diseases involved are scabies, urticaria, chicken pox, impetigo, industrial dermatitis, and glandular fever. Perhaps the commonest sources of error are: (1) Taking one manifestation only of the disease, such as the rash, and diagnosing on this alone scarlet fever is the sum total of a number of signs and symptoms. (2) Paying too little regard to the history. (3) Omitting to look at the patient's skin, or arriving at an erroneous conclusion after inspection.

Toxic Erythema—Thus the presence of a scarlatiniform rash does not of itself mean that the patient is suffering from scarlet fever. I have grouped all these cases under the rather loose heading of 'toxic erythema,' and this comprises rashes attributable to drugs, chiefly atropine, enemata, rubbing oils, food poisoning, wearing of rough clothing or blankets next the skin, fits of crying in children (a fruitful source of 'rash' after throat examination), and a host of others for which no adequate cause could be found. In almost all the rash dominated the picture, and the other symptoms, such as vomiting and sore throat, were absent. Many of these patients subsequently desquamated, but the desquamation was unlike the pin-hole variety found in scarlet fever.

Tonsillitis accounted for the next 20% of the mistakes, and some of these were missed because no careful examination of the patient's skin had been made, the diagnosis being based on the appearance of the throat and tongue, and some because a transient rash, not an uncommon event even in tonsillitis had appeared and a wrong conclusion had been deduced. The rashes seen in tonsillitis are erythematous—not punctate—patchy in distribution, and of short duration.

Rubella—Problems of real difficulty may, however, arise in distinguishing a second-day rubella from a mild scarlet fever, and I have come to the conclusion that it is well nigh impossible in certain cases. Some 18% of the errors occurred in the differential diagnosis of these two diseases, and there were some doubtful cases which have not been included. I noticed particularly in the last epidemic of rubella, that a number of undoubted cases had considerable faucial congestion and when on the second day the rash had disappeared from the face, leaving a scarlatiniform erythema on the rest of the body, it was very difficult sometimes to make the necessary distinction. In addition to the usual distinguishing features of German measles—namely, mild generalized adenopathy, various muscular pains, catarrhal symptoms and pyrexia—there is one physical sign which is very constant in patients with clean mouths and this is a marginal gingivitis. On inspection of the mouth the gums are found to be red, swollen, 'heaped up' and overlapping the teeth, particularly between the upper centrals and laterals. This sign in conjunction with the other well known manifestations of the disease will often be found most helpful.

Measles and Varicella—The two diseases which so often simulate scarlet fever and which account for another 14% of the pitfalls are measles and chicken pox. Measles is nearly always confused with scarlet fever in the prodromal stages of the disease, one or two days before the true rash appears, when the body may be covered with an eruption indistinguishable from scarlet fever and the throat and tongue may well be passable imitations of the latter disease. A close inspection of the buccal mucosa will reveal Koplik's spots and quarantine of the scarlet fever ward be avoided! The same remarks apply to chicken pox, in which a scarlatiniform rash may appear before the true rash. An inspection of the palate will usually reveal one or two early vesicles, giving the key to the situation. To add to the difficulties here, it is not infrequent for scarlet fever and chicken pox to occur at the same time, but true scarlet fever usually appears after the chicken pox is fully developed and shows the signs appropriate to that disease.

I have no space to deal with the less important diseases sent into hospital as scarlet fever, such as urticaria, scabies, and impetigo, and their differentiation is obvious enough. Clinical diagnosis is still the best means of recognizing scarlet fever. The Dick and Schultz-Charlton tests and results of throat swabs are often misleading and inconclusive, and I rarely employ them now. A helpful sign in scarlet fever which aided in making a retrospective diagnosis in a doubtful case was the

appearance in due course of pin-hole desquamation, but it is well to remember that if scarlet fever antitoxin has been given early in the disease, subsequent desquamation often fails to appear

Typhoid Fever

Typhoid fever is a disease of such protean manifestations that it is hardly surprising to find a total error of 37% in the 63 cases notified. I have not included as an error those cases which were sent in as typhoid and subsequently turned out to be other diseases of the enteric group, as clinical diagnosis is well-nigh impossible except perhaps in large-scale epidemics. The chief difficulties seem to arise with (1) various chest diseases, (2) other intestinal diseases, and each of these groups accounts for some 30% of the total faulty diagnosis. The remainder are found in such other cases as tuberculous peritonitis, acute miliary tuberculosis, pectoral abscess, pityriasis rosea, malignant endocarditis, and infective hepatitis. One other interesting alternative occurred recently, and this merits further description owing to its general medical interest.

Four cases of lobar pneumonia, one of bronchopneumonia, and one of empyema were noted, none of these were very obscure in their signs and symptoms, and would most certainly have been excluded had a careful examination of the chest been made. As a rule, pneumonia as a complication occurs late in the disease, and the signs in the chest, coupled with the cough, dyspnoea, and pain in the side, are all against the diagnosis of typhoid fever except in the rare form of pneumo-typhoid in which the disease has all the symptoms and signs of lobar pneumonia at the outset. In this connexion it is perhaps worth noting that herpes of the lips is very unusual in enteric fever. In fact, a critical examination of the patient's chest and a blood smear showing leucopenia and absence of eosinophils would automatically rule out pneumonia and many other conditions superficially like typhoid fever.

Generalized miliary tuberculosis may cause real difficulty, but the early loss of weight, rapid pulse, and possible leucocytosis may help to distinguish it. Jaundice is so rare in typhoid fever that its mere presence is sufficient to exclude the disease, and the only case in this series showing jaundice proved to be infective in origin. With regard to intestinal diseases the simple enteritis lacks the quiet and insidious onset of enteric. The sudden vomiting, griping abdominal pain, diarrhoea, and tenesmus are all unlike the vague feeling of real illness which ushers in the onset of typhoid fever. Malignant endocarditis may simulate typhoid very closely: the high temperature, enlarged spleen, perhaps abdominal distension, all combine to make an exact assessment difficult. A search for a possible diac lesion, haematuria and petechiae in the skin will help excluding the former disease.

A case of special interest occurred quite recently at the hospital. A man 32 years of age, a baker by trade, was admitted with a remission of typhoid fever. He had been ill at home for two weeks with severe headaches, insomnia, pains in his limbs, a high temperature, and gastro-intestinal upset, vomiting, and loose stools. On admission his temperature was 104°, pulse 132, respirations 36; and the only physical signs I could find were a slight icteric tinge in the conjunctiva, diminished air entry at the left base with a few post-tussive rales, an enlarged thyroid, and muscular pains and tenderness in the upper arms and calves of his legs. A white count revealed a leucocytosis of 20,000—polymorphs 62%, lymphocytes 18%, eosinophils 17%, and monocytes 3%. In view of his high eosinophil count I made careful inquiries as to his occupation and habits of life. It turned out that he was a pork pie baker and that every day he ate a few ounces of raw pork to see if it was sufficiently seasoned before putting it in the pies. Suspicion was at once aroused as to the possibility of trichinosis, and his subsequent signs and symptoms were very typical of the disease. The calf muscles became swollen and tender, his tongue was enlarged to such an extent that he could hardly protrude it, and the swelling of his thyroid remained. The muscles of both upper extremities were soon involved, and he was very ill. At no time was there any facial oedema. Gradually the high fever settled, the muscular tenderness and swelling abated, and his thyroid returned to normal size. At this stage I removed a piece of his left deltoid muscle, and on examination this was found to contain *Trichina spiralis*. He was eventually discharged quite fit and well. I mention this case in greater detail as a very uncommon possibility when confronted with a case of "P.U.O.," and also to draw attention to the fact that a man's occupation often involves processes not imagined by the interrogator.

Perhaps the most helpful points in considering a doubtful case of typhoid fever and before sending specimens to the laboratory are as follows:

- 1 Gradual onset with headache and malaise
- 2 A relatively slow, perhaps dicrotic, pulse with a rising temperature
- 3 Constipation or diarrhoea
- 4 Low blood pressure
- 5 Abdominal distension, with palpable spleen
- 6 Bronchitis and epistaxis
- 7 The state of the tongue and throat, the latter may be congested
- 8 The rash when present, bearing in mind that it may be sparse and require a careful search
- 9 Absence of abdominal reflexes

Dr J. D. Rolleston drew attention to this last sign many years ago, and, provided that other nervous diseases are excluded, I have found it to exist in a large number of proved cases.

Naturally, most cases will have to be confirmed either by blood culture or by agglutination tests, and newer technique in these laboratory methods enables differentiation to be made between an active infection occurring in an inoculated person and even the carrier state.

Acute Anterior Poliomyelitis

Acute anterior poliomyelitis appears to be an even more baffling disease from the diagnostic point of view, for out of a total of 30 notified cases there is an error of just over 40%, and these include a list of nervous diseases which would do credit to Queen Square Hospital, mechanical faults which could be seen in the out-patient department of any general hospital and the usual makeweights which had apparently no connexion whatever with the disease. These nervous diseases were: cerebellar tumour, cerebral tumour, disseminated sclerosis, traumatic neuritis (drunkard's palsy), a transverse lesion of the spinal cord, a hemichorea, and a post-diphtheritic palsy, easily demonstrated by immobility of the palate, nasal voice, and regurgitation of fluids through the nose.

I feel quite incompetent to discuss differential diagnosis in nervous diseases, so will pass straight to the mechanical factors influencing locomotion which were sent in under this heading.

One boy, unable to walk, was found to be suffering from a septic sore on the heel, another from inguinal adenitis secondary to a sore on the foot, and yet another from a tuberculous hip; finally, we had a man with lumbago. A few cases of scarlet fever and influenza, and a pneumococcal meningitis complete the list.

Perhaps a very brief summary of the features of the spinal type of the disease may help to distinguish it from some of the above-named conditions.

The pre-paralytic stage is associated with sudden onset, catarrhal symptoms such as coryza and sore throat, vomiting, pyrexia, and malaise—in fact, much like the onset of any acute infection. During this stage two signs are useful: the spinal sign, in which there is resistance to passive anterior flexion of the neck, and Amoss's sign, which is useful for older children. If the patient is sat up in bed and asked to fold the arms, he may attempt so to do, but quickly places his arms behind, so that the body weight is borne on a tripod, consisting of his arms, with the spine as the "third leg."

If these signs and symptoms are present it is quite justifiable to send the case into hospital with a provisional diagnosis of infantile paralysis. Often, however, it is impossible to recognize the disease in the pre-paralytic stage with any degree of certainty, although its presence in the district will often arouse suspicion at these rather suggestive symptoms. This stage may be succeeded by an evanescent meningeal stage in which headache, drowsiness, and irritability are prominent symptoms, or may proceed to the paralytic stage straight away. It is often possible to overlook this if too much attention is paid to the constitutional signs and symptoms. I have seen this happen in hospital, and only a few weeks ago I missed a case which I was looking after personally.

Before the actual paralysis occurs there is much muscle tenderness, hyperaesthesia, and stiffness of the neck and spine, so that the patient greatly resents interference by the examiner. Rarely, all these prodromal signs and symptoms may be wanting, and the sudden onset of paralysis may be the first signs of illness. I have observed such a case in this hospital.

When the paralysis occurs it is usually maximal at the beginning, but I have notes of one case in which there was a four-day interval

between paralysis of the right shoulder-girdle and of the left leg, the latter occurring after the temperature had returned to normal—rather an unusual occurrence. The tendon reflexes are usually absent or greatly diminished in this phase and the paralysis is flaccid.

Many varieties of history, signs, and symptoms are seen in different individuals, and the encephalic form may justifiably be regarded as a tuberculous or other type of meningitis, unless facilities exist for examination of the cerebrospinal fluid.

Cerebrospinal Fever

During the war most practitioners have had a fairly large experience of cerebrospinal fever, but nevertheless it is interesting to consider the diseases which at first sight were thought to be meningococcal meningitis. Some of these were indistinguishable from cerebrospinal fever on clinical grounds alone, and out of 140 cases notified there was an 18% error, much reduced if other types of meningitis are excluded. Sixteen such cases occurred—9 tuberculous meningitis, 4 benign lymphocytic meningitis, 1 pneumococcal, 1 streptococcal, and 1 syphilitic meningitis. Again some confusion has arisen in various chest conditions, mostly in children, presenting signs of meningism: two cases of lobar pneumonia, one of bronchopneumonia, and one of spontaneous pneumothorax were wrongly thought to be cerebrospinal fever, although the last-mentioned case presented very few signs or symptoms referable to meningitis. Among the miscellaneous conditions seen were transverse myelitis, aneurysm of the middle cerebral artery, and one case each of measles, rubella, and scarlet fever.

It is impossible to differentiate with certainty the various forms of meningitis clinically before submitting a specimen of the cerebrospinal fluid to the laboratory, but in all the cases which subsequently turned out to be of tuberculous origin there was a history of gradual onset, a vague prodromal period of ill-health, or a history of some chest trouble which gave a pointer to the possible origin of the trouble.

Pneumonia in children may simulate meningitis very closely. The sudden onset, the signs of meningeal irritation, the high temperature, and perhaps paucity of physical signs in the chest are all misleading.

The measles and scarlet fever cases were probably sent in through the mistaken view that the rash was that of meningococcal meningitis, but there were no other signs to suggest a meningeal lesion. The patient with rubella was sent in because she complained of a stiff neck. This particular symptom sometimes occurs several days before the rash appears, and may well give rise to some doubts when cases of the more serious disease are prevalent.

Miscellaneous

I have mentioned the commoner infectious diseases; there are others, and combinations of the various infections, which I could include, such as bronchitis, frequently sent in as whooping-cough, erysipelas, which has been confused with eczema, carbuncle, dacryocystitis, herpes zoster, and cavernous sinus thrombosis; but of all the mixture of odd infections the most frequent mistake is the case labelled "measles and bronchopneumonia." Perhaps, however, this mistake may be a matter of expediency rather than a lack of clinical acumen. Ordinarily, cases of uncomplicated measles are not admitted, but attach the magic word "bronchopneumonia" and a bed is found somewhere!

In spite of this there are a great number of honest errors of judgment, and I think the reason is probably that the doctor is called in either just as the rash is appearing or when it is just fully developed, so that the child is restless and looks ill. At this stage the fever is considerable—the temperature commonly elevated to 103°–104°, there is considerable catarrh in the chest, the respirations are frequent and short, and there is nearly always a dry cough. The physical signs in the chest at this stage are those of a mild bronchitis, but the whole picture looks at first sight rather like a bronchopneumonia. Very soon, within 24 to 36 hours, the rash begins to fade, the symptoms abate, and the temperature drops, and it is during the next few days that true bronchopneumonia is likely to develop. It is only exceptionally that pneumonia occurs in the prodromal stage or coincidently at the time of eruption.

I have tried,* so far as is possible, to avoid figures in this paper, nor do I wish to imply any criticism of other doctors' work. I am sure there would be ample material for another paper based on my own personal mistakes. Anyhow, it will show that life in a fever hospital is not so dull, that it does not consist entirely in looking after cases of scarlet fever, and that good clinical work can still be found in this branch of medicine—despite the war and the forms!

I have to thank Dr T. Pearson, medical officer of health, City of Plymouth, for permission to publish this paper. I should also like to acknowledge the help I have obtained from the standard works on infectious disease for reference on doubtful points, particularly *Harriss and Munn* and my old chief's book, *Rolleston and Ronaldson*. Few who have worked under Dr J. D. Rolleston could fail to be stimulated by his magnificent teaching on the infectious fevers.

GASTRO-INTESTINAL BLEEDING DUE TO VITAMIN K DEFICIENCY COMPLICATING LABOUR

BY

EILEEN MALONE, L.R.C.S., L.R.C.P.I., L.M.

In 1929–33 a haemorrhagic chick disease was observed in a number of laboratories (Brinkhous, 1940), in most cases incidental to experiments in which chicks were fed purified diets low in fats. During observations on the effect of various proteins on the growth of chicks spontaneous haemorrhages were noticed. Administration of lemon juice, ascorbic acid, cod-liver oil, and wheat-germ oil failed to prevent these haemorrhages in chicks fed on the purified diets. It was suggested by Dam, in 1934, that this condition constituted a new dietary deficiency disease, and his suggestion that the deficient factor be called vitamin K has been adopted. These diets were low in fats, and McFarlane, Lane, and Richardson gave evidence of the fat-soluble nature of the vitamin: they noted that fish meal prevented haemorrhage unless it had been extracted by ether.

Haemorrhagic chick disease was recognized as being due to deficiency, and the relationship of this dietary factor to blood clotting was established. A low plasma prothrombin was suspected. A haemorrhagic tendency appeared when the low prothrombin levels were reached when feeding chicks on K-deficient diets for several days. Both the low prothrombin and the haemorrhagic tendency were cured by feeding vitamin K.

That mammals may develop such a deficiency was shown in conditions in which the absorption of this fat-soluble vitamin is hindered by absence of bile in the intestine. Hypo-thrombinaemia and haemorrhage ensued, and were cured by the administration of vitamin K. Vitamin K occurs richly in alfalfa, spinach, cabbage, cauliflower, carrot-tops, and soya beans, it is less potent in tomatoes and orange peel. There is a little in liver and egg yolk.

The causes of vitamin K deficiency are deficient diet, obstructive jaundice, and biliary fistula leading to absence of bile in the intestine. Haemorrhagic disease of the newborn shows a low prothrombin level and is controlled by vitamin K. Jaundice appears to have no relation to the deficiency. Haemorrhage due to low plasma prothrombin may occur in ulcerative colitis, intestinal obstruction, and fistulae.

Attention is directed to a most complete and excellent review of the literature on plasma prothrombin and its relationship to vitamin K by Brinkhous (1940).

In view of the above facts it may be interesting to record a recent case of mine treated with vitamin K.

Case Report

A farmer's wife was taken ill in Sept., 1943, with acute pain in the back and vomiting. Her temperature varied from 100° to 103° for four days. She was diffusely tender over the abdomen, but no definite localizing signs were obtainable. Her condition becoming worse on the evening of the fourth day, I sent her into hospital, twelve miles distant. The urine showed no abnormalities up to that time. In hospital her case was diagnosed as a simple catarrhal jaundice, and bile appeared in the urine. A blood count revealed

2,500 white cells, but otherwise was normal. Her last menstrual period was Aug. 18, and she thought she was pregnant; her only child was then 6 years old. She returned home in eleven days; she looked ill and vomited more or less severely for about ten weeks. The Aschheim-Zondek test was positive. During this time she had a slight discharge of blood from the vagina, and was given wheat-germ oil. A polypus was found on examination; this was removed in December. All through her pregnancy she continued to have a tendency to vomit occasionally. At the start of her illness she took nothing but glucose and water, and after one week honey, tea with sugar and skimmed milk, and a little bread. On her return home her diet consisted of carbohydrates in the form of glucose, bread, jelly, and marmalade, and proteins in the form of meat and chicken. She also ate baked apples and vegetables, but no butter or eggs. Gradually butter and full-cream milk were introduced, and lastly eggs in four weeks' time. By the sixth week she was on normal diet. She spent the last three weeks of her pregnancy in bed because of lassitude and severe cramping pains in both groins and in the rectum. The spleen was never palpable. The patient's husband developed jaundice one month after her return from the hospital, and her sister and niece two and three months later, respectively.

At term on May 18, 1944, at 10 a.m., after a slow labour, she was delivered spontaneously of a normal live male infant (10 lb. 14 oz.). Placenta and membranes, intact, were expressed half an hour later. An old perineal scar reopened, and was repaired under local analgesia (two internal and three external sutures). At 10.45 a.m. she bled freely per rectum. Pituitrin 1 c.cm., morphine gr. 1/4, and routine treatment for shock followed hot vaginal and rectal lavage. There was no rectal tear. Pituitrin was repeated during the afternoon. Plain and glucose water were given freely by mouth. At 3.50 p.m. she vomited first clear then blood-stained fluid (approximately 60 c.cm.). Her general condition was improving. Morphine was repeated at 5 p.m. and vitamin K 10 mg. (prokayvit B.D.H.) was administered intramuscularly into the buttock. The patient bled no more, and made a good recovery. The next day prokayvit 5 mg. was injected intramuscularly. Rectal saline was given; this returned blood-stained and was not repeated. She was put on liquid paraffin t.i.d. On the sixth day after delivery she passed a melaena, after that normal stools. On June 2 a pathologist reported as follows:

Pathological Report 1.—Blood count: Hb, 59%; R.B.C., 3,310,000 per c.mm.; platelets, 236,000 per c.mm.; colour index, 0.89; leucocytes, 3,800 per c.mm.—polymorphs 74%, lymphocytes 26%. Fair numbers of reticulocytes present. The red cells show slight anisocytosis. Blood urea, 25 mg. per 100 c.cm. Blood fragility: Haemolysis starts in 0.36% and is complete in 0.30% saline. There is no increase in the fragility of the red cells. Urine: S.G., 1010; pH, 6.8; no albumin, no sugar; urea, 0.82%; fair numbers of red cells, a few pus cells, no casts seen. Fair numbers of coliform bacilli seen in fresh smears. Culture: A very large growth of coliform bacilli obtained. Van den Brogh reaction: Completely negative, both direct and indirect. Blood bicarbonate: 64.3 c.cm. CO₂ bound by 100 c.cm. plasma at N.T.P. Prothrombin clotting time: 39 secs. (control, 25 secs.); definitely prolonged.

On June 5 the patient was given 15 mg. of prokayvit intramuscularly, which was repeated on June 6, when she left our infirmary. He visited the laboratory on June 7, and the following report was sued:

Pathological Report 2.—Blood count: Hb, 70%, R.B.C., 3,836,000 per c.mm.; colour index, 0.92; leucocytes, 6,250 per c.mm.—polymorphs, 69%, lymphocytes 7%, monocytes 1%, eosinophils 3%. An occasional reticulocyte present. No abnormal white cells seen. Platelets abundant. Prothrombin index: June 5, 67%; June 8, 111%.

It should be noted that the patient received the first vitamin K injection on May 18, the second injection on May 19. On June 2 the first prothrombin index was determined, and was found to be 67% of normal (100% = 25 secs.). On June 5 the third vitamin K injection was given, and this was repeated on June 6; on June 8 the second prothrombin index was determined, and was found to be 111%. The first and second administrations of vitamin K were therapeutic, the third and fourth experimental, to detect a rise in the prothrombin index.

A hippuric acid excretion test has since been made, with the following results. No other liver function tests were available.

Time	Urine Collected	Specific Gravity	Hippuric Acid Excreted
9.30 a.m. ..	200 c.cm.	1006	0.25 g.
10.30 a.m. ..	173 c.cm.	1012	0.05 g.
11.30 a.m. ..	153 c.cm.	1011	0.07 g.
12.30 p.m. ..	102 c.cm.	1010	0.03 g.

In a follow-up pathological examination, dated Sept. 7, the prothrombin index was found to be 85% of normal; the total hippuric acid 6.26 g. (normal about 5 g.).

The amount of hippuric acid excreted by normal individuals approximately ten times the amount recovered from this patient. The hippuric acid test suggested that some degree of liver damage was present, although, clinically, there were no objective signs indicate liver dysfunction. As Andrus and Lord (1942) have shown patients with parenchymal liver damage of severe degree do not respond to vitamin K, and hypoprothrombinaemia persists in such subjects. Sweet, Lucia, and Aggeler (1942) showed that the hippuric acid test is a more delicate index of liver function than prothrombin concentration, although the latter detects destruction of the parenchyma as well.

Commentary

It is probable that the bleeding manifested by this patient was due to vitamin K dietetic deficiency in the first two months of gestation, inasmuch as she subsisted on a fat-free diet during most of that time and only gradually resumed ingestion of fats during a rather prolonged convalescent period.

That the haemorrhagic tendency resulted from vitamin deficiency is supported by the marked rise in prothrombin index from 67% to 111% after the second two injections of the vitamin; in addition, the clinical recovery of the patient after the initial administration of the vitamin corroborates most substantially this point of view.

A lapse of 15 days took place between the therapeutic and the experimental administration of vitamin K, and the prothrombin index at the onset of labour might have been very much lower than when first estimated. The results of the hippuric acid excretion test indicate impairment of liver function, although to establish this beyond doubt would require further laboratory studies, which, unfortunately, could not be carried out because of the lack of such facilities, and because of the difficulty of transporting a non-ambulant patient for such studies. That the prothrombin level rose so much after the experimental administration of vitamin K indicated very strongly a pre-existing deficiency in that factor. Another factor to be considered is the hydraemia of pregnancy, which by its occurrence as a physiological concomitant feature, may reduce a borderline prothrombin content to a lowered one particularly if the diet, as in this case, be deficient in vitamin K. In such a patient post-partum haemorrhage from the placental site would prove an even more serious complication of labour, particularly if the possibility of a vitamin K deficiency either was unknown because of an inadequate neonatal history or was overlooked.

Summary and Conclusions

The case history of a patient developing gastro-intestinal bleeding during the last stage of labour and early puerperium is recorded, with evidence supporting the view that the haemorrhagic tendency resulted from a lowered blood prothrombin level; clinical recovery followed the administration of vitamin K.

Pregnant women who have suffered from an obstructive jaundice and consequent dietary deficiency in fats would benefit by having a prothrombin index taken before the onset of labour, so that vitamin K administration may be instituted, if necessary, to prevent a haemorrhagic tendency from developing as a result of hypoprothrombinaemia.

My grateful thanks are due to Dr. Mackarell, pathologist of Leicester Royal Infirmary, for his reports and advice, and to Sister Robinson for her unremitting watchfulness and care of the patient.

Wartime restrictions prevent even so deserving a cause as the Grenfell Association from notifying the public of the Christmas cards and purse calendar which are being sold again in aid of the association's work in hospitals, nursing stations, schools, etc., along the 1,000-mile coast-line of Labrador. Readers are therefore asked to make a special note that in the cards four designs are available, price 6d. each with envelope, postage extra, from the offices of the association at 66, Victoria Street, London, S.W.1. The price of the purse calendar is 3d., postage extra. These represent as good value as is to be obtained, quite apart from the help which their sale means to the Grenfell Mission.

SPONTANEOUS RUPTURE OF AN APPARENTLY NORMAL SPLEEN

BY

LIONEL E. JONES, M.S., F.R.C.S.

"Surgeon to Burntwood Emergency Hospital"

Spontaneous rupture of an apparently normal spleen is rare enough to warrant publication. Susman (1927) had a case in a man aged 53 and reviewed the literature of 8 previously reported cases. His patient had had indigestion and flatulence for three months, and indigestion had been a feature of four out of the six cases he reviewed. He suggested that in the spleen there was a localized lesion which was itself destroyed by the bleeding and which was the cause of the dyspeptic symptoms. He stressed a relationship between splenic and gastric activity.

Later Hamilton Bailey (1930) reported a further case of spontaneous rupture in a man aged 20: the spleen was normal on macroscopic and microscopic examination. He reviewed the cases reported by Susman and found a further two in the literature, bringing the total to 12. Hamilton Bailey felt that forgotten trauma should be accepted as the cause. If that theory is discarded we are plunged into a morass of speculation in which it is unprofitable to linger."

Black (1933) reported a case in a woman aged 52. The sudden onset of severe abdominal pain was preceded by some weeks' uneasy feeling under the heart. She was found to have an intraperitoneal haemorrhage from a ruptured spleen. The spleen was normal in size, and microscopy showed hyalinization of the wall of the central artery. Black said that the spleen aged early, that at 36 years 50% of spleens show hyaline asclerous change. He believed this change rendered it liable to haemorrhage and that torsion of the pedicle was the immediate cause in his case.

Zuckerman and Jacobi (1937) added a further case, in a woman aged 39. They reviewed the preceding cases and found further records in the literature, bringing the total reported to 22. In their patient the spleen was abnormally mobile owing to the absence of the lieno-phrenic ligament. Similar findings were present in the case reported by Halliwell (1933). Zuckerman and Jacobi pointed out that the condition is apparently uninfluenced by sex or age. Two of their cases occurred under the age of 20, and those remaining were more or less evenly distributed in each decade from 20 to 60. This age distribution, they felt, was strong evidence against vascular degeneration being the causative factor. They suggested that the common factor was venous congestion due to kinking of an unusually mobile splenic pedicle. This was due to a development defect in the peritoneal relations of the spleen resulting in the absence of the lieno-phrenic ligament.

Coleman (1939) had a further case. His patient was a man aged 58 with a long history of previous indigestion. The spleen was normal in size. The histological report stated that there was well-marked arteriolar sclerosis, and the haemorrhage may have been due to rupture of one of the damaged vessels. Coleman suggested that disturbance of gastric function caused congestion of the portal vein and its radicles and led to rupture of a damaged vessel.

Dubash and Langley (1944) reported spontaneous rupture of the spleen occurring in a patient in bed suffering from an acute axillary lymphadenitis. Although this spleen showed no acute inflammatory reaction and cannot be considered normal, it is of interest to note that it was abnormally mobile.

Case Report

A soldier aged 36 was admitted to an Emergency Hospital at a.m. on Sept. 18, 1943. His leave had started on the 17th, and he spent his day travelling. He left his unit at 7 a.m. and reached his home at 1 p.m. He had no food on the journey, but had a midday meal on arrival home. He then had a light tea, followed later by supper. At the last meal he had celery. He went to bed at 10 p.m. feeling perfectly well, but within a few minutes he had abdominal pain, which became very severe, reaching its maximum intensity within two minutes. The pain was on the left side of the abdomen between the lower ribs and thigh, being described as a burning sensation running from above downwards and continuing

without remission. He felt sick, and vomited once immediately after the pain started. His bowels were regular. He had never had indigestion. Micturition was normal.

On examination the patient was half sitting and half lying, curled up on his left side. Any movement from this position was resented. His general condition and colour were good. The temperature was 98.4° and the pulse 70. The abdomen was tender and rigid, especially in the left upper quadrant. The percussion note was normal. No peristalsis was audible.

A diagnosis of perforated gastric ulcer was made and a laparotomy undertaken. As the pain was most severe on the left side a midline incision was used to open the abdomen. On entering the peritoneal cavity large quantities of blood escaped. The bleeding was found to be coming from the spleen, and after extending the incision laterally to the left costal margin a splenectomy was carried out. Clots and the bulk of the fluid blood were removed; the other abdominal viscera were normal, and the incision was closed. The patient's post-operative condition was good and no transfusion was necessary. His progress was uneventful until the third week. He then had some pain and tenderness in the left hypochondrium accompanied by slight fever, the temperature rising to 99°. This was possibly due to injury to the tail of the pancreas; the condition subsided in about ten days.

On Sept. 27 the blood count was: R.B.C., 3,330,000; Hb, 60%; colour index, 1.03; W.B.C., 10,400—polymorphs 70%, lymphocytes 26%, large mononuclears 1%, transitionals 0%, eosinophils 2%, basophils 1%. The anaemia was believed to be due to blood loss, so the patient was given iron by mouth. On Oct. 11 his red cell count had risen: R.B.C., 4,320,000; Hb, 74%; colour index, 0.89; W.B.C., 7,600. No malaria parasites were seen in thick films. Blood pressure, 138/74.

After operation the patient was closely questioned to find out whether the rupture could be accounted for by injury. Three months previously he had fallen against a tap and struck his right side. His lower ribs had been painful for a month, but the pain was never bad enough to make him report sick.

The spleen was normal in size and consistency. At the junction of the upper and middle thirds of the cut surface the pulp showed six or seven small haemorrhages about the size of a pea. One of these areas on the convex surface communicated with an extensive subcapsular haematoma. The capsule had a large rent through which the blood reached the peritoneal cavity.

Dr. J. L. Edwards, who examined the spleen, reported on its histology:—"The Malpighian bodies are well defined. The central arteries are hyaline. There has been recent haemorrhage into the pulp. There is a reticular increase in the pulp. No malaria parasites are seen in Giemsa preparation. Eosinophil leucocytes are fairly numerous in the pulp."

Discussion

In the light of previous reported cases the main points of interest of this case are: (1) the naked-eye appearance of the haemorrhage in the spleen; (2) the history of previous trauma; (3) the absence of previous dyspepsia; (4) the presence of degenerative changes in the blood vessels of the spleen; (5) the spleen was not abnormally mobile.

It is suggested that the appearance of multiple haemorrhages was misleading and that there was one haemorrhage burrowing in the splenic substance, stripping the capsule and bursting into the peritoneum. The appearance of multiplicity was due to cutting the tortuous haematoma in several places. The only previous trauma to the lower chest and abdomen occurred three months earlier. The pain was confined to the right side of the lower chest and did not stop the patient from working. On subsequent examination the spleen failed to show either adhesions or evidence of old haemorrhage.

Although this patient had had no previous indigestion he had been travelling most of the day and had eaten mainly vegetables. He himself attributed his misfortune to eating celery. At laparotomy stomach, duodenum, and gall-bladder were found to be normal.

The blood vessels of this spleen showed well-marked hyaline change. It is probable that the underlying cause in all cases of spontaneous rupture of the apparently normal spleen is an intrasplenic haemorrhage. This may be a ruptured vein or splenic sinus following congestion. In many cases congestion has been noted. The cause of the congestion probably varies. Different causes have been cited—viz., partial torsion or kinking of an unusually mobile pedicle (Zuckerman and Jacobi, 1937; Halliwell, 1933; Black, 1933; Dubash and Langley, 1944), pregnancy (Burnett and McMenemy, 1935),

hepatoma (Dardinski, 1932), or recent thrombosis of a splenic vein (Rhame, 1928).

It is probable that in some cases there is an arteriolar rupture. The splenic artery degenerates early. Black states that at 36 years 50% of spleens show degenerative changes. The splenic artery may show gross degenerative changes with aneurysm formation when the rest of the arteries in the body are normal (Parsons, 1937).

In the case reported above the spleen was not abnormally mobile—there was no evidence of venous obstruction, and in view of the arteriolar degeneration present it is possible that the haemorrhage was arteriolar in origin.

Summary

A further case of spontaneous rupture of an apparently normal spleen is reported and a brief review of the literature is given. It is suggested that rupture is secondary to an intrasplenic haemorrhage. It is unlikely that any one common cause of the haemorrhage will be found to explain all cases.

PNEUMOPERITONEUM

BY

DUNCAN LEYS, M.D., F.R.C.P.

Physician, Royal Northern Infirmary, Inverness; Consulting
Physician, Highlands and Islands Medical Service

The term "pneumoperitoneum" is used to describe the presence of free gas in the peritoneal cavity without evident peritonitis. The condition is regarded as rather a curiosity, but d'Allaines (1932) was able to analyse 34 published cases, and to add one from his own experience. The fact that three cases can be reported here, all of which were observed within the space of a few months, suggests that spontaneous pneumoperitoneum is not really very uncommon, and that to be aware of the existence of the syndrome is to make it likely that one will observe it.

Case I

An unmarried woman aged 30 was admitted to the Royal Northern Infirmary under Dr. T. N. MacGregor for removal of fibroids of the uterus. Her previous health had been good except for dyspepsia several years. She developed a post-operative collapse of the right lung with secondary infection. This was treated with sulphanilamide, but resulted in a small right-sided pleural transudate (sterile). After this had subsided she complained of a sharp pain in the right side, had a rise of temperature to 101° F., and x-ray screening (Dr. G. Gottlieb) showed gas beneath the right diaphragm (which had not been present in previous radiographs). She had some tenderness and some muscle spasm in the upper abdomen, and there was complete disappearance of liver dullness. Her general condition, however, was not that of generalized peritonitis. Further treatment with sulphadiazine was given, and after four days her temperature was normal and symptoms absent, but there was still some abdominal tenderness. This gradually disappeared, and she was discharged from hospital. She was x-rayed again three weeks later (Dr. Gottlieb), and gas was still to be seen below both domes of the diaphragm. There was an ill-defined pyloric antrum with some deformity and stiffness, apparently due to adhesions. The duodenal cap was deformed, probably from adhesions to the gall-bladder. No ulcer crater was seen. The emptying time was delayed, with a moderate two-hour residue. The appendix was partially filled, fixed to the midline, and tender on palpation.

This patient reports, 18 months later, that she has since remained in good health.

Case II

A married woman aged 60, with six children, was admitted to the Royal Northern Infirmary for attacks of abdominal pain with nausea and occasional vomiting, constipation, anorexia, loss of weight, and attacks of diarrhoea preceded by severe abdominal pain, the stools being fluid and dark, without excessive mucus. Her

general condition was good except for recent loss of weight. Her complexion was sallow. Red cells numbered 4.8 millions, with haemoglobin 89%. The heart action was normal except for extrasystoles. Stomach splash was present three hours after food. The benzidine test was consistently positive in stools. Fractional test meal—Maximum free acid, 0.15%; traces of blood throughout; starch present to the third hour. Radiograph (Dr. Gottlieb): ptosis of the stomach with no clear definition of pylorus or duodenum; a large residue of barium present at four hours; gas seen below both domes of the diaphragm.

At this time there was no tenderness, distension, or rigidity, and little discomfort. She was kept in bed, given a diet largely of milk and regular gastric lavage, and was x-rayed again three weeks later, when the appearances were much the same, though an ulcer crater could be seen at the base of the deformed duodenum. A large barium residue was seen at five hours (Dr. Gottlieb). After further gastric lavage the residue steadily diminished and the patient was symptomless. She left hospital to continue under observation as an out-patient.

Over a period of about four months she was seen at intervals of a few weeks, her only symptom being a feeling of abdominal distension "towards the evening, when there was a sensation as of something crackling." She was readmitted, however, four months after her discharge in a coma from alkalosis following several days of repeated vomiting. Tetany was present. Blood urea was 220 mg and blood calcium 6.8 mg. per 100 c.cm. Intravenous glucose-saline rapidly improved her condition, and she later submitted to gastro-enterostomy (Mr. A. J. Hamilton), from which she made an untroubled recovery. Operation showed a narrow scarred pylorus, but no signs of perforation.

Case III

An unmarried woman aged 35 was referred to me in 1941 for abdominal pain of irregular occurrence, but sometimes of the hunger type and relieved by food; the pain had prevented her from working as a cook for 10 months. She had been previously studied, without a positive diagnosis being made, at the Glasgow Western Infirmary. Her general condition was good. No physical signs were found. A fractional test meal showed a maximum free acid of 0.11%, with starch present to the third hour. Radiographs (Dr. Campbell Tainsh) showed a normal oesophagus, stomach, and duodenum, with no gastric residue at six hours; the appendix was not outlined. No blood was found in test meal or stools.

A year later she was admitted as an emergency to the Lawson Memorial Hospital, Golspie, under Mr. B. S. Simpson, with abdominal pain and distension of three days' duration. She was in a state of surgical shock. General restorative measures and the passage of a flatus tube improved her condition, but the next day there was increased distension and pain. At operation, as soon as the peritoneum was opened, there was an outrush of non-odorous gas and the abdomen became deflated. No evidence of peritonitis was found, nor could any other lesion be discovered. A caecostomy was carried out. After operation she was in good condition for a few hours, but there was then a recurrence of pain and distension, with deterioration of her general condition, and the abdomen was reopened 48 hours after the first operation. Once again there was an outrush of odourless gas and no evidence of obstruction or peritonitis. The abdomen was closed, and on the following day there was once more an acute recurrence of pain and distension. A needle was inserted in the posterior axillary line beneath the ninth and tenth ribs, and there was a prompt outrush of gas, with complete relief of symptoms.

There was no further recurrence of symptoms. The patient made an uneventful recovery and the caecostomy wound was closed. I saw her at the Lawson Memorial Hospital at this time and could detect no physical signs. She was admitted to the Royal Northern Infirmary two weeks later for further study, and immediately after admission developed a pain beneath the ribs on the left side which was worse on taking a deep breath and prevented her from sleeping. The abdomen was slightly distended and tender on the left side of the epigastrium. These symptoms disappeared after a bowel movement, and subsequently there was no further pain or distension. The patient was afebrile. Radiographs (six weeks after the first symptoms) showed no abnormality in oesophagus, stomach, and duodenum, and no evidence of gas beneath the diaphragm (Dr. Campbell Tainsh).

Comment

It will be noted that these three patients were women, and I have only been able to discover a report of one male case—that of d'Allaines (1932)—and no case in childhood. All the patients described here and a great majority of those reported elsewhere have had previous symptoms referable to the gastro-intestinal tract, usually suggestive of ulceration. The gas in two analyses quoted by d'Allaines (made by Montanelli and Urban) was atmospheric except for a rather higher content

of nitrogen. The symptoms in published cases have been sometimes trivial and sometimes, as in the third case reported here, very severe. None of my patients complained of the pain beneath the left shoulder which is reported by Neumann (1943) as characteristic of artificial pneumoperitoneum (an observation confirmed by personal experience). The normal intra-abdominal pressure as measured by a manometer connected with the peritoneal cavity was -9 cm. of water in the knee-elbow position, but slightly positive in the erect position (Eisenmenger, 1935; quoted by Moberg, 1937). Moberg himself found the intra-abdominal pressure in a rabbit normally negative. My own observations in two cases of artificial pneumoperitoneum gave a normal slightly negative pressure with a very quick rise to positive pressures after introduction of quite small quantities of air at the site of the manometer needle; one could, however, continue to introduce air, without much further rise in pressure and with very little discomfort to the patient, to a total of anything up to one or more litres. No pain except slight discomfort at the shoulder was complained of by these two patients. Coombs (1922) found no immediate alteration of pressure when air or fluid was introduced into the peritoneal cavity.

Almost all the reported cases of spontaneous pneumoperitoneum have been thought to be due to escape of gas from the stomach or the first part of the intestine by a perforation so situated as to allow the escape of gas only, and healing so rapidly as not to be followed by the escape of other duodenal or gastric contents. There are at least two other possible sources of free gas in the peritoneum: (a) vaginal, via the Fallopian tubes; and (b) thoracic, via the diaphragmatic hiatus. The forcing of air through the Fallopian tubes, presumed due to vaginal douching with careless use of a syringe, has been reported by Moberg (1937), and, by the same author in another case, from supposed alteration in intra-abdominal tension secondary to gastric dilatation. This latter patient, an elderly woman with carcinoma of the pylorus, was in the habit of adopting a stooping position to provoke vomiting, and Moberg considered that she produced an unusually low pressure in the peritoneum with subsequent suction of air through the Fallopian tubes. Dr. T. N. MacGregor informs me that it is unusual to require a pressure exceeding 4 cm. Hg for artificial inflation of the Fallopian tubes, and that he considers spontaneous suction of air through the vagina very unlikely. Only one of my patients (Case III) had been using vaginal douching for leucorrhoea before the occurrence of her symptoms, and the recurrence of distension in her case makes it quite obvious that this could not have been the source of her pneumoperitoneum. It is nevertheless odd that almost all the reported cases should have been in women. An exceedingly rare cause of intraperitoneal gas is so-called "pneumatosis cystoides peritonei," which is due to infection by parasites.

Lastly, at least one case has been recorded (Hinkel, 1940) in which pneumoperitoneum was thought to be the result of an extension of gas from the thorax to the peritoneum by way of the diaphragmatic hiatus. His patient, a woman aged 70, had sudden symptoms of abdominal distension and tenderness, without severe constitutional symptoms and without fever. She was discovered to have an old left basal pleurisy with a high left dome of the diaphragm, and a bronchogram showed, just above the diaphragm and close to the heart shadow, a large emphysematous bulla which was considered to be the probable source of the gas.

The case reported by d'Allaines is the only one I can find in the literature which bears a close resemblance to Case III, reported here as having had severe symptoms without any definite evidence of perforation at operation. d'Allaines suggested that the explanation in his case lay in a perforation of the stomach so minute and so close to the oesophageal opening as to be inaccessible to observation. He recalled one patient of his, with a perforation on the anterior wall of the stomach just beneath the diaphragm, who gave a history suggesting an escape of gas preceding the appearance of the actual peritonitis by several days. He recalls, in support of his explanation, the fact that many surgeons have observed perforations to heal satisfactorily after laparotomy in which no procedure was undertaken except that of drainage of the peritoneal cavity.

Summary

Three cases of free gas in the peritoneum without evident peritonitis (pneumoperitoneum) are reported, all presumed due to minute perforations of stomach or duodenum.

Medical Memoranda

An Unusual Case of Meningococcal Meningitis

The occurrence of two attacks of meningococcal meningitis in the same patient within a short period seems worthy of record. The case is one of a series of 30 severe cases of this disease in which there were four deaths (two moribund on admission).

FIRST ATTACK

The patient, a pagan private aged 25, was of good muscular physique. On admission he was unconscious, with marked signs of cerebral irritation. The general condition showed toxæmia, with temperature 104°. C.N.S.: neck very rigid, incontinence, Kernig's sign positive, knee- and ankle-jerks increased, with bilateral plantar extensor reflex, abdominal reflexes absent. Lumbar puncture yielded turbid fluid under pressure; globulin was increased; centrifuged deposit contained pus cells and scanty meningococci. Two grammes of soluble sulphapyridine were given intravenously, and the same amount four hours later; then 1 g. of sulphapyridine intramuscularly four-hourly. (Total course of 35 g.)

Two days after admission the breathing became distressed, with moist rales in both lungs and patchy consolidation. Recovery took place from this hypostatic pneumonia. Five days after admission the patient suddenly became unconscious and had repeated convulsions. Spasmodic twitching began in right facial muscles, with conjugate deviation of eyes to left. The spasm spread to the muscles of the upper and lower limbs on the right side, finishing with conjugate deviation of eyes to right and spasms of the left side of the body. Convulsions ceased after one hour, and further recovery was uneventful. Lumbar puncture gave clear fluid; no increase in globulin, cells 7 c.mm in centrifuged deposit. No micro-organisms seen. The patient was discharged fit on March 1 (21 days after admission). He had no complaints and was ambulant during the last 12 days. He returned to full duty.

SECOND ATTACK

The patient was readmitted on March 27 complaining of headache and pain in the back of the neck for 24 hours. Condition on admission: temperature 103°; neck rigidity marked; Kernig's sign positive; knee, ankle, and abdominal reflexes absent; plantar reflexes not obtained. Lumbar puncture yielded cloudy fluid under pressure; marked increase of globulin; pus cells and meningococci present in centrifuged deposit. Soluble sulphapyridine, 2g., was given intravenously, and sulphapyridine, 1 g. intramuscularly, every four hours (total course of 53 g.).

Sixteen days after admission patient was afebrile and ambulant. On the 17th day he complained of weakness on the right side of body. The temperature was 100.8°. There was right facial palsy with general loss of tone and power of the muscles of right upper and lower limb. Pupils reacted equally to light and accommodation and were equal in size. Movements of the tongue were unaffected. Hearing and vision were normal. Reflexes were generally sluggish except for increased abdominal reflexes on the left side.

His general condition deteriorated, with increasing right-sided weakness and increasing neck rigidity and a positive Kernig's sign. White cell count showed a leucocytosis of 17,000 with 70% polymorphonuclears. Lumbar puncture: turbid fluid with increase of globulin, pus cells, and scanty meningococci in deposit. He was transferred to another hospital so that further investigations could be carried out. Death took place shortly after transfer. Post-mortem examination disclosed a superficial cerebral abscess over the left temporal lobe. Direct smear showed scanty meningococci.

I am indebted to Major P. E. Rees-Davies, officer commanding, for permission to publish this case.

C.C.S., West African Force. Lieut. R A M.C.

Reviews

OCCUPATIONAL THERAPY

The Rehabilitation of the Injured. Occupational Therapy. By John H. C. Colson. Foreword by E. A. Nicoll, M.D., F.R.C.S.Ed. (Pp. 226; illustrated. 15s.). London: Cassell and Co. 1944.

The ideals and aims of rehabilitation have been reiterated *ad nauseam* in all sorts of places and on all sorts of platforms. It is, as Lord Horder has said, a subject so much in the air that it is in danger of remaining in the air, and any contribution that brings it down to earth is to be welcomed. The present volume certainly does that. It is, we are told, the first of a series of books which the author is writing under the general heading of *The Rehabilitation of the Injured*; and occupational therapy is dealt with first, not because it is more important than its stable companions—remedial exercises, recreational therapy, and physiotherapy—but because it is the one about which there is the greatest dearth of practical guidance.

The author treats his subject, not from the diversional standpoint but as a disguised form of remedial exercise used for the re-education and redevelopment of specific muscle groups and the mobilization of specific joints. The disguise takes the form of purposive movements with a creative interest, and in his interpretation of the latter the author is not fettered by over-artistic tendencies. A well-scrubbed lavatory floor is as much an object of beauty to the man who has scrubbed it as an exquisitely woven scarf of many colours—or so it would be in any department over which Mr. Colson held sway.

The basic principles of remedial exercises are expounded in an early chapter, and it is shown how these can be preserved in occupational therapy. The next section deals with a variety of handicrafts, each of which is discussed under three headings: (1) "Remedial Use," which deals with indications, aims, craft analysis, and remedial application; (2) "Craft Technique," which gives clear working instructions for those who wish to learn the occupation; (3) "Constructional Work," which amplifies the previous section. This arrangement of material makes the book extremely useful to the busy surgeon who wishes to acquaint himself with the principles of occupational therapy but has neither time nor desire to wade through a mass of technical detail. The crafts chosen are simple enough to be learned by short-term patients, and most of them are within the compass of the dull and the "ham-handed" as well as the intelligent and dexterous, a point not always sufficiently appreciated. In the section on weaving several ingenious looms are illustrated. These are adapted respectively for knee, ankle, shoulder, forearm, and finger cases. Finally, there is a description of the author's "universal" loom, which, despite its almost frightening resemblance to a prehistoric Wurlitzer organ, manages to incorporate the remedial possibilities of all the lot.

There is a special chapter on woodwork, with a section devoted to various outdoor and indoor occupations ranging from simple domestic chores to really heavy timber work suitable for the final stages of hardening. This attitude towards occupational therapy is refreshing, and should go far towards removing the doubts of those surgeons to whom it is still "something rather arty-crafty, more suitable for old ladies with Colles's fractures than for miners with broken backs." The quotation is from the foreword by Mr. E. A. Nicoll, who goes on to confess that for his agnosticism he was compelled to sample each occupation in turn, and thereby found himself successively qualified as a farm labourer, a handicraft worker, and a domestic servant.

This book is clearly written and well illustrated. It has a practical and original outlook, and deserves to be read not only by occupational therapists but by every surgeon who is responsible for the treatment of injuries.

BIOMICROSCOPY OF THE EYE

Biomicroscopy of the Eye. Slit-lamp Microscopy of the Living Eye. By M. L. Berliner, M.D. Vol. 1. (Pp. 709; illustrated. 84s.) London: Hamish Hamilton Medical Books.

Slit-lamp microscopy of the living eye is essentially the work of Alvar Gullstrand, who by 1911 had evolved the necessary apparatus, and of Alfred Vogt, who in ten years between 1920

and 1930 had mapped out the field so thoroughly that contributions by other observers have added little of fundamental significance—an achievement almost unique in the history of ophthalmology. It is fortunate that before his passing in 1935 Dr. Vogt had succeeded in completing the third and final volume of his monumental treatise on the subject. This three-volume treatise is nominally the second edition of a single volume published in the early 'twenties, an English translation of which appeared at the time but is not readily available. Apart from that translation English literature has so far had to be content with a translation of a book by Kobayashi and the *Illustrated Guide to the Slit-lamp* brought out by Harrison Butler in 1927. Perhaps owing to the lack of an adequate text slit-lamp microscopy in this country and the United States has not occupied the place to which it is entitled in clinical ophthalmology. The one outstanding contributor to the subject in this country has been Mr. Basil Graves, and it is gratifying that in this new and sumptuous treatise full recognition is given to his pioneer efforts and substantial contributions.

Dr. Berliner has produced one of those rare books that profoundly influence clinical practice. Here, for the first time in English, is an adequate presentation not only of the technique of slit-lamp microscopy but also of slit-lamp appearances and the effect that this knowledge has had in clarifying clinical pictures. The present volume deals essentially with the conjunctiva and cornea, discussion on the lens being reserved for the second volume, which is still to come. How significant biomicroscopy has become in clinical practice is well shown by the successive chapters on the cornea. Here the English reader can at last find something like order in the chaos that passes for an account of corneal lesions in the standard text books. Dr. Berliner has wisely avoided loading his text with illustrative individual cases, and has presented his material in a systematic fashion in clear and crisp English. The lavish use of photographs, sketches, and colour plates make for easy reading in what is to many clinicians a relatively unfamiliar field. Perhaps the most pleasant feature of the book is that nowhere are the findings presented as esoteric knowledge divorced from the day-to-day work—a pitfall only too apparent in many individual contributions in periodical literature. The present volume concludes with a chapter on gonioscopy by H. S. Sugar. This derivative of slit-lamp microscopy has received hardly any attention in this country, and Dr. Sugar's factual account, drawing on a mass of personal observation, should help to popularize a method which is giving excellent results in the hands of our American colleagues.

From the point of view of the English reader there is one criticism which might perhaps be met by Dr. Berliner in preparing subsequent editions. There are so many models of the slit-lamp on the market that for geographical reasons different types have established themselves in different countries. Dr. Berliner does well to describe fully the original Gullstrand technique, for, as he points out, this was the basis of all further work. The early Zeiss model is still widely used in this country and has many advantages over some of the later and more rigid types. Some account of this model would be helpful to many ophthalmologists.

INFANT PSYCHOLOGY

The Rights of Infants. By Margaret A. Ribble, M.D. (Pp. 118. 51s. or 11s. 6d.) New York: Columbia University Press; London: Oxford University Press.

From a long study of psychological problems in adults and children, concluding with observations on 600 normal newborn babies in three different maternity hospitals in New York City, Dr. Margaret A. Ribble has written a fascinating monograph *The Rights of Infants*. Her subtitle, "Early Psychological Needs and their Satisfaction," is a good description of the subject-matter of the book. Although Freudian views are frequently expressed, and the author explains that during part of her studies she worked with Anna Freud, there is a clear-sighted common sense about Dr. Ribble's writing which puts Freud's contributions to psychology in proper proportion, and shows more insight into the modern mother's everyday problem than many a theoretical expert has usually shown that he she possesses. Chapters on "learning to feel" and "getting

MORYL

TRADE MARK CARBACHOL BRAND

Parasympathetic Stimulant

A powerful stimulant of the parasympathetic nervous system, chemically related to acetylcholine, but more active and more stable. Indicated more especially in post-operative intestinal stasis and urinary retention, "Moryl" is also useful in eclampsia and pre-eclamptic conditions, hypertension, paroxysmal tachycardia, anxiety neurosis, ozaena and glaucoma.

(C 11)

Samples and literature on request: Savory & Moore Ltd., 61, Welbeck Street, London, W.1

TETRONOX

TRADE MARK TABLETS BRAND

Hypnotic—Sedative

Enhanced power of barbitone through careful combination with other drugs—reduced toxicity; no cumulative action or injurious effects on circulation, respiration or gastro-intestinal tract. "Tetronox" has a wide field of indications in psychiatry and is furthermore of value in menstrual discomforts, post-operative and post-partum sedation, occupational insomnia, premature waking, etc.

(15)

INCREASED PREVALENCE OF HYPERACIDITY

The influence of war-time conditions is responsible for the marked increase in the number of patients presenting symptoms of gastric upset.

Generally the sufferer gives a history of hurried meals at irregular hours, with a stress factor arising from long hours of work and restricted relaxation.

'Milk of Magnesia' is invaluable in securing rapid control of discomfort and distress. Composed of a colloidal suspension of magnesium hydroxide, it soothes the inflamed mucosa, neutralizes the excess acid without liberation of gas and its mild laxative action ensures removal of toxic waste products.

'Milk of Magnesia' may confidently be prescribed in the mild case of dyspepsia or the acute ulcer stage where sustained alkaline treatment is essential.

'Milk of Magnesia' contains approximately 8.45% Magnesium Hydroxide in colloidal suspension.

'MILK OF MAGNESIA'

(Regd.)

THE CHAS. H. PHILLIPS CHEMICAL CO. LTD., 179, ACTON VALE, LONDON, W.3.

★ 'Milk of Magnesia' is the trade mark of Phillips' preparation of magnesia.

VITAMIN D

and its addition to infant milk foods

Just twenty years ago, the first of the standardised and concentrated vitamin products, 'Ostelin' vitamin D, was introduced in convenient form for exact use in mixtures and in drop doses. This was a notable achievement in the prevention and treatment of rickets. • In 1928, this concentrate of vitamin D was added to the infant food, Ostermilk. And now, in 1944, the amount of vitamin D in Ostermilk has been increased to 700 international units in each reconstituted pint—a further contribution to the prevention of rickets. • The earliest contribution to child welfare goes back to 1908 when the first dried-milk for infant feeding was introduced, a food which played an important part in the reduction of epidemic gastro-enteritis. • All this important pioneering work in nutrition at the Glaxo Laboratories, inspired by the belief that nutritional disease is preventable, has had its effect on present-day standards and on present-day concepts of infant feeding. • Research continues, backed by large technical resources, in the still unexplored fields of nutrition and disease.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX
BYRON 3434

PETHIDINE

HYDROCHLORIDE

FOR THE CONTROL OF PAIN

The powerful analgesic action of Pethidine Hydrochloride is rapidly developed and maintained for many hours. By oral or parenteral administration it may be used for pre- or post-operative medication to produce obstetric analgesia, to control the pain associated with malignant growths, cardio-vascular and neurological conditions, and to relieve dysmenorrhoea and biliary, renal and intestinal colic. Pethidine Hydrochloride is well tolerated in therapeutic doses, and has little habit-forming tendency.

For oral administration

'TABLOID' ^{BRAND} PETHIDINE HYDROCHLORIDE
—25 mgm. and 50 mgm.—each strength in bottles of 25, 100 and 500.

For injection

'HYPOLOID' ^{BRAND} PETHIDINE HYDROCHLORIDE
—100 mgm. in 2 c.c. in boxes of 12 and 100. Also available 50 mgm. per c.c. in 1 c.c. ampoules in boxes of 12 and 100 and in rubber-capped bottles of 50 c.c.

ready to think" are particularly good, and there is a section on "fathers" which might well have been longer. An early chapter on "oxygen hunger" is less convincing, for it does not seem to be entirely based on modern physiological facts. There is a good bibliography and a better index than short monographs of this type usually contain. Psychologists and paediatricians will find much valuable information and many stimulating ideas in these pages.

Notes on Books

There are certain matters, or particular aspects of a subject, which are most suitably dealt with through the medium of articles in appropriate journals rather than by the more substantial and permanent publication of a book, and this we feel applies especially to *The Surgery of Abdominal Trauma*, by Mr. GEOFFREY E. PARKER (J. and A. Churchill; 10s. 6d.). This short book constitutes a record of the author's experiences in abdominal military surgery obtained in North Africa and Italy, together with case summaries of 94 such cases. So far as general principles go the author agrees with the many writers of surgical articles which have already appeared in this *Journal*. In the case records he has critically examined the conduct of the cases and pointed out with commendable frankness where the treatment adopted might have been further improved. The over-all recovery rate of 66% is, as Col. J. M. Weddell points out in a foreword, a very creditable record, and shows that the methods advocated in the handling of these serious cases can be safely followed by newcomers to this branch of surgery.

The 1943 issue of the *Year Book of Industrial and Orthopaedic Surgery* (Year Book Publishers of Chicago; \$3.00) lives up to the high standard set by Dr. CHARLES F. PAINTER in previous editions. A wide range of subjects in the fields of traumatic surgery and orthopaedics is covered, and the concluding section deals with industrial medicine and surgery. Many new developments in orthopaedic surgery are covered. The editor presents a brief précis of each article with the minimum of editorial comment. This may sometimes tend to give a wrong impression: for instance, two favourable accounts of the Sister Kenny treatment of poliomyelitis are included, and the impression might be gained that informed opinion in the U.S.A. is in favour of the method. As is essential in orthopaedic subjects, the text is illustrated by a large number of good x-ray pictures and diagrams. The general lay-out is pleasing and the book is of a convenient size. It can be recommended to orthopaedic surgeons and others as a convenient summary of current orthopaedic articles which have appeared in the medical press recently; but once again we have to add with regret that this volume, like too many of the other Chicago *Year Books*, is not obtainable through Messrs. H. K. Lewis in London, and is said to be already out of print in America.

Mr. C. E. VULLIAMY is well known to many as the ingenious and learned author of two historical concoctions that satirized the Victorian age. He continues the pursuit in a new book *Doctor Philligo* (Michael Joseph Ltd.; 12s. 6d.). Once more he has "had access" to a private journal and reproduces passages from it, with an introduction and explanatory notes, and a portrait (dug up, we suppose, from some old photograph album) which professes to be that of John Arthur Sedley Tobias Philligo (1838-1915), who practised in and around the Cotswold village of Dropwater for 37 years. The parts of the journal "chosen for publication" cover the period 1887-1902 and they purport—very artfully—to record the day-to-day experiences and opinions of an odd but orthodox country doctor in the later years of Queen Victoria's reign, who had been educated at Harrow, Trinity Hall, and St. Bartholomew's. Those who relished *The Polderoy Papers* will enjoy this equally elaborate sequel. Mr. Vulliamy's fun is sedate. He draws his imagined characters and happenings against a careful background of social and political history in the larger world beyond Dropwater and the circle of Dr. Philligo's friends and family.

Facio-Maxillary Injuries, by KENNETH W. STARR, F.R.C.S., and A. J. ARNOTT, D.D.Sc., is reprinted from the *Dental Journal of Australia*. The authors of this small volume of some 70 pages have made a clear and concise condensation of their personal experience in facio-maxillary injuries while attached to the 113th Australian General Hospital. The book will be of interest to all surgeons and dental surgeons who have this highly specialized work to do, for the authors have been able to draw on the experience and teaching of all the large centres in this country. Though much of the detailed dental technique is missing the general principles are well stated and illustrated. The section on tissue replacement and the use of chip grafts deserves special mention.

Dr. A. H. DOUTHWAITE has once more taken charge of *Hale-White's Materia Medica, Pharmacy, Pharmacology and Therapeutics* for its 26th edition (J. and A. Churchill; 14s.). This very popular manual, first published 52 years ago, now reaches its 130th thousand. Dr. Douthwaite notes in his brief preface that the rapid extension of pharmacological research, especially in relation to the sulphonamides, anticoagulants, hormones, and penicillin, has necessitated some increase in the size of the book, which has been thoroughly revised; but in fact only 30 pages are added, and the price is unchanged. The new edition contains all the therapeutically important drugs described in the Fifth and Sixth Addenda to the *British Pharmacopoeia* and many references to monographs in the *Supplement to the British Pharmaceutical Codex*. Near the index, which has been progressively enlarged, is a list of drugs not essential in wartime or in which strict economy should be exercised because they are scarce.

The Advancement of Science, Vol. III, No. 9 (British Association, Burlington House, London, W.; price 5s.), is largely made up of the report of the Committee on Post-war University Education, which has already been published in separate form. The other contents include "Notes on Museums," by Dr. Alma S. Wiltlin and Sir John Myres, and an article on "Science in the U.S.S.R.," by the Soviet Academician Alexander Fersman. Dr. O. J. R. Howarth, secretary of the association, supplies some notes on its organization and future.

Preparations and Appliances

ROCKER FOR ARTIFICIAL RESPIRATION

Dr. C. W. HOPE-GILL (Billingshurst, Sussex) writes:

I have been so much struck by the efficiency and simplicity of design of a device for the carrying out of the rocking method of artificial respiration that I feel it deserves further publicity. The device has been constructed by Mr. A. G. Hampshire of the Billingshurst C.D. Rescue Party (leader, Mr. A. Smith), and consists of a rocker and portable trestle for use with standard C.D. stretchers.

Details of the rocker are shown in the accompanying diagrams, which were executed by Mr. A. R. Bielby, a member

of the party. The rocker is provided with six pegs spaced so as to engage with the mesh of a C.D. stretcher. The pegs are of 3/4-in. dowelling and project 1½ in. above the rocker. The centres of the outside pegs are at corners of a rectangle 17½ in. × 6½ in. At each end of the head of the trestle 1¼-in. iron plates are attached to form cups which hold the rocker securely when the trestle is erected.

In use the patient is firmly fastened to a stretcher while artificial respiration by Schäfer's method is applied. Meanwhile the trestle and rocker are erected, the rocker being placed in a horizontal position. The stretcher is then lifted and placed on the rocker. The pegs engage easily in the mesh of the stretcher and no further securing is necessary. Artificial respiration is continued without a break by the rocking method. The pegs are smaller than the square meshes of the stretcher. This ensures ease of mounting the stretcher on the rocker, and can be used to give the jerk usually considered desirable at the end of each stroke.

RELIEF AND RECONSTRUCTION IN EUROPE

When the last war ended in November, 1918, an organization which supplied relief to Belgium and occupied France had been working for four years. Some two months were wasted in a struggle for control before the Relief Administration was set up, and further disputes delayed the relief to Germany promised by the terms of the Armistice; but observers were studying conditions in Europe, and ships had sailed with supplies in December, 1919. Hoover, who became Director-General of the Relief Administration, had four years' experience as Director of the Commission for Relief in Belgium and authority as Food Administrator in the U.S.A. This time preparations were begun early. In September, 1941, a meeting of representatives of the Allies at St. James's Palace agreed to set up a committee, under the chairmanship of Sir Frederic Leith Ross, to frame estimates of the amounts of materials that would be needed by the Allies. Over a year ago this committee submitted its estimates of the supplies required for a thorough reconstruction of Europe. After seven months of negotiation the agreement to form the United Nations Relief and Rehabilitation Administration (UNRRA) was signed on November 9, 1943, by the representatives of 44 United and Associated Nations. The objects specified were: to supply food, clothing, and shelter; to aid in the prevention of pestilence and in the recovery of health of the people; to arrange for the return of prisoners and exiles; and to assist in the resumption of urgently needed agricultural and industrial production and the restoration of essential services. The last two objects included the supply of seeds, motors and livestock, raw materials, machinery, spare parts, and processing materials. This Administration makes use of the existing Boards both to obtain supplies and to control shipping; it has had no power to arrange production to meet estimated needs. Nor will UNRRA deal directly with relief in its early stages, as did the Relief Administration in 1919. After the first stages of military operations relief will be administered by Civil Affairs under military authority for a period estimated, provisionally, as six months; UNRRA appears to act as a middleman.

It has been extremely difficult to get an estimate of the degree of scarcity in Europe. We have known that even in Western Europe the rations supplied too few calories and that these rations could not always be obtained, though they have been supplemented by food from markets of varying shades of blackness. Since the Allied Armies entered France there has been a tendency to underestimate the scarcity of food and its effects. Soldiers have seen abundance of foods which are scarce in England, such as butter, in producing areas in which they accumulated owing to breakdown of transport; they have been entertained by hosts who brought out their reserve stocks of

food to celebrate their liberation. Many country districts are well nourished, and in Paris encounters with prominent patrons of the black market have given reporters a false impression of the nutrition of the population. Actually most people in the larger towns have lost 10 to 20 lb. in weight, children are thin and pale, and there is no reason to doubt the increase of tuberculosis. The great difficulty is transport: much of the rolling stock is unfit for use, and hundreds of railway bridges have been destroyed; repairs are delayed, as materials and engineers are needed for military operations. The 2½ million inhabitants of Paris need some 2,000 tons of food a day, even in concentrated forms before the war 6,000 tons were brought into the city daily but at the end of September the total daily supply was only 1,500 tons. The milk supply had fallen to one-fifth of the pre-war level, and no dried or condensed milk has so far been provided. Those who can, cycle out into the environs of the city on Saturday and come back laden with vegetables. Prices are high: a simple meal in a modest restaurant costs 300 francs, while an ordinary worker gets about 3,000 francs a month. In southern France milk has been scarce; in Marseilles the bread ration at the end of September was raised to 200 grammes per day, which is only some three-quarters of the amount eaten per head in England, where bread makes up much less of the diet. It is said that there is enough food in France if it could be transported; but the adequacy of the supplies must be a matter of conjecture until communication is re-established.

In Italy conditions are far worse. The Germans tore up the railway lines and removed the rails. The transverse lines needed for bringing food from the interior have not been repaired. Many villages have been razed and all power stations have been destroyed. With no goods offered to them in exchange and a Government without power or popular support, peasants will not surrender the food they produce. The aid promised by UNRRA—medical care, care for children and pregnant women and displaced persons—does not go to the root of the trouble. In the discussion about sending relief to Italy it was stated that the infant mortality rate in Rome had risen to 500 per 1,000; the Yugoslav representative replied that the rate in Dalmatia was 800. Actual production of food in Yugoslavia is hopelessly insufficient; few peasants are left to till the fields. Livestock have been taken and crops destroyed; the Germans have compelled the peasants to grow industrial crops in place of food. The people are eating bread made from acorns and using the cobs of the ears of maize. Sentries are dying of starvation at their posts. The Greeks have been in an exceptional position, as in peacetime they imported nearly one-third of their grain—about half a million tons of wheat. Their home production has fallen, and such supplies from outside as have been allowed have not been up to their pre-war imports. Of Poland we know little except that the Germans have taken large levies of food and are scorching the earth as they are driven back.

A large amount of food will undoubtedly be needed for relief; there should be enough grain to supply calories; but even in France animal products will be scarce because livestock have been killed off. Any stocks that have

accumulated will not be enough to make good this scarcity ; the greater part of the animal products supplied as relief must come out of current production. Without some reduction in consumption in Great Britain and the USA the quality of the food supplied may be no better than after the last war, when the dinners provided for children contained no animal products besides lard and under a pint of milk during a whole week.

Even when the fighting stops the greatest difficulty everywhere will be transport. It is estimated that some 20 million people will want to return to their homes. They will throw an extra strain on a crippled and overworked transport system, if their migrations are not organized and controlled they will upset the rationing system of any areas through which they pass and carry with them the danger of epidemics. These dangers have not been forgotten, but no schemes for meeting them have been published. It is reported that the only connexion that UNRRA will have with Germany will be in repatriation of nationals of the United Nations who have been forced to work in that country, and bringing relief to those who favoured the allied cause or are in concentration camps. Whatever policy towards the people of Germany may be adopted in the end, the people of surrounding countries cannot be indifferent to the danger of epidemics among a population lacking housing, fuel, soap, and food. It is probable that in the end some hasty expedient to supply relief to the Germans will be adopted for sanitary reasons.

The great fault at the end of the last war was that large-scale official relief ended prematurely in the summer of 1919 food, clothing, and medical stores were supplied, but little was done to revive production in Europe. UNRRA, by its terms of reference, is limited to meeting urgent needs, and it is questionable how far its funds will do even this. The proposed industrial rehabilitation may be excluded and the agricultural programme cut down. At the second meeting of the Council of UNRRA in September members stressed that temporary relief and *ad hoc* rehabilitation will not restore Europe. The Council has drawn the attention of Member Governments to the need for providing further means for continuing rehabilitation. Seeing that one and a half years elapsed between the meeting at St. James's Palace in 1941 and the appearance of the first draft of the UNRRA agreement, and that a further seven months passed before the final version of the agreement was accepted, there is a danger that this recommendation has come too late.

THE HARVEIAN METHOD IN LITERATURE

In Harvey's time the Royal College of Physicians restricted its influence to a circuit with a radius of seven miles from London. Such parochialism is impossible to-day, and it is significant of the increasing part which the Provinces are expected to play in the work of the College that for the first time the Harveian Oration should have been delivered this year not in London but in Manchester, where Sir Edmund Spriggs chose for his title "The Harveian Method in Literature". The reason for the change of place was the Government's request that meetings should not be held in London under the conditions then prevailing. As the roll

of orators mounts up through the centuries the difficulty of a fresh approach to the subject of Harvey's work increases, and we congratulate Sir Edmund on having found one. Much has been said and written on literary doctors, but to trace the influence of scientific thought on general literature is a novel and, as it proves, a fruitful idea. Harvey as a man of his time was not entirely freed from the bonds of scholasticism, as passages in his *de Generatione* show. It was one of Osler's profoundest remarks that we all drag about with us the chains of errors in which we were originally trained. Nor is it surprising that Harvey's discoveries were unpalatable to his contemporaries, for, as Wilfred Trotter said, there can be no approach to truth without a threat to one's personality, the individual world we build up dislikes interference. It is therefore to Harvey's credit that he followed as far as he could a method which the orator defined as "the use of observation and experiment guided by knowledge and by thought". Bacon was rather the preacher and Harvey the doer of the word. Sir Edmund went on to claim that a gradual approach to more truth in literature can be traced after Harvey's time. Imaginary romances began to be replaced by studies of real incident and of human nature, and on many later writers an influence came from those who had some scientific knowledge, not a few of whom had been medical students or practitioners. The study of natural law affects all mental processes, including observation, order of thought, self-criticism, and judgment. It will lead a writer to be true to physical facts and conditions. It will make him consider whether, in unfolding any human problem, he has looked around for adequate control observations before displaying the trend of his judgment or opinion. And of this thesis copious illustrative examples were given, supporting the speaker's view that even the novel and the poem acquired a more solid foundation with no detracton from beauty of expression or play of thought.

A particularly interesting part of Sir Edmund's oration was his study of pessimism in literature, several distinguished writers seem to have been led by the objective methods of science to a state of more or less misery, though they did not always live up to their doctrines, often "facing one way and rowing the other". Such unhappiness of outlook may be temperamental, or due to an unfortunate childhood or to ill-health. The attempt to know or deny what scientific method can neither assert nor exclude brings to some intellectual and sensitive persons a frustration, which is hardly reasonable though it may excite our sympathy. Because they cannot know all, they are tempted to say all is vain. It was, by the way, the medically trained Keats who recognized that one of Shakespeare's greatest characteristics was his capacity for "being in uncertainties, mysteries, doubts, without any irritable reaching after fact and reason". It is foolish to ply the universe with questions to which no answer could be given within our comprehension. As Sir Edmund phrased it, "the cure is not to fix one's goal too rigidly beforehand, but to subject oneself to experience. One's world can indeed be shattered to bits by trying to mould it nearer to the heart's desire". And he went on to point out to the pessimists that "it is unscientific to draw conclusions

from the morbid without taking into account control observations upon a large number of average people. Reality is opulent, various, and vital; deformity, mental or physical, is not the rule, and the aim of Nature is not death, but life." It is to the credit of medical authors that, though dealing with disease in their daily work, they have generally realized this fact. As our readers were reminded last week, Robert Bridges deliberately underwent a medical training because he believed he would be a better poet by practising a profession which brought him into contact with human life. "In general," said Walter Bagehot, "an author is out of the way of employing his own eyes and ears." This remark leads to the very crux of the Harveian method. Indeed it is abundantly clear that the scientific attitude has had profound influence upon literature and all human thought. After Harvey, we may add, Isaac Newton's discoveries coloured the whole thought of the eighteenth century, just as Darwin did in the latter half of the nineteenth, and as Freud is doing to-day. Conceptions of evolution and of the working of the unconscious mind are to be met with in every form of literature.

By this oration Sir Edmund Spriggs takes his place in the distinguished roll of scholar-physicians, a roll which must ever increase if, undazzled by technical advances, medicine is to retain its position as a humane and learned profession.

SHAW VERSUS MEDICINE

"He who can, does; he who cannot, teaches," wrote Mr. Bernard Shaw in his revolutionary days, and for the past sixty years he has been teaching and preaching at a good-humoured English public who have richly rewarded him for the amusement he has provided them. For the past 38 years hundreds, perhaps thousands, of doctors have cheerfully handed in their money at the box office in order to get a good laugh out of *The Doctor's Dilemma*, quite unperturbed by the attack made by Shaw upon the medical profession, because it was very plain that he did not understand the nature of a doctor's work. Whatever else he has learnt in order to try to teach others, he seems to have learnt one lesson—that of humility; and it is the absence of this quality in his recent book which has annoyed some of his reviewers. Since the publication of *The Doctor's Dilemma* in 1906 Mr. Shaw seems to have confirmed himself in his own ignorance of medical matters, and now abuses the great position he holds in the public life of this country by misrepresenting facts. "Men," he writes, "have submitted to castration . . . but compulsion of everybody willfully to dangerous blood poisoning repeated for every virus discoverable by the new electron microscope, to sterilization, to extirpation of the ovula and tonsils, to birth delivery by the Caesarean operation, to excision of several folds of the bowel and of the entire appendix, to treatment of syphilis and malaria by doses of mercury and arsenic, iodine, and quinine, all of which have been advocated by eminent physicians and surgeons, and some of them legally enforced to-day. . . ." This suggestion of compulsion is not true of medicine in this country. He says of the modern treatment of venereal disease, presumably meaning the treatment of gonorrhoea by sulphonamides and penicillin, "There is the gravest doubt as to whether the prescribed treatment of venereal disease is not mischievously mistaken." Of salvarsan he observes, "The truth was that it combined mercury with arsenic": the truth is that mercury does not enter into

the composition of salvarsan. Mr. Shaw goes on, "When as in the case of syphilis, the suppressive agent is a malignant poison, it is strongly held in certain quarters that the terrible secondary and tertiary recurrences of the worst symptoms are not the disease at all but the specific effect of the poisons with which it has been treated." Our surgeons he observes that "scepticism as to the utility of drugs is shared by surgeons. They use drugs only to produce temporary insensibility to pain." This remark shows the extent of Mr. Shaw's ignorance of modern surgery. Mr. Shaw brings up again his old bugbears of vaccination and vivisection, and, as he apparently wishes to be seriously considered as a statistician, we have invited the foremost medical statistician of the day, Prof. Major Greenwood, to examine the statistical exercises of an amateur (see page 570 this week). Some insight into the emotional basis of Mr. Shaw's ratiocination is provided by his statement, "Of all legalized tyrannies none is more unbearable than those which lay violent hands on us and our children and inject poisons into our veins or thrust them down our throats." Mr. Shaw thinks that Isaac Newton wrote nonsense when he passed from mathematics to theology; it is possible that Mr. Shaw is not intellectually so much greater than Newton that, when he puts play writing aside and turns to pathology, he can write good sense.

"CHILD SPACING"

In 1925 Robert Woodbury, then director of statistical research in the Children's Bureau, U.S. Department of Labour, published a monograph entitled "Causal Factors in Infant Mortality, a Statistical Study based on Investigations in Eight Cities." The conclusion he reached was that "infants born after short intervals had a marked high rate of mortality from all causes. Evidently some factor that is intimately connected with the short interval—perhaps through the influence of frequent births upon the mother's health—affected adversely the chances of life of the infants who followed closely after preceding births. In round figures, infants born after an interval of but one year after the preceding birth suffered a mortality rate 1 times that of infants born after an interval of two years or more. Dr. Nicholson J. Eastman¹ believes that this monograph has had more influence on the pattern of planned births in the U.S.A. than any half-dozen other publications. He describes Woodbury's monograph as a reserved and scholarly study, largely objective in character. Though Woodbury made no suggestion as to what might be done to reduce infant mortality in the short-interval group, those interested in the furtherance of birth control were quick to acclaim this publication and draw their own conclusions; indeed, this monograph has become the corner-stone of contraceptive practice and of the "child spacing" now so readily advocated by the medical profession. The facts and conclusion of the Woodbury study have even been spread abroad by the *Readers Digest*.

Because of the wide influence of this monograph Eastman felt that it would be wise to review that portion which dealt with the short-interval problem. This he has done, and has in turn presented a careful analysis of a further 38,000 obstetrical cases. Though he does not question the accuracy of the figures in the Woodbury study, he shows that the usual interpretation has been false in one important aspect. Eastman divided his cases into four groups according to the interval since the last delivery: these were—very brief (less than 12 months); brief (13–24 months); moderate (25–48 months); and long

¹ *Amer. J. Obstet. Gynec.*, April, 1944.

(more than 48 months). The stillbirth and neonatal death rate was much higher in the "very brief" group than in the three other groups, largely confirming Woodbury's data. At first sight this might be interpreted as wholly due to the short interval between births; on further examination, however, the fallacy of this argument was apparent. If a full-time child is to be born within a year of the preceding birth there are only three months available for conception; in contrast, there are five months and eleven months respectively in which conception may take place if a premature birth or abortion is to occur. In other words, one would expect the incidence of premature labour and especially abortion to be disproportionately high in this group; this is borne out by the data.

Eastman's analysis is careful and exhaustive, and his conclusions are of the greatest importance to those who have the welfare of the community and of its mothers at heart. He believes that the following conclusions are clear-cut and inescapable:

"(1) Infants born from twelve to twenty-four months after a previous viable delivery (that is, during the second year) have at least as low a stillbirth and neonatal mortality as do infants born after longer intervals. (2) The longer the interval between births the more likely the mother is to suffer from some form of hypertensive toxæmia of pregnancy. The incidence of this complication is lowest when the interval is twelve to twenty-four months, significantly higher when it is twenty-four to forty-eight months, and much higher when it exceeds four years. In the present study this was equally true of white and coloured ward patients and of private patients. (3) In patients who have had a previous hypertensive toxæmia of pregnancy, the likelihood of repetition becomes progressively greater as the interval becomes longer. (4) The incidence of the following conditions is no greater when the interval is twelve to twenty-four months than when it is longer: premature labor, anaemia, post-partum haemorrhage, and puerperal infection; nor are mothers in this brief interval group less able to nurse their babies. The weight of the mature babies was approximately the same regardless of the interval."

He believes, and has shown without reasonable doubt, that the high stillbirth and neonatal rate in the "very brief" group is largely due to a much higher proportion of abortions and premature births than occurs in the other groups. Though the time factor is chiefly responsible for the high incidence of abortion and premature labour in this group, he does not exclude the possibility that other influences may play a part. The data suggest that pregnancies conceived within five months of childbirth do show a slight increase in the incidence of premature labour. Perhaps more important, he believes that in recommending birth spacing for the health of the mother and infant the medical profession may be overlooking the greatest talisman that pregnant women can possess—namely, youth. Child spacing means maternal ageing, which, after an optimum age (probably in the early twenties), inevitably means a slightly higher risk to the mother and child.

THE NURSING OF TUBERCULOSIS

The nursing of tuberculosis is a more complicated art than it used to be. No longer are sanatoria merely rest homes in the mountains. The modern hospital for treating pulmonary tuberculosis carries on much acute surgery, and a corresponding advance is needed in the skill of ward sisters and nurses. A report by the Tuberculosis Association and Joint Tuberculosis Council presents the situation—a difficult one—as it confronts both professions to-day. Some 8,000 nurses are needed for the 25,000 beds used in the treatment of pulmonary tuberculosis, and there is a serious deficit of likely candidates. Yet, according to

this report, the risk of tuberculous disease in sanatorium nurses is no higher than among general hospital nurses. Although there is a widespread belief that a girl should not enter a tuberculosis hospital under 21, the committee feels that 21 is no safer an age than 18. Supervision and early detection of the symptoms of disease (particularly of Mantoux-negative nurses) is more likely to take place in a sanatorium than in a general hospital, and is, of course, infinitely more feasible for nurses than for girls in industrial life. The joint committee proposes changes in the education of nurses for this branch of work. The Tuberculosis Association certificate is generally recognized as the hall-mark of postgraduate study, and the committee thinks holders of this certificate should obtain State recognition in the form of a supplementary register. In this they would have a status corresponding to that of fever trained nurses, who are entered in a special section of the *Nurses Register*. Failing a State register, the committee recommends that holders of the Tuberculosis Association certificate should be allowed to use the title "tuberculosis nurse." There is everything to be said for a system of training and education which encourages members of the nursing profession to go in for this neglected branch of work. The opportunities for an intelligent nurse in the treatment of tuberculosis to-day are wide. She need not fear that any of her gifts will remain unused. The phobia of infection remains, and we hope this report will make it more widely realized that the nursing of tuberculous patients, conducted under conditions proper to a sanatorium, and with adequate medical supervision of the nurses in the form of x-ray examination and tuberculin tests, is no more dangerous for a girl than the hygienically unsupervised life in a factory or office.

FITTING THE MAN TO THE JOB

The July-August issue of *Industrial Welfare and Personnel Management*, the journal of the Industrial Welfare Society, includes an article on personnel selection in post-war industry by Brig. J. R. Rees, consulting psychiatrist to the Army. There are many in industry who are anxious to carry into their peacetime industrial groups the techniques of "man-management" and personnel welfare so usefully and satisfactorily employed in the Services. Brig. Rees speaks for the Army and considers there is no more interesting phase of its experience of personnel management, nor one that has greater implications for post-war industrial efficiency, than the methods used to secure the right man for the right job—personnel selection, grading by intelligence, and scientific placing. The Army has shown that if men and women can be fitted into jobs for which they have aptitude, and in which they can be interested and gain pride and competence, they do better and remain fitter than they otherwise would. The Service treatment of the "dullard" group is but one instance. From this group in normal times comes the country's highest sickness and delinquency rate. The Army has found that if dull men, even very dull men, can be properly employed, as a group, on jobs within their competence and under kindly and tolerant supervision, they do first-class work—doing their own particular job much better than intelligent men do, and having a very low sickness and crime rate. Perhaps even more important is the method of choosing key men and women for jobs that require authority and leadership. The Army has put much scientific work and thought into methods for selecting officers. The underlying principle is capable of adaptation for the selection of officers for purposes other than war—including directors in industry.

MR. SHAW ON DOCTORS

BY

MAJOR GREENWOOD, F.R.C.P., F.R.S.

[As Mr. Bernard Shaw has attacked medicine and the medical profession in his new book "Everybody's Political What's What," we asked Prof. Greenwood to pick out some points for criticism in a review that should help non-medical as well as medical readers to get the matter in perspective.] -

If it is possible for a humane man living in the year of our Lord, 1944, to be happy, Mr. Bernard Shaw should be a happy man. He began life with few material advantages, his earlier writings were consistently and grossly misrepresented; now, in the evening of his days, he is among the half-dozen writers of English universally known and read. Those who disagree most vehemently with many of his opinions will, if they have what Disraeli described as the rare virtue of gratitude, thank him for some happy hours and valuable instruction. Mr. Shaw has never hesitated to denounce other men in the strongest language, not only when he was young and unknown, but now, when he is old and famous. If, in commenting upon some of Mr. Shaw's assertions, I forget what is due to a man old enough to be my father, I hope that the Editor will use his blue pencil ruthlessly. Every man is in debt to his profession, but our profession has no need of wounding invective; *non tali auxilio nec defensoribus istis tempus eget*.

We all know that words change in meaning with time; the word *prove* is a good example; once—as illustrated by the saying "The exception proves the rule"—it meant to test or to try; now it means to most of us "to demonstrate the truth of by evidence or argument." In this latter sense we can hardly prove anything intellectually save by a deductive process. I cannot prove there are milestones on the Dover Road to a man who has never left Boston. I can say I have seen them; neighbours of his who have travelled along the Dover Road can say they saw them. If he is a normal being he will accept that evidence, and also believe there are milestones on the Dover Road; but if the existence of those milestones conflicts with some doctrines he believes intensely the testimony of his neighbours would not shake his conviction, nor would the testimony of his own eyes. Few people hold beliefs inconsistent with the presence of milestones on the Dover Road. Many believe that the injection of "filth" or "poisons" into the bodies of healthy children is horrible; Mr. Shaw is one of these people, and no evidence we could produce would shake his belief. All one can do is to try to state a case fairly for the consideration of those whose beliefs are not so vivid; and, of course, one is under two disadvantages. The first is that Mr. Shaw is one of the most accomplished writers of our time; the second, that he is not hampered by regard for dull exactitude of statement. He says himself: "It is always necessary to state a case startlingly to make people sit up and listen to it, and to frighten them into acting on it. I do this myself habitually and deliberately" (p. 49).

The method of Miss Pross applied by a first-rate writer is formidable, because one is easily betrayed into anger. Thus, when we are told that Lister was a half-wit, or read an innuendo that diphtheria prophylaxis has had something to do with the increased prevalence of epidemic poliomyelitis, or—worst of all—a, to me, horrible insinuation that the treatment of venereal disease may be responsible for its signs and symptoms, there is a temptation to play Mr. Shaw's own game—viz., to repay abuse with abuse and by playing it badly to lose the game.

Mr. Shaw writes: "Eminent mathematicians of my acquaintance have gone to Monte Carlo, where, having proved that certain results of spinning the ball on a roulette table could occur only once every thousand years, they saw them occur three times in seven weeks." No mathematician, however eminent, could prove—in either sense of the word—that any result could occur only once in any number of trials; what he could prove (in the modern sense of the word) is that on a particular hypothesis such or such result will on the average occur only once in so-and-so-many trials. If on trial the result happens much oftener—or much less often—than his calculation requires, he will ask himself whether the hypothesis upon which

the calculation was based may not be inapplicable, and will reject the hypothesis if there is an acceptable alternative. Suppose we have a statistically ideal, and very rarely realized, experiment. We have patients all of the same age, sex, occupation, nationality, all at the same stage of a disease, half treated expectantly, half receiving treatment A. Suppose that a statistician fulfilling one of Mr. Shaw's statistical requirements—viz., he must not be a "doctor"—makes the appropriate calculations and finds that if remedy A had no influence the advantage in fatality rate the treated had over the untreated would occur only by "chance" on the average once in a billion trials. Then, if A has a rationally acceptable basis, most people will prefer the hypothesis that treated and untreated groups were not *in pari materia* to the hypothesis that a very unlikely event has happened. At the risk of being pedantically dull, I must stress this point. If treatment A had consisted in sticking a postage stamp, (without the knowledge of patients or staff) on half the bedsteads, odds of billions to one would not generate any belief in the therapeutic virtues of postage stamps. Of course astronomically improbable events happen every day. The chance that a pack of cards shall be dealt in any assigned order is the same and less than one in a billion; we suspect a joke or a fraud only if the particular order in which the cards fall suggests design.

Here we have the case for the scepticism of a Charles Creighton. If vaccinia was a different disease from variola, or, as I think we should now say, the viruses had no biological kinship, Edward Jenner was doing something wholly without rational precedent or analogy. Like many book-learned men, Creighton despised the views of the unlettered, and, judged by a Creightonian standard, Jenner was unlettered. Creighton contemptuously dismissed Jenner's observations on the habits of the cuckoo not recorded by learned authors as a tissue of absurdities (they have been verified in our own time), and to him vaccination was also a scientific absurdity. If, therefore, statistics did—in the sense of my comparison—show long odds against the differentiation of the groups vaccinated and unvaccinated being a chance happening, he could not accept a hypothesis that vaccination itself differentiated the groups. He did not adopt so readily the view that the statistics were faked, as Mr. Shaw does—no doubt Mr. Shaw would remind us that Creighton was after all a doctor—but he did not accept their *prima facie* suggestion. All through, the gravamen of his charge was the biological absurdity of the process.

Almost a generation after Creighton's critique of Jenner, Monckton Copeman successfully inoculated a monkey with variola and by inoculation from the monkey produced vaccinia in a calf; later still Mervyn Gordon by cross-immunization found an affinity between variola and vaccinia virus, but none between variola and varicella. So it seemed to most of us, not of course to Mr. Shaw, that Jenner's preposterously false analogy was after all a true analogy—a lucky guess or an intuition of genius. That is why to moderately sceptical people—I have been told that my own department is known as the cold-water department, so perhaps I am not wildly credulous—it is easier to accept the hypothesis that the advantage on paper of the vaccinated is not due to chance.

Mr. Shaw, of course, would agree: he would offer at least two alternatives to "chance." The first—the one I think he prefers—is that the statistics have been deliberately falsified by the doctors; the second, that vaccinated persons have generally been better fed and better housed than the unvaccinated. I will not play Mr. Shaw's game by flying into a temper, but try to consider how such data as those of the Metropolitan Asylums Board hospitals, which monotonously showed in each large age group a much lower fatality rate on the vaccinated than on the unvaccinated, could have been faked. We must believe that the doctors were such masters of prognosis that on the admission of a patient they could tell whether he would die or live, that, however obvious the vaccinal scars on an arm, obvious to the nurses and the patient's friends, they could go on weighing down the scales of the unvaccinated group with well-vaccinated patients doomed to perish. If I favoured Mr. Shaw's vocabulary I should say that only a half-wit could believe anything so silly. The alternative that only well-fed and well-housed people were vaccinated—which dialectically makes hay of the complaint that compulsory vaccination was an odious tyranny

practised on the poor—is not supported by any cogent data and has against it Macdonnell's analysis of Glasgow experience (it is true that a doctor, Brownlee, provided the data, but then Macdonnell was not a medical man, which guarantees his statistical impartiality by Shavian standards).

But Mr. Shaw will still boast that after the introduction of compulsory vaccination there were epidemics of smallpox. It is true that Jenner himself believed, fanatically believed, that no properly cow-poxed person could take smallpox, so that if after compulsion all the inhabitants of England, France, and Germany alive in 1870 had been vaccinated the event proved that Jenner was mistaken. Of course even in Government-fearing Germany many were not vaccinated, and the question is not whether Jenner put his claim too high but whether on the whole, on the average, vaccination has saved lives. Many people have lost their lives in Anderson or in Morrison shelters, but I think when the time for rendering a statistical account comes it will be found that these shelters saved lives. Our gratitude to the inventors will not be diminished even if we find—as we may—that the value of the protection was less than they had hoped it would be. Mr. Shaw is not one of Disraeli's rarities; he is not a grateful person. He agrees that the revolution in surgical practice due to Lister saved many lives, but because Lister overstated a case and did not anticipate discoveries made fifty years later Lister is a half-wit at whom a gentleman who is not known to have saved any lives may point the finger of scorn.

I have lingered over the smallpox tale, tedious as it must be, having been told much oftener than twice; but the case for diphtheria prophylaxis involves no new statistical principle; the pros and cons are as before. One relatively new argument has been used—namely, that before active immunization was introduced diphtheria mortality and morbidity rates were declining and we have confused *post* and *propter*. It is only a relatively new argument, because Creighton had argued that by the end of the 18th century smallpox was an obsolescent disease. The best discussion I know is in Dr. W. T. Russell's recent report to the Medical Research Council (that Mr. Shaw may not dismiss Dr. Russell unread, I note that he is a Doctor of Science, not Medicine). In New York and in Toronto the annual case rates of diphtheria were declining from the beginning of this century; in the former city diphtheria prophylaxis was not introduced on a large scale before 1928, in the latter not before 1931. Dr. Russell graduated the trends of the pre-immunization periods by exponential curves. He then extended, extrapolated, the curves over the period of active immunization. The result was that the "predicted" rates were much higher than the observed rates. This, impressive enough to a layman, is even more so to a statistician who plays the fascinating game of prophecy, because one almost always finds that the prophecy is better than the truth: part of the reason is that as one approaches zero rates improvement is likely to be much slower than the comparatively simple curves which give a good graduation allow. Most people will, I think, accept the result as cogent evidence that active immunization did greatly quicken up the decline. The alternative, which Mr. Shaw will adopt (unless, of course, he prefers to believe that from the start of immunization the statistics were faked), is that aesthetic sanitation which had reduced the incidence so successfully over 28 years was suddenly intensified in these two cities just when active immunization began.

Mr. Shaw devotes a chapter to the praise of statisticians, and although I am excluded from this class by the possession of a medical diploma, I still wish to be grateful, because I can remember the time when there was no passion for statistics in the medical profession. But a passage on page 246 supposed to be descriptive of writers in *Biometrika* forces one to conclude that it is not only a medical qualification which obstructs admission to or involves expulsion from the statistical paradise. Should a non-medical statistician reach conclusions of which Mr. Shaw does not approve, his mathematics will not save him—he too will be a half-wit if not a knave, in fact "as credulous, as prejudiced, as thoughtless as to the facts they were measuring and the assumptions from which they started as Isaac Newton himself."

I have confined myself to an examination of the case for and against modern methods of prophylaxis, because, whether my

conclusions are right or wrong, at least I have studied the evidence closely and had a good deal of experience of statistical methods. Other topics of Mr. Shaw's book tempt me to be polemical. Mr. Shaw seems to me wholly to misunderstand the fundamental principles of the experimental method, and it seems a pity he did not listen more attentively to the expositions of his friend Sir Almroth Wright—one of the very eminent investigators not classed as a half-wit. But many colleagues understand that subject better than I do, a remark which applies to Mr. Shaw's view of medical tyranny.

SOCIAL MALAISE AND DISORDER

VIEWS OF THE MEDICAL WOMEN'S FEDERATION

For some time the Medical Women's Federation has been anxious to express its views on certain aspects of social medicine. At a recent meeting of its Council the work of a small subcommittee was approved in the form of the memorandum printed below:

Medical women are frequently invited to express their views on the reported increase in venereal diseases, and the Medical Women's Federation considers that it may be timely, in view of anticipated medical and security legislation, to set out in general terms conclusions collectively arrived at as a result of the experience of its members during the last war, the uneasy interval, and this war. While there is naturally divergence of professional opinion as to the best methods of handling so controversial a problem, there is complete agreement that the eventual solution must depend in large measure on a clear recognition of the relation of venereal disease to social and personal maladjustments, which has been much accentuated by war conditions. V.D. cannot be regarded merely as an acute contagious illness which affects only those directly infected; it can never be eradicated solely by medical precautions and treatment however sound and effective in themselves; and it is to the wider implications of the presence of venereal diseases, with their deplorable results on the health of the nation, that the Federation desires to direct attention.

The Federation holds the view that doctors, while having an obligation to society for the treatment of individual patients, have also a duty to interest and educate public opinion in medico-social questions so that these may be approached with understanding and sympathy.

It is realized that the war has brought out splendid qualities in many people, and that young people in particular are displaying magnificent courage, endurance, and selflessness; yet at the same time, partly as a result of the very conditions calling forth such qualities, it is clearly seen that there also exists an accompanying state of serious social malaise. Social disorders are associated with a failure to develop and practise an ideal of conduct, as well as with a lack of discipline and sense of personal responsibility. Such conditions are likely to lead to an increased state of unrest and a diminishing degree of happy satisfaction in life.

Among the signs of social malaise and disorder are found:

1. A lowering of the standards of honesty and of consideration for others.
2. An increase in delinquency, including juvenile delinquency.
3. A more widespread and growing habit of indulgence in alcohol among young people.
4. The loosening of family ties.
5. Sexual incontinence, promiscuity, an increase in soliciting, and a consequent rise in the incidence of venereal disease.
6. The toleration of a low standard of certain types of reading matter and of public entertainment.

We believe that an acceptance of materialistic ideals as the main standard for living has led to spiritual poverty and unthinking egoism. The sense of insecurity of life, the loss of home background and other dislocations of war have added to the confusion. The immediate satisfaction of an impulse is often accepted as justifying any action. This is seen in the increase of petty misdemeanours, and still more in irresponsible sex relationships.

We believe that continence (apart from marital relationship) is the ideal for both sexes if the vitality of the race and the happiness of individuals is to be ensured. We condemn the

view that incontinence is not detrimental so long as precautions are taken against disease and pregnancy. It is now recognized that continence is not harmful to either sex.

All primitive urges supply the energy for man's activities; in order that they may find effective and satisfying outlets, certain basic wants must be met. These include stability of family life, education in its widest sense, scope and training for suitable work, encouragement in the right use of leisure, opportunity for independence of thought and creative activities, and development of that spiritual outlook which alone can secure an active, happy, and ordered society.

For the achievement of this ideal, the Medical Women's Federation presents the following as minimal essentials:

1. The recognition of the vital importance of home and family life with opportunities for early marriage, and the provision of good living conditions within reach of all.
2. Training from an early age in the development of personal moral responsibility and social obligation.
3. Religious training both at home and at school.
4. Physical training together with instruction in the functions, hygiene, and control of the body.
5. Training in the understanding and expression of the emotions.
6. Extension of education into adult life. This should include the teaching of parentcraft to both sexes, and opportunities for manual and creative work.
7. The encouragement of a high standard of literature and public entertainment, and of appreciation of beauty in Nature and art.
8. The provision of suitable opportunities for social contacts and recreation.
9. Adequate provision for the disabled and for those who are inherently irresponsible.

The Federation is fully aware that there is nothing new or revolutionary about such recommendations, but considers that they should be given due weight in the formulation of proposals for the prevention and control of venereal disease and other social disorders.

UNIFORM STANDARD FOR PENICILLIN

SIR HENRY DALE'S STATEMENT

Sir Henry Dale, P.R.S., announced to a Press conference on Oct. 20 that international agreement had been reached by the Health Committee of the League of Nations on a uniform standard and unit of penicillin, and that there could be no doubt that workers in this country and America, and eventually throughout the world, would be using the same standard dosage. The agreement was arrived at at a meeting in London attended by representatives of Great Britain, the United States, Canada, Australia, and Free France.

In a historical retrospect Sir Henry Dale said that it was in 1921 that the Health Committee first took in hand the question of measurement of a number of biological remedies in terms of their activity. This was done in order to obtain international uniformity, so that one unit of activity would mean the same wherever it was prescribed. The first agreements of his kind were obtained in the case of antitoxins, notably the antitoxin of diphtheria. Another good example was the standardization of insulin in 1925. The same standard was adopted outside the League—in Russia, which was not then a member, and in the United States, which never became a member; the same standard was continued in Germany and Italy after they had left the League. Standardization was also applied to hormones and vitamins.

International Agreement

The newest remedy, penicillin, naturally called for similar action at the earliest possible moment. It had been a simple matter during the war to arrive at an international agreement, because here was one of the few discoveries which, it could be claimed, had been made entirely in this country, though, on the other hand, the developmental research and the enterprise responsible for a large part of the production of penicillin was due to effective action in the United States. Thus, while it was a British discovery, the United States had undertaken a large part of the manufacture and supply. The manufacture actually started earlier here than there, but at the time penicillin came in, practically all manufacturing resources were absorbed by war production, while the United States was not similarly embarrassed.

The new international standard penicillin would be finally purified and crystallized in the United States, but the material for this

purpose would be freely supplied by manufacturers here as well as across the Atlantic. There was no substance in the talk about tirings in the manufacture of penicillin. The manufacturers in both countries had pooled their information from the very first and had given their results to the Medical Research Council, thus making the manufacture of penicillin during the war a real national effort.

At the recent conference in London which had determined a standard there were present three representatives of the U.S.A., three of this country, together with Dr. Cameron of the Health Department in Ottawa, and Major Bazeley of the Commonwealth Serum Laboratory, Canberra. After these arrangements had been made the possibility of contact with liberated France was opened up, and an invitation was sent to Dr. J. Trefouel, director of the Institut Pasteur in Paris, who joined the conference in time to review a provisional agreement and give his confirmation. A number of other persons had joined in the deliberations, notably Sir Alexander Fleming, who could be described as the father of penicillin, and until he went to Australia, Sir Howard Florey, who brought penicillin to the practical stage. Other specialists were present from South Africa and India. The results which the conference had achieved, said Sir Henry Dale, when viewed as a contribution to scientific knowledge might seem small, but the setting up of a world-wide standard was of obvious importance.

WAR AND COMMUNICABLE DISEASES

Brig-Gen. James S. Simmons, speaking in New York at the 73rd Annual Convention of the American Health Association, discussed various phases of the war and communicable diseases.

Speaking of the health problems that had arisen during the past 15 months in Sicily, Italy, and a good portion of North-West Europe, General Simmons said it should be constantly borne in mind that the entire civil public health programme was being implemented by a very small number of American and British medical officers. Reliance must of necessity be placed largely upon local resources in medical personnel.

Typhoid and dysentery, typhus fever, smallpox, malaria, venereal disease, and scabies had so far offered the greatest problems. In both Italy and North-West Europe the incidence of typhoid and paratyphoid fever rose in the wake of combat operations, but sharp outbreaks had been limited to a relatively few communities. In January, 1944, the peak month, over 1,000,000 new cases were reported, but the epidemic was quickly controlled with only 39 cases being reported during the last week of February. Typhus had not yet been a problem in North-West Europe, though the test would doubtless come during the winter months.

The civil public health programme called for early re-inauguration of the smallpox vaccination programme. Despite this, two outbreaks had occurred in Italy. One was small and easily controlled. In the other over 800 cases occurred in a large city during a four-months period. No outbreaks have been reported from North-West Europe. In February, 1944, the civil public health group re-established an active malaria control programme in Southern and Central Italy which was expanded during the pre-malaria season.

The U.S. War Department announced in Washington on Oct. 4 that tetanus had been virtually eliminated in the American Armed Forces as a result of compulsory immunization of all officers and men. Major-Gen. Norman T. Kirk, Surgeon-General of the Army, stated that no case of tetanus had been reported among completely vaccinated troops. There had been a handful of cases throughout the entire Army, but these occurred only when the immunization process had not been completed. "Some men had developed tetanus before vaccination. The U.S. Navy, which also requires tetanus immunization, has had no cases of the disease among sailors or marines wounded in battle up to Sept. 15, 1944, according to the Navy Bureau of Medicine and Surgery.

Brig-Gen. R. W. Bliss, Assistant Surgeon-General of the U.S. Army, who recently returned to Washington from a tour of inspection through the Pacific war theatre, said that during the entire trip he did not see one mosquito or fly. "When we first took over the Pacific Islands there were clouds of insects everywhere, actually making it difficult to see. To-day, if we locate one mosquito we consider it comparable to finding a four-leaf clover. To me, that's the outstanding achievement of medical science in this war. There were no malaria mosquitoes on Saipan, but there was a type that carried dengue, which is as disabling as malaria itself. At first we had a great many cases of dengue. But after a few weeks of insect control, dengue practically disappeared. Medical sanitary companies divided the islands into a square like a checker-board, and drained and filled swamp areas constantly. The amazing D.D.T. insecticide which did such a wonderful job in controlling typhus in Naples was sprayed by hand and by planes. These planes were rigged up with special apparatus. They flew back and forth across a given area much like a man mowing a lawn."

Correspondence

R.M.B.F. Christmas Gifts

SIR.—Once again it is my privilege to appeal to your readers throughout the country to remember the beneficiaries of the Royal Medical Benevolent Fund during this coming Christmas. These beneficiaries are aged or infirm medical practitioners, their widows and dependants, and as an old man myself—now in my 100th year—I have their welfare much at heart. It has been my custom for many years to appeal for Christmas gifts on their behalf, and a large sum must be raised if we are to give £3 to each, as we would like to do, and as we succeeded in doing last year.

If my colleagues could read the warm expressions of gratitude which are received each year they would feel that their contributions have been well spent, and I am confident that they will respond again as in other years. Donations, large or small, should be sent to the Honorary Treasurer, Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, London, S.W.15, marked "Christmas Gifts."—I am, etc.,

THOS. BARLOW,
President.

War Surgery: Thoughts and Facts

SIR.—Gen. Mitchiner's thoughts on four years of war surgery (*Journal*, July 8) are stimulating and provocative. Generalizations and impressions are valuable when backed with the authority and experience that Gen. Mitchiner possesses. It is because we held his opinion in such regard that there is a danger that the opinion may be accepted in place of a review of the facts. A knowledge of the results of treatment of flesh wounds in the Italian Theatre of War does not support Gen. Mitchiner's view that little progress has been made in the prevention and control of sepsis. The surgical set-up in this theatre provides early primary surgery by surgeons experienced in wound debridement and decompression, swift evacuation to general hospitals, and delayed primary suture about the fifth day. Records kept at three hospitals in the early stages of this method of treatment were:

Surgeon A—252 wounds, primary union in 240.
Surgeon B—228 wounds, primary union in 186.
Surgeon C—195 wounds, primary union in 181.

These were consecutive cases whose only selection in three different surgical divisions was that there should be a sufficiency of skin for suture. The wounds were of all kinds, from large penetrating ones with deep muscle destruction to superficial tangential wounds. In the result, primary union was obtained in 607 wounds out of 675 (90%), and the average time from wounding to return to duty of cases without other lesions was 35 days. Treated by closed-plaster, etc., large numbers of these men would have become long-term cases for U.K., or Category E.

These figures are merely the results of a few weeks' work in three hospitals, but the same procedure is taking place generally in this Theatre of War. I am permitted by Gen. Hartgill, D.M.S., A.F.H.Q., and Brig. Edwards, Consulting Surgeon, A.F.H.Q., to mention that in the Cassino battle, May 11 to 31, 1,032 wounds were sutured by this technique. The closed-plaster method, far from being accepted (as Gen. Mitchiner claims) as "the best treatment for all types of wounds in the field subsequent on excision," is not employed except for the rare case where, for exceptional reasons, repair by suture or early graft is impossible. This method of wound treatment has truly resulted in prevention and control of sepsis, and represents an advance in surgical thought and technique of considerable value to the wounded man and to the Army.

How much of this advance is due to surgery and how much to the use of penicillin as well is not yet estimated. There is no doubt that penicillin has made possible repair of infected wounds that formerly would have been thought dangerous to touch. But closure of an infected wound is the only surgical principle that penicillin has revised. Gen. Mitchiner's suggestion that "penicillin works best in a puddle of pus" and that drainage of pus will therefore be avoided is a dangerous one. A puddle of pus, whether Gram-negative or Gram-

positive, remains what such a puddle has always been when shut up within the tissues—a source of trouble. From a personal series of over 500 wound sutures in which penicillin was used locally, I could quote several instances where a collection of Gram-negative pus in the depths of a wound led to partial breakdown of the suture line. In wound repair with local use of penicillin pus must be drained, and I am careful to point out to surgeons the importance of siting the penicillin tubes in a sutured wound so that any pus can be aspirated twice daily as a preliminary to further instillation of penicillin solution. Alternatively, if the wound is grossly infected at the time of repair, a rubber-dam drain is provided. It is important that this principle should be followed if local penicillin therapy is not to be discredited.

I hope that Gen. Mitchiner will not think that these statements deserve his description of "self-congratulatory coma." They are not only thoughts on war surgery; they are also facts.—I am, etc.,

F. H. BENTLEY, Lieut.-Col., R.A.M.C.,
O.C. Penicillin Control Team, C.M.F.

Lung Complications after Operation

SIR.—It surprises me that some writers on pulmonary complications following abdominal operations make no reference to the valuable papers of Messrs. Band and Hall published in the *British Journal of Surgery* (1931-2, 19, 387). There it is pointed out that after operations on the upper abdomen the diaphragm is kept relatively immobile (physiologically) to keep the damaged part at rest, and that movement of the bases of the lungs then depends on free movement of the lower part of the thorax. If these are restrained by a firm bandage stasis must be produced. This is but a trifling reference to a paper which should be carefully read and taken to heart by all abdominal surgeons. The diaphragm alone can do the necessary rhythmic pressure on the bases or the lower ribs. Paralyse both, and stasis is inevitable.

It will be well recognized by surgeons that after a radical mastectomy the firmest bandage can be applied to the lower thorax without any chest complication. Here the diaphragm does the work. Since having the privilege of hearing in Edinburgh a first-hand description of Messrs. Band and Hall's experiments and conclusions, about the time the work was published, I have attached the greatest importance to this freedom of the lower chest after any abdominal operation. One of the ward sisters at Addenbrooke's Hospital devised a bandage which has proved most serviceable. The important point is that the top of the bandage should not ride above the level of the lowest ribs, and the under-straps should be broad and efficient. To ensure that the upper part of the incision is not exposed a piece of strapping is passed from the upper part of the bandage to the sternum to keep the dressing in place. The many-tail bandage may be a serious menace to the free movement of the ribs, especially if it rides up owing to faulty under-straps.

An interesting demonstration of the risks attending the slipping up of a many-tail was seen a short time ago. After an upper abdomen operation in the morning, when visiting the ward in the evening and inquiring about the patient, I was told that all was well. Looking at the chart I found that respirations were registered as 30. This necessitated an examination of the patient. A many-tail bandage without under-straps was found riding up and so firmly holding the lower ribs. One of the special bandages was applied, so freeing the ribs, and the patient asked to take deep breaths. Next morning the breathing was about 20. Left alone, it is almost certain that some atelectasis would have followed.

In conclusion, I appeal to all interested in this matter to study the admirable piece of work mentioned above, which was carried out in the surgical research department of the University of Edinburgh.—I am, etc.,

Cambridge.

W. H. BOWEN.

Débridement

SIR.—Sir Harold Scott's letter in your issue of Oct. 14 again raises the question of what exactly is meant by the term "débridement." Is not the position that the French term "épluchage" corresponds to our term "excision," and means a thorough excision of all dead or damaged tissue in the

wound area. The term "débridement" corresponds with our term "revision" (= to examine with a view to correction), and means examination, the removal of all frankly dead tissue and foreign bodies, and the establishment of adequate drainage. The former is perhaps more often talked about than practised, but it is well to realize that the two procedures are quite distinct, and that unless the terms used to describe them are kept within their meaning considerable misunderstanding is inevitable.—I am, etc.,

London, W 1

E. G. SLESINGER.

According to Harrap's French Dictionary *débridement* means: "surg. incision, slitting up (adhesion, etc.)"; and *sphacilage*, "cleaning," "picking," "weeding," "thinning out," or, in familiar language, "hypercritical examination."—ED., B. M. J.

Calcinosis Universalis

SIR,—I am much interested in your excellent medical "brains-trust" note under the above heading (Oct. 14, p. 519), but as I have had chance opportunities of studying the subject perhaps you will permit me to make a few remarks which I think are not merely of academic interest.

The case of the child aged 6 is almost exactly similar to that of a little girl aged 7 years which I demonstrated at the 17th International Congress of Medicine (London, Aug. 8, 1913, Part 2, 179); I would prefer the term "subcutaneous calcinosis" or "multiple calcification in the subcutaneous tissue," as there is no proof that any other parts are involved. Radiographs in my case proved that the areas of calcification were already diminishing in July, 1913, but unfortunately the child left England soon afterwards. Improvement has been shown in other children (Kennedy, Craig and Lyall, Sheldon). Such improvement has been observed under various treatments, or without any special treatment, and I am inclined to think that calcinosis of this type in children (mostly girls) is spontaneously likely to come to a standstill, or regress, under normal diet. The former danger from septic complications is, I suppose, greatly diminished by the use of chemotherapeutic drugs if required.

Surely myositis ossificans idiopathica is a progressive disease which nothing can stop, and, though it may be aggravated by trauma, is sharply to be distinguished from traumatic localized myositis ossificans and from subcutaneous or universal calcinosis in children. I have never seen or heard of the latter disease being associated with myositis ossificans. It has been suggested, with some degree of plausibility, that calcinosis of the multiple subcutaneous or universal type is a "storage disease" comparable to the now fairly well recognized "glycogen storage disease," which may apparently come to a standstill, or regress, as the affected children grow up.—I am, etc.,

London, W 1

F. PARKES WEBER.

"Skiagram"

SIR,—Has not the time come when an effort should be made—and internationally—for a standard term to be used for the photogram produced by x rays? To some this would appear to be long overdue, and it would redound to the credit of the English-speaking peoples if they were the nations to bring this about.

At the present time—1944—there are no fewer than nineteen words which have been used in connexion with "a negative produced upon a film sensitive to the action of x rays." Chronologically they may be tabled thus:

- | | | |
|-----------------------|------------------|-----------------|
| 1. X ray | 8. Roentgenogram | 14. Sciagram |
| 2. X rays | 9. Actinograph | 15. Shadowgraph |
| 3. X-ray picture | 10. Actinogram | 16. Shadowgram |
| 4. X-ray photograph | 11. Radiograph | 17. Skiogram |
| 5. X-ray plate | 12. Radiogram | 18. Skiagraph |
| 6. X-ray film | 13. Sciagraph | 19. Skiagram |
| 7. Rontgen photograph | | |

Much confusion and uncertainty are caused by such a variety of terms. Some very absurd expressions are still in common use, such as, "Take an x ray of this fractured bone"; "Has a radiogram been made?" and so on. In reviewing what should be considered as the best—and international—word, it may be said that two terms stand out—namely, skiagram

and x-ray film. Of these two almost certainly the first skiagram—would appear to be the better. This word etymologically sound, for its origin is from two Greek words "skia" a shadow, and "gramma" writing. The following are the cogent reasons for its use from now onwards as the word to designate the results upon a film sensitive to the action of x rays:

(a) It applies a "shadow writing," which is a negative produced by x rays.

(b) It has never been used for any other purpose, nor is it likely to be used, if it were to become "standardized" and that internationally.

(c) It has a distinctly "scientific sound" about it, and has years now been used "scientifically."

(d) Once standardized, it would become used in all scientific books, in reports upon patients, in courts of law, etc.

The following are possible reasons for not using the term "x-ray film": (a) It is somewhat cumbersome. (b) The term x ray thus applied is unscientific. (c) The term "film" is used in several senses: (1) a sensitized material upon which a negative is produced; (2) a common term for a "movie" or "silent film" strip, upon which prints have been produced; (3) a "moisture on glass," a "haze," and a "membrane."—I am, etc.,

London, W 1.

W. McADAM ECCLES

Mass Radiography

SIR,—The memorandum from the Ministry of Health on mass radiography published in the *Journal* (Sept. 9, p. 3) admits the present failure of the scheme, which I have feared from time to time in your columns and elsewhere. The communication states that difficulties "have made it impossible to develop schemes for the general use of mass radiography throughout the country," and it is claimed that wartime production and lack of skilled professional staff are the chief obstacles. As to the difficulties of equipment manufacture much of this could be overcome if all x-ray manufacturers in the country were invited to co-operate instead of confining the production mainly to one firm. Concerning technical operators they can be trained very quickly for this type of work, and as all facilities for training radiographers for general x-ray work are booked fully until 1946 in London, surely some of these who have been disappointed, along with others willing to train, might be invited to take up mass radiography.

Nevertheless these two official reasons put forward to account for the present failure are minor issues, and, to my mind, the real cause for the present setback is inadequate organization. The existing units are not worked to capacity, being grossly understaffed. Instead of creating a large number of units to carry out a small number of examinations, because of the limited number of personnel attached to each unit (which is the present working of the scheme), the present technical staff should be doubled or even trebled, and then operate the personnel in shifts or relays so that the standard of work is maintained; the number of cases examined per unit would then more approach or even pass the figures claimed by Continental workers of 3,000 or more cases a day. The British units appear to be only capable of examining fewer than this figure per week. To safeguard the life of the x-ray tubes batteries of tubes should be employed, bringing a new tube into operation after, say, 500 exposures. The work could be done even with the plants now available, but it is essentially a question of organization, and medical men are reputed to be bad organizers.

Dr. Leggett (Sept. 30, p. 450) observes that the Ministry shows a desire to retain mass radiography in their own hands to the exclusion of all others, and pertinently inquires if the method they selected is the best, and, unless it is, he thinks that workers using alternative methods should not be excluded. One should take a broad view of this ruling (though it has no support in law), and I think most of us have been prepared to accede to the wishes of the Ministry in order to give the official plan every chance to succeed and maintain a uniform standard of work. For my part I have with much misgiving fallen in with the decision of the committee of the British Red Cross concerned to discontinue the services of their mobile portable motor mass radiographic unit in order to meet the

wishes of the Ministry. Other units, also outside the scheme have voluntarily ceased functioning, but if the Ministry and local authorities continue to display lack of organization and drive the matter my reappearance for review elsewhere than in your columns, and I have in mind the uneasiness already noted by some of the business heads of firms that have had experience of the existing facilities.

A responsible head of a large modern manufacturing firm whose employees have been examined by one of these local authority units draws attention to a number of fresh aspects which Whitehall may or may not already appreciate but do not seem to have fully incorporated in their scheme to date and I cannot do better than quote freely from a letter I have received from this firm.

"My difficulty is to see the value of one single x-ray survey of all workers in one factory unless there is some definite policy of following this up at intervals of, say, a year or two years. A very small proportion of cases of early tuberculosis are discovered, and the cost of this discovery is very high. A staff to operate the x-ray machine is required, and there is a certain amount of time taken up by the medical officer who interprets the films. The time lost in the factory and the administrative cost of the arrangements possibly amount to £500 or £600. No one in industry would erudge this in the very slightest degree, but I think it is fair enough that the management should inquire as to whether the means justify the end, and whether or not, if it was going to cost £500 or £600 each time, a better and more effective arrangement could not be reached. I am not reactionary about the value of mass radiography, but I feel that the factory unit is by no means the best way of applying it, although it happens to be a convenient one. It would be of much more value if you could x-ray all individuals in a given area of, say, 2 or 3 square miles, and even then surely it has only got value provided there is some continuity and it will be repeated at given intervals. Short of mass radiography that is applied to whole groups of individuals, I think it would be of considerable value if apparatus existed in certain areas where general practitioners or factory medical officers could send every case for a x-ray examination that gave the slightest suggestion of the possibility of early tuberculosis. I think the ideal of the application of mass chest radiography is something for the perhaps distant future, and that in the meantime it would be very much better if those concerned with it were to give attention to a realistic and practical application of the very valuable facilities. From the point of view of industry I want to make clear a point that some speakers and writers on the subject have not perhaps fully appreciated. Industrial medical services are not primarily looked upon by the managements as something that should pay dividends or save the company money, and I am certain that if the case for mass radiography as a valuable social service were fully made out industry would co-operate. There is an indirect value in offering medical service to a staff in general morale. Although I have mentioned the cost of one survey by mass radiography, most industries would, I think, be willing to spend considerably more than this if the case were well made out for the advantage of the staff generally. I feel that at the present time, in the absence of any follow up policy, the case is not a good one."

The manager of another firm informs me that he sent his employees in small batches to the local hospital, and thereby saved his firm many working hours and financial outlay.

It is clear that the present official scheme for mass radiography in this country requires speeding up, reorganized on the lines I have advocated from time to time, and above all it requires bolder direction and not necessarily from doctors, but perhaps with an efficient business head in control to organize it—I am, etc.,

NORMAN P. HENDERSON

Protein Hydrolysates in Infantile Diarrhoea and Vomiting

SIR—I was most interested in the valuable and instructive contribution on infantile diarrhoea and vomiting (Sept 30, p. 425) by Drs. Alexander and Eiser and your leading article on infantile gastro-enteritis appearing in the same issue. In the latter the suggestion was put forward that protein hydrolysates administered orally or intravenously seemed worthy of a trial in the treatment of gastro-enteritis.

Although the series of cases is not large and wartime conditions and the pressure of hospital work have prevented accurately controlled observation, a step has already been taken in this direction at the Southend General Hospital. Ever since casein hydrolysate was made available to us some fifteen months ago in a form suitable for intravenous or oral adminis-

tration, we have made a practice of treating cases of diarrhoea and vomiting, whether due to gastro-enteritis or parenteral infection, by the oral administration of casein hydrolysate. This line of therapy was prompted by the desirability of maintaining an adequate calorie and particularly a sufficient protein nitrogen intake, when diarrhoea and vomiting could be controlled only by withholding the more usual forms of nourishment and by restricting everything given by mouth—to glucose saline, Hartmann's solution, or boiled water. On theoretical grounds the possibility of using a solution of casein hydrolysate and glucose appealed to us in that such a mixture, requiring no digestion, would be absorbed rapidly and completely from the upper reaches of the small intestine. It also seemed reasonable to suppose that a combination of glucose and pure amino acids would be unlikely, of itself, to perpetuate diarrhoea and vomiting due to parenteral infection or to cause an exacerbation of symptoms in gastro-enteritis.

The results of treatment were at first disappointing. It was soon discovered however, that solutions of casein hydrolysate in a concentration of more than 2% were unsuitable, in that they caused gastric irritation and aggravated vomiting. The most satisfactory results have been obtained by employing a 1.25% solution of casein hydrolysate in 4.3% glucose (The casein hydrolysate was supplied by the courtesy of Herts Pharmaceuticals Ltd., Welwyn Garden City). This combination has been well tolerated by the majority of infants suffering from diarrhoea and vomiting, whether due to gastro-enteritis or parenteral infection. The most significant observations that I have been able to make in connexion with this treatment of such cases are as follows:

(1) In the majority of cases of gastro-enteritis in which dehydration has been absent, diarrhoea and vomiting have been controlled as effectively by casein hydrolysate-glucose solution given in the first 24 to 48 hours of treatment as they can be by the more usual practice of withholding all forms of nourishment during the same period. Thus an initial (and possibly indirectly harmful) period of starvation has been avoided, and the body provided with protein nitrogen to the extent of 2.2 g per kilo daily. (This figure is achieved by giving 2½ oz per lb body weight of the solution daily.)

(2) Although the total calorie intake is only a little greater than one third of the body's requirements (18.7 as against 45 per lb), infants have been maintained satisfactorily for periods up to 5 days, and diarrhoea and vomiting controlled without having to resort to parenteral fluid administration.

(3) In cases of diarrhoea and vomiting due to parenteral infection the method has been found invaluable in supplying the protein nitrogen requirements during the period in which the site of infection was being sought and adequately treated.

(4) The premature resumption of milk feeds after an initial period of treatment with the casein hydrolysate mixture has frequently resulted in a recurrence of diarrhoea and vomiting. These symptoms have been controlled if casein hydrolysate is again substituted or if suitably diluted milk feeds alternate with those of casein hydrolysate.

(5) By supplying adequate fluid and protein requirements early in cases of gastro-enteritis and by controlling diarrhoea and vomiting without a preliminary period of starvation, dehydration has been frequently prevented, and the need for the administration of parenteral fluids rendered unnecessary thereby.

There is no doubt in my mind that the method of insuring an adequate protein nitrogen intake described above is theoretically sound and efficient in practice provided it is used with discretion, and here a note of warning must be sounded on no account should the method be used as a substitute for intravenous infusion when this is indicated. In other words, the treatment of severe dehydration, once established, is outside the scope of the treatment which I have described.

Although we began treating cases of gastro-enteritis and diarrhoea and vomiting with casein hydrolysate with a view to providing an adequate protein nitrogen intake during the initial stages of illness, it would appear from the observations of Alexander and Eiser that prevention of liver damage in gastro-enteritis is likely to prove the most important indication for this form of treatment. The best results will probably be achieved by intravenous infusion of casein hydrolysate or other suitable preparations of amino acids in all severe cases of gastro-enteritis.

It will be interesting to see the outcome of large-scale controlled experiment on gastro-enteritis treated by protein

hydrolysates. In the meantime I hope that these preliminary observations will act as a stimulus to further efforts in this field.—I am, etc.,

DAVID LEWES,
Medical Registrar, Southend General Hospital.

"Dissident Doctors"

SIR,—The Dr. Samuel Smith referred to in your annotation of Oct. 14 last is a member of the Socialist Medical Association but not of its council or executive. He is also, I understand, a member of the B.M.A. From the S.M.A. point of view he was exercising his democratic rights as an individual member in sending to his friends and acquaintances the duplicated memorandum referred to.

Statements of S.M.A. policy are made openly from the official address.

Prophets are indeed without honour in their own country, for you, Sir, have seen Dr. Smith's memorandum, whereas I had not even heard of its existence till I read my *B.M.J.*—I am, etc.,

SOMERVILLE HASTINGS,
President, Socialist Medical Association.

SIR,—It would, no doubt, be difficult to say how far your warning in the *Journal* of Oct. 14 against the introduction of doctrinaire politics into medicine should be directed against the profession as a whole. One fact, however, does require to be emphasized: that there never was a time when the need for a rational and scientific attitude to political problems was greater than it is at the present day. There should be no question that a body of intelligent men and women engaged in applying the scientific method in the professional half of their lives are not justified in relapsing, in the other half, into an infrascientific state of mind when social and political issues are under discussion.

It is over 50 years since Karl Pearson pointed out in *The Grammar of Science* that the scientific method was applicable in the social as well as the physical sphere, that one of the aims of this method is to enable judgments to be formed independent of the idiosyncrasies of the individual, and that the scientific habit of mind is an essential for good citizenship. Your esteemed contemporary (*Lancet*, 1944, 1, 571) aptly summed up the situation a short time ago in stating that the scientific method was the only possible basis for an ordered life, individual or national. No demonstration is required to indicate the strong position the profession would be in if it could claim, and show, that its judgments on the present important medical-political problems were based on an objective and scientific consideration of the data.—I am, etc.,

London, W.1.

FREDERICK DILLON.

SIR,—I have been reading your annotation in the *B.M.J.* on the subject of dissident doctors. As I see it, the meaning of the article is, apart from personalities, "Socialist doctors are entitled to join the B.M.A., but should maintain a decent silence about their political opinions." Believing, as we do, that the White Paper is, in the main, in the interests of the health workers and the people, we naturally support it. But it is only a beginning. We believe with our splendid Archbishops in equality of opportunity for all, we believe in the abolition of poverty. We believe that Socialism is the most potent factor in the prevention of war. Is it likely, Sir, that when we have this gospel to proclaim we should be silent? Rather with almost religious fervour, in season and out of season, by any legitimate means, we shall seek to further our views, believing in the rightness of our cause, and following the glorious example of the U.S.S.R.—I am, etc.,

London, N.16.

D. S. BRYAN-BROWN.

SIR,—As a regular reader of the *B.M.J.*, if not an active member of the Association, may I be allowed to express an opinion about both the article "Dissident Doctors" and the Doctor who appears to have incurred your vast displeasure. You state Dr. Smith is one of those members who whilst parading the fact they are members of the B.M.A. are not

content to work within it in a democratic way. Surely your article is the very negation of democracy. Government Parliament, local bodies, etc., consists of free expression of opinion, argument, and counter-argument, thus arriving at the best laws or solution in the matter *sub judice*. This certainly applies to the Government's White Paper, and I hold Dr. Smith has every right to voice his views not only to the vociferous minority but to all medical men. We all have our own views and need not be proselytized.

I, too, am an East End doctor, and my views are diametrically opposed to his, being all in favour of "private enterprise" with the minimum of interference by the State, despite the many efforts of Dr. Smith to convert me. The medical profession are not sheep to be led.

As regards the remark "shortage of doctors, etc.," I would like to say Dr. Smith conducts a very large practice in the most efficient manner. It is only his boundless energy and philanthropy that make me ashamed.—I am, etc.,

London, E.3.

E. O. MORPHY, M.B., D.P.H.

SIR,—It is high time that the ostrich-like attitude concerning the political functions of the medical profession displayed by your annotation in the *Journal* of Oct. 14 is challenged. Many doctors, even the B.M.A. Council themselves, have recently and repeatedly stressed the greater importance in the promotion and maintenance of health of such primary fundamentals as food and housing over secondary factors such as the provision of personal medical services. In doing so they indirectly admit the political functions of our profession, whose aim I assume is the betterment of human health. If it is believed that better town and country planning, housing, feeding, and education, at least two of which are dependent on the value of income relative to prices (rent and cost of food)—to say nothing of improved personal health and social security services—by means of which the occurrence of sickness or accident will not cause financial loss to the sufferer and embarrassment of the above-mentioned income-price ratio—are necessary for the raising of the level of the nation's health, surely it is the business of members of the medical profession not only to proclaim these beliefs but also to take all possible steps to further their implementation. The scientific method of taking such steps is by utilizing the political machinery of the country, and the fact that a proportion (is it such a minor one?) of the profession is now waking up to this fact should be the occasion for rejoicing rather than moaning.

Some of us doctors consider ourselves citizens first and doctors second, and therefore owe our allegiance to the greater democracy, or to democracy before a possible technocracy. Therefore we feel that it is morally our duty to support whatever democratic political or medico-political organization we believe is most likely to press for the improvements we desire, and to put them into practice if elected to power. And, therefore, whether we join on the one hand Common Wealth or the Conservative Party or on the other hand the S.M.A., the M.P.A., the Sword of the Spirit, or the Child Health Planning Group in addition to continuing our membership of the B.M.A., I maintain that the B.M.A.'s *Journal* in attacking the activities of two of the four organizations in the second group above is not only unjust but also blind.

The Churches have for centuries been more acutely aware than the medical profession of their political duties in their endeavours to influence public policy. The fact that such so-called "interference" has not always seemed either righteous or satisfactory in the light of history does not invalidate the underlying general moral principle. Members of the medical profession might well emulate their clerical colleagues, Nonconformist, and, more recently, also Church of England, in standing more frequently for membership of their local authorities, bodies which doctors often criticize and blame without being prepared to take the obvious step of standing for election themselves, and, if successful, endeavouring to reform or guide the authority from within, a process in which hitherto the medical officer of health has usually been engaged in a lone struggle. This leads to the final observation that in a properly organized national health service the doctor, with his valuable working time economized by the provision of clerical and auxiliary medical personnel, should at last have

enough leisure to enable him to play his rightful part—one aspect of which I have just indicated above—in a democratic fellowship.—I am, etc.,

DEVON.
F. JOHN GARRATT LISHMAN.

* We agree that medical men as citizens should utilize "the political machinery of the country" in order to play their part in "a democratic fellowship." But are the Socialist Medical Association and the Medical Policy Association parts of this machinery? The former, at least, wants the B.M.A. to attack the latter.—Ed., *B.M.J.*

Reserve of Medical Students

SIR,—I have been approached on several occasions by medical students whose reservations have been cancelled by the Ministry of Labour because they have failed in one examination in the medical course. The most onerous effect of this procedure is seen in cases where a student has failed in the second M.B. examination at a university but has passed the equivalent examination of the English Conjoint Board, and upon the latter achievement has been accepted for his clinical training at a London teaching hospital, and some months later—in one instance after the student had completed nine months' clinical training to the satisfaction of the hospital authorities—has been called up and forced to relinquish all prospects of qualification. The Minister in reply to myself (*Hansard*, July 29, 1943) described his procedure as follows:

"One of the conditions for the continued reservation of a medical student is that he shall be periodically certified by the responsible authority of the university or other training establishment as making satisfactory progress in his studies. This restriction is necessary not only for some general reasons but because the number of places for medical students is limited, and an unsatisfactory student is not only failing to qualify himself but is preventing someone else from doing so."

I submit, Sir, that this is putting too high a premium upon the result of one examination. There must be few of us who have not failed at some part of the very arduous preparation for the medical profession. I have repeatedly pointed out in such cases to Mr. Bevin that the consequence of his regulations is to withhold from qualification a number of candidates for the medical profession and thus invalidate the success of schemes for post-war reconstruction which depends so largely upon securing an adequate number of doctors to work them. The demand is likely to be at least three times as great as the present supply, and inasmuch as the minimal period for training a doctor is some six years, preparation for that demand should be put into operation now.—I am, etc.,

House of Commons.

E. GRAHAM-LITTLE.

The Hospital Case and the G.P.

SIR,—After reading Sir Adolphe Abraham's stimulating letter on postgraduate study (Oct. 7, p. 480), may I offer a humble suggestion whereby some of the issues raised may be approached. A little closer co-operation between hospital consultant staff and G.P.s may result in more instructive handling of the clinical material which presents itself in the realms of one's own practice.

The G.P. sends his case to hospital either because he is unable to diagnose it or he needs special therapeutic facilities, or both. Having referred his case to hospital he usually loses trace of it for some weeks, after which time he may or may not receive a letter stating either the diagnosis arrived at by his superiors in the field or the treatment to be followed. Would it not be a great deal more instructive if the rationale followed in arriving at the diagnosis were also explained to the G.P.? May I give you just one illustration.

I referred a case recently to a well-known surgeon at a local hospital. An abdominal tumour was palpable (at least in my opinion, for what it may be worth). I have not heard one word from the hospital. The patient rang me up and said she was being admitted for investigation two days later and she has now been in hospital one week. I have taken the trouble to visit the hospital twice in an effort to follow up the case. I have gleaned from the sister of the ward that she has no information for me, "two stools have been done and come back negative," and that is all. The

tentative diagnosis I made was "renal tumour and calculus." I am left wondering what possible connexion there may be between a renal tumour and a negative stool. No one has confirmed the palpable tumour or told me its possible identity.

Could not the gods of the profession occasionally step down from their pedestals to confer with, nay advise and teach, their subjects. I feel that were this possible the interesting cases which do present themselves to the G.P. would be made a great deal more instructive.—I am, etc.,

KATE FORREST.

Artificial Insemination

SIR,—The letter from Dr. Harper in your issue of Oct. 14 needs an answer. It would have been well had he verified and weighed his facts rather more carefully before blossoming into print about this very complex subject of artificial insemination. The following points must be made clear:

Artificial insemination is certainly never done without the full and willing consent of the barren husband at any clinic or in any case with which I have dealings, nor, I imagine, would it ever be by any bona-fide doctor in his senses. Artificial insemination from a donor is called for only in a very small group of barren marriages (perhaps 2% or less of all cases seen)—i.e., those in which the husband is completely and irremediably sterile and the wife fertile, where adoption is unacceptable because the wife desperately wants a baby of her own, and where, in consequence, the marriage may be in danger of breaking down. In such cases, with the full and written consent of the sterile husband, artificial insemination, carried out as a private arrangement between the couple and the doctor, may be the best possible solution, leaving the world at large to regard the child as the husband's. It is worth placing on record that most of the requests for artificial insemination come from the sterile husbands themselves, anxious to make such reparation as they can to their wives for the children they cannot beget. Moreover, in my experience the wives are of the type who do not seek the easy way out of finding a "fancy man." It seems possible that there will be a better and more rational selection of genes if the wife receives an artificial insemination from a semen donor on a carefully chosen panel than if in her chagrin and desperation she commits an impetuous act of adultery. In any case, if we are to concern ourselves with the quality of genes there are plenty to engage our attention in the community at large before we concentrate upon that rare bird the artificial donor. Adoption undoubtedly is the solution for some, but an adopted child carries no genes from its adopted parents, whereas a child conceived as the result of artificial insemination does at least carry them from one.

In building up a panel of semen donors it is best to choose married men with offspring and to talk to their wives first, and only if these are willing for their husbands to act as semen donors are the husbands themselves approached. It is also well to select only those couples who appear to be intelligent enough to comprehend the reason for the appeal. (In the case quoted by Dr. Harper my judgment must have been at fault.) A clean bill of health, a sound intelligence, and a high grade of fertility are all essential in a donor; wherefore the building up of such a panel is no easy matter and places a grave responsibility on the doctor who attempts it. In this help might well be given by such expert bodies as the Medical Research Council and the Eugenics Society.

The legal position with regard to artificial insemination from a donor has not yet been defined in this country. In America, where artificial insemination has been done for many years, it is an accepted part of legitimate medical practice in carefully selected cases; even there the legal position is still fluid. When Dr. Harper says that the matter requires full ventilation and direction from competent authorities we must all agree. It is noteworthy, however, that demand by the citizen for legal protection in this matter has not yet been voiced nor has organized religion committed itself.

One last point. If by "veterinary" Dr. Harper had meant scientific, which it is to be suspected he did not, it would have been a well-deserved compliment to the Cinderella of the professions.—I am, etc.,

Credition, Devon.

MARGARET HADLEY JACKSON.

hydrolysates. In the meantime I hope that these preliminary observations will act as a stimulus to further efforts in this field.—I am, etc.,

E. O. MORPHY, M.B., D.P.H.

SIR,—It is high time that the ostrich-like attitude concerning the political functions of the medical profession displayed by your annotation in the *Journal* of Oct. 14 is challenged. Many doctors, even the B.M.A. Council themselves, have recently and repeatedly stressed the greater importance in the promotion and maintenance of health of such primary fundamentals as food and housing over secondary factors such as the provision of personal medical services. In doing so they indirectly admit the political functions of our profession, whose aim I assume is the betterment of human health. If it is believed that better town and country planning, housing, feeding, and education, at least two of which are dependent on the value of income relative to prices (rent and cost of food)—to say nothing of improved personal health and social security services by means of which the occurrence of sickness or accident will not cause financial loss to the sufferer and embarrassment of the above-mentioned income-price ratio—are necessary for the raising of the level of the nation's health, surely it is the business of members of the medical profession not only to proclaim these beliefs but also to take all possible steps to further their implementation. The scientific method of taking such steps is by utilizing the political machinery of the country, and the fact that a proportion (is it such a minor one?) of the profession is now waking up to this fact should be the occasion for rejoicing rather than moaning.

Some of us doctors consider ourselves citizens first and doctors second, and therefore owe our allegiance to the greater democracy, or to democracy before a possible technocracy. Therefore we feel that it is morally our duty to support whatever democratic political or medico-political organization we believe is most likely to press for the improvements we desire, and to put them into practice if elected to power. And, therefore, whether we join on the one hand Common Wealth or the Conservative Party or on the other hand the S.M.A., the M.P.A., the Sword of the Spirit, or the Child Health Planning Group in addition to continuing our membership of the B.M.A., I maintain that the B.M.A.'s *Journal* in attacking the activities of two of the four organizations in the second group above is not only unjust but also blind.

The Churches have for centuries been more acutely aware than the medical profession of their political duties in their endeavours to influence public policy. The fact that such so-called "interference" has not always seemed either righteous or satisfactory in the light of history does not invalidate the underlying general moral principle. Members of the medical profession might well emulate their clerical colleagues, Non-conformist, and, more recently, also Church of England, in standing more frequently for membership of their local authorities, bodies which doctors often criticize and blame without being prepared to take the obvious step of standing for election themselves, and, if successful, endeavouring to reform or guide the authority from within, a process in which hitherto the medical officer of health has usually been engaged in a lone struggle. This leads to the final observation that in a properly organized national health service the doctor, with his valuable working time economized by the provision of clerical and auxiliary medical personnel, should at last have

enough leisure to enable him to play his rightful part—one aspect of which I have just indicated above—in a democratic fellowship—I am, etc.,

Devon

F JOHN GARRATT LISHMAN

"* We agree that medical men as citizens should utilize the political machinery of the country " in order to play their part in 'a democratic fellowship'. But are the Socialist Medical Association and the Medical Policy Association parts of this machinery? The former, at least, wants the B.M.A. to attack the latter—Ed B.M.J.

Reserve of Medical Students

SIR—I have been approached on several occasions by medical students whose reservations have been cancelled by the Ministry of Labour because they have failed in one examination in the medical course. The most onerous effect of this procedure is seen in cases where a student has failed in the second M.B. examination at a university but has passed the equivalent examination of the English Conjoint Board, and upon the latter achievement has been accepted for his clinical training at a London teaching hospital, and some months later—in one instance after the student had completed nine months' clinical training to the satisfaction of the hospital authorities—has been called up and forced to relinquish all prospects of qualification. The Minister in reply to myself (*Hansard*, July 29, 1943) described his procedure as follows:

One of the conditions for the continued reservation of a medical student is that he shall be periodically certified by the responsible authority of the university or other training establishment as making satisfactory progress in his studies. This restriction is necessary not only for some general reasons but because the number of places for medical students is limited, and an unsatisfactory student is not only failing to qualify himself but is preventing someone else from doing so.

I submit, Sir, that this is putting too high a premium upon the result of one examination. There must be few of us who have not failed at some part of the very arduous preparation for the medical profession. I have repeatedly pointed out in such cases to Mr. Bevin that the consequence of his regulations is to withhold from qualification a number of candidates for the medical profession and thus invalidate the success of schemes for post war reconstruction which depends so largely upon securing an adequate number of doctors to work them. The demand is likely to be at least three times as great as the present supply, and inasmuch as the minimal period for training a doctor is some six years, preparation for that demand should be put into operation now—I am, etc.,

The Hospital Case and the G.P.

SIR—After reading Sir Adolphe Abraham's stimulating letter on postgraduate study (Oct 7, p. 480), may I offer a humble suggestion whereby some of the issues raised may be approached. A little closer co-operation between hospital consultant staff and G.P.s may result in more instructive handling of the clinical material which presents itself in the realms of one's own practice.

The G.P. sends his case to hospital either because he is unable to diagnose it or he needs special therapeutic facilities, or both. Having referred his case to hospital he usually loses trace of it for some weeks, after which time he may or may not receive a letter stating either the diagnosis arrived at by his superiors in the field or the treatment to be followed. Would it not be a great deal more instructive if the rationale followed in arriving at the diagnosis were also explained to the G.P.? May I give you just one illustration.

I referred a case recently to a well known surgeon at a local hospital. An abdominal tumour was palpable (at least in my opinion, for what it may be worth). I have not heard one word from the hospital. The patient rang me up and said she was being admitted for investigation two days later and she has now been in hospital one week. I have taken the trouble to visit the hospital twice in an effort to follow up the case. I have gleaned from the sister of the ward that she has no information for me, "two stools have been done and come back negative," and that is all. The

tentative diagnosis I made was, 'renal tumour and calculus'. I am left wondering what possible connexion there may be between a renal tumour and a negative stool. No one has confirmed the palpable tumour or told me its possible identity.

Could not the gods of the profession occasionally step down from their pedestals to confer with, and advise and teach, their subjects? I feel that were this possible the interesting cases which do present themselves to the G.P. would be made a great deal more instructive—I am, etc.,

KATE FORREST

Artificial Insemination

SIR—The letter from Dr. Harper in your issue of Oct. 14 needs an answer. It would have been well had he verified and weighed his facts rather more carefully before blossoming into print about this very complex subject of artificial insemination. The following points must be made clear.

Artificial insemination is certainly never done without the full and willing consent of the barren husband at any clinic or in any case with which I have dealings, nor, I imagine, would it ever be by any bona fide doctor in his senses. Artificial insemination from a donor is called for only in a very small group of barren marriages (perhaps 2% or less of all cases seen)—i.e. those in which the husband is completely and irremediably sterile and the wife fertile, where adoption is unacceptable because the wife desperately wants a baby of her own and where, in consequence, the marriage may be in danger of breaking down. In such cases, with the full and written consent of the sterile husband, artificial insemination carried out as a private arrangement between the couple and the doctor, may be the best possible solution, leaving the world at large to regard the child as the husband's. It is worth placing on record that most of the requests for artificial insemination come from the sterile husbands themselves, anxious to make such reparation as they can to their wives for the children they cannot beget. Moreover, in my experience the wives are of the type who do not seek the easy way out of finding a fancy man. It seems possible that there will be a better and more rational selection of genes if the wife receives an artificial insemination from a semen donor on a carefully chosen panel than if in her chagrin and desperation she commits an impetuous act of adultery. In any case if we are to concern ourselves with the quality of genes there are plenty to engage our attention in the community at large before we concentrate upon that rare bird the artificial donor. Adoption undoubtedly is the solution for some, but an adopted child carries no genes from its adopted parents, whereas a child conceived as the result of artificial insemination does at least carry them from one.

In building up a panel of semen donors it is best to choose married men with offspring and to talk to their wives first, and only if these are willing for their husbands to act as semen donors are the husbands themselves approached. It is also well to select only those couples who appear to be intelligent enough to comprehend the reason for the appeal (In the case quoted by Dr. Harper my judgment must have been at fault.) A clean bill of health, a sound intelligence, and a high grade of fertility are all essential in a donor, wherefore the building up of such a panel is no easy matter and places a grave responsibility on the doctor who attempts it. In this help might well be given by such expert bodies as the Medical Research Council and the Eugenics Society.

The legal position with regard to artificial insemination from a donor has not yet been defined in this country. In America, where artificial insemination has been done for many years it is an accepted part of legitimate medical practice in carefully selected cases, even there the legal position is still fluid. When Dr. Harper says that the matter requires full ventilation and direction from competent authorities we must all agree. It is noteworthy, however, that demand by the citizen for legal protection in this matter has not yet been voiced nor has organized religion committed itself.

One last point. If by 'veterinary' Dr. Harper had meant scientific, which it is to be suspected he did not, it would have been a well-deserved compliment to the Cincerebella of the professions—I am, etc.,

Credition Devon.

MARGARET HADLEY JACKSON.

SIR,—The rational view of the moral aspect of this problem would seem to follow from considering the normal and definite way in which procreation of children takes place. It is not a manipulative procedure by a third party, or an operative procedure, but proceeds by way of sexual intercourse between man and woman. To do without sexual congress is a perversion which should be morally condemned. It involves masturbation, which should be condemned also on other grounds. This disposes of the case where it is proposed to inseminate a woman with the semen of an unknown donor.

The only cases in which artificial insemination may morally be resorted to are those in which, although coitus takes place, there is no reasonable likelihood that the semen can penetrate the uterus—e.g., malformation of the cervix, ectopia vesicae successfully operated on so that semen is ejaculated into the husband's rectum. In such cases normal intercourse is not dispensed with. The procedure follows such coitus; it is not morally wrong though it may be difficult and unsuccessful.

The medico-legal aspects of the problem are not referred to by Dr. Richard Harper. They have been discussed in the *Journal* of Jan. 9, 1937.—I am, etc.

London, N.16.

E. H. STRANGE.

Gestation Period and Ovulation Time

SIR,—The present abnormal circumstances, whereby thousands of couples are permitted occasional, and thus memorable, opportunities for cohabitation offers to medical men an unrivalled opportunity for collecting data on the above subject. Despite the many researches detailed in such works as *The Time of Ovulation in Women*, by C. G. Hartman (London, Baillière, Tindall and Cox, 1936), controversy still arises over the relatively simple matter of gestation time, while the more abstruse affair of ovulation time in relation to menstrual period is obscure in the extreme. I would like to suggest that practitioners consulted for the first time by pregnant women make a note of all who admit to pregnancy from single coitus and publish their findings on the resulting gestation periods. If women were encouraged to keep a calendar record of their menstrual history an estimate of the ovulation time in relation to the menstrual cycle could also be made with some accuracy, provided that a decision is arrived at on the question of survival time of spermatozoa in a fertile state in the female genital tract. This could be done by washing out inseminated monkeys and using the washings for artificial insemination of other female monkeys who are fit for impregnation. From such data an accurate estimate of the day of ovulation in the cycle can be made and thus a sounder basis be secured for opinions on the matter of the so-called "safe period."

Starling's Physiology (8th edition, Churchill, London, 1941) suggests a period of 280 or 281 days from conception to expulsion of the foetus, being a multiple of 10 menstrual cycles, while W. H. Howell (*Textbook of Physiology*, 14th edition, Saunders, Philadelphia, 1940) merely says 280 days after the last day of the last menstrual period, while some textbooks of obstetrics say 272 days from conception to parturition. Recent experience has led me to believe that a proportion of healthy women are producing normal infants with a gestation period about 285 days on the average. With regard to the time of ovulation there might be said to be two schools of thought: those such as Knaus (1929), Bourne and Williams (1942), Pryde (1941), Shaw (1925), and Allen (1930), who are fairly dogmatic on the subject and venture a limited period of ovulation occurring from the 8th to the 17th day of the cycle; and those such as Siegel (1916), Hammond and Asdell (1926), Langman and Burr (1942), or Hamblen (1939), who are more vague. The following details of a case which can be vouched for illustrate some points in this theme:

A healthy 3-para aged 29 years gave birth to a mature child on Sept. 24, 1944, at 21.30 hrs., weight 8 lb. 11 oz., after 10-hrs. parturition. Single coitus took place on Dec. 13, 1943, at 05.00 hrs. Menstrual cycle for two years 26 days plus or minus 2, usually 26 days, flow 5½ days, L.M.P. Dec. 5 to 10, 1943. The period from insemination to delivery was thus 286 days 16½ hours, or, perhaps of more interest, the period from fertilization, when the embryo may begin to act upon the mother by production of diffusible agents, until the commencement of labour, when the maternal organism decides to expel the foetus, was about 285 days. This period resembles 11 menstrual cycles for this subject.

If the survival time for viable sperm is a maximum of 48 hours, as suggested by Starling, then ovulation in this case occurred on or about the 10th day of the cycle.

In conclusion I should like to suggest that it is advisable to record data at the first interview and contain oneself in patience for the final result rather than record answers from tired and "hazy" women in the puerperium. Coitus dates can thus be checked with husbands before they forget their occasional leaves.—I am, etc.,

York.

The Hazard of Anaesthesia

SIR,—May I make a belated contribution to the question of anaesthetic hazards. I doubt very much whether publication of our individual mistakes is really going to help others. It is difficult to learn from other people's errors, however willing we may be. There must be a stage in each doctor's career when he has to start with a great deal of theoretical knowledge and not much practical experience. I do not see how the young anaesthetist is to get experience except by practice, nor how the public is to be protected. It is certainly desirable that an inexperienced anaesthetist should choose his cases so far as possible, but no one can say precisely beforehand how any anaesthetic is going to shape.

My first essay at open ether ended in fatality. I was suddenly called upon to give an anaesthetic in a major abdominal section where the staff anaesthetist had failed to arrive. I knew nothing about the case; I had never given open ether. The house-surgeon in charge assured me that the patient was sound, and he added that you could not possibly kill anyone with open ether. Yet I did—or the system which permitted such a happy-go-lucky arrangement. It did not save my conscience that a famous pathologist found a degenerated heart muscle and several lesions in the lungs, or that the jury exonerated and even thanked us all. I knew that my inexperience plus a faulty system were to blame.

Later on in South Africa I built up a considerable anaesthetic practice, giving anaesthetics regularly for a well-known local surgeon, and my colleagues—both medical and nursing—paid me the compliment of calling on me to anaesthetize themselves, their wives, families, and relations as occasion arose, and I can therefore claim to have acquired some degree of skill. It may be that my early fatality helped me to a greater skill than I might otherwise have attained, and therefore benefited many other people. I should like to think so.

With regard to Dr. J. M. H. Hannan's letter (May 6, p. 634), I rarely give anaesthetics now, and am unfamiliar with all the more modern methods, but I agree with him about open ether. Though I lost my first case with it, it became my stand-by afterwards, and I would still back it, properly given, against any other anaesthetic with which I am familiar. I believe that the anaesthetist's armamentarium should be as simple as possible, and apart from that there are two essentials: slow induction and plenty of air. In big operations accompanied by much shock I used to add continuous subcutaneous saline. If a patient is taken under slowly, regardless of an impatient surgeon, and if he is kept a good colour throughout, he will give little trouble, and will have a minimum of vomiting and discomfort afterwards. It is the patient who is pushed under who becomes cyanosed, secretes plenty of saliva, strains his heart, and vomits afterwards. But you will never go far wrong with gradual induction and free airway. I still think my greatest triumph was putting a child under in its sleep without waking it up. I dislike anaesthetics for tonsils and adenoids above all other cases for the reasons that the child is frequently unhealthy, respiration is obstructed by the condition itself, and more so by the operative procedure. My nearest approach to another fatality was a T. and A. case in

a private house, which I saved by adrenaline into the ventricle. I think the surgeon was even more relieved than I, as the parents were personal friends of his. Slow induction and plenty of air.—I am, etc.,

Nanyuki, Kenya Colony.

G. DUNDERDALE.

Arsenic in Malaria

SIR,—Recent references in your columns to quinine and quinine substitutes in the treatment of malaria prompt me to suggest an alternative method that might be tried in cases resistant to such treatment.

It has been my experience that an intravenous injection of neo-kharsivan (0.45 g.) is invariably effective in terminating malaria artificially induced for the treatment of such conditions as general paralysis of the insane. One injection is sufficient and no relapses occur. Various (theoretical) contraindications to such arsenical treatment instantly suggest themselves. In my experience, however, no adverse effects occurred even in patients weakened by as many as fifteen to twenty rigors. Whether neo-kharsivan would be effective against strains other than *P. vivax* (the strain commonly employed in the treatment of general paralysis of the insane) cannot be said, but I suggest that arsenical treatment might be tried in cases of malaria, naturally acquired, which do not respond to quinine, etc.

I should add that the foregoing method of treatment is not an original suggestion. It was, I believe, first suggested by Dr. W. McAdam in the observation wards of the Southern General Hospital, Glasgow. As one of his successors, I can testify to its efficacy.—I am, etc.,

R. GOOD,
Capt., R.A.M.C.

Dermatitis in Coal-miners

SIR,—In his article in the *Journal* of Sept. 30 (p. 430) Dr. Knowles mentions constitutional factors as playing a part in connexion with the oncoming of dermatitis, but refrains from telling us exactly what he means by such a statement. He admits that only a small percentage of miners develop industrial dermatitis, so it ought not to be difficult to obtain more detailed information as to the peculiar "constitutional factor" which plays a determining part. I have pointed out that "miner's knee" is a form of rheumatism determined to some extent by kneeling, but only in those who belong to what I call the "acid class." This class is made up of those whose food contains too little of the lime-containing foodstuffs—milk, eggs—and too much of the acid condiments—vinegar, pickles, sauce—which tend to destroy the vitamins in the food to which they are added. In members of the "acid class" there is nearly always evidence of blood deterioration, which lessens their oxygen-carrying capacity, and if carbon monoxide be present in increased quantities such people have their susceptibilities intensified greatly, because the oxygen carried is still further reduced.

Dr. Knowles states that the highest percentages of cases of dermatitis occur in pit F, which is deep and hot, and where there is a higher percentage of carbon monoxide gas than in the other pits. Had the miners working in these pits dealt with by Dr. Knowles been examined before starting in a colliery, he would have been in a better position to assess the constitutional factor, and consequently to prevent disease.—I am, etc.,

Swansea.

G. ARBOUR STEPHENS.

The Cat's Milk

SIR,—In the *Journal* of July 8 (p. 58) a letter by Dr. W. N. Leak once again raises a matter which to my mind is of paramount importance. A few days after reading it and heartily agreeing with him I received a letter from my wife describing a visit to a mutual friend who has just borne her first baby after a somewhat long and trying labour. I quote the following extract:

"M' has not felt very thrilled or maternal. I gather, but that, I think, is the fault of the nursing home. She has never seen more of the baby than his face and his toes. She is not allowed to unwrap him at all. It might be anybody's baby brought in for her to feed, and there is no time allowed for mothering. 'X' [a

casual acquaintance] saw him long before she did; she was mad about that. She wasn't allowed to see him till the evening, though she was perfectly well all the time. I thought she wasn't as well as she should be; too many visitors and pain with stitches. . . ."

Quoting such an account and observing individual mothers and infants under varying circumstances in a country practice, seeing the astonishingly plentiful evidence of successful breast-feeding in this country, where Nature takes her course in the most open-handed manner, may not have the value of controlled experiment. In some fields of work where an unknown number of factors are at work, I think that what *feels* right may at long last be "scientifically proved right," and I am certain that conditions described in the letter I quote do not feel right, whatever may be the causes of that state of affairs.

Air mails are precious and surface mail slow; if that were not the case Service M.O.s over-seas might write more often. Red tape exists and I do not know its full length, so I sign myself

"R.M.O., ITALY."

Asylum Doctors' Pay

SIR,—Since the nursing and catering staffs of mental hospitals have under recent awards all received considerable increases in pay, is it not time that the medical officers should be considered?

A matron may receive £600, plus £200 emoluments; yet the average rate for a medical officer with a D.P.M. is £450 to £500 a year—frequently only £400. The scale which governs these deplorable rates is so antiquated that few even know of its existence. The continuance of this niggardly remuneration is not likely to increase the repute of a branch of medicine which in the past has not enjoyed the prestige it deserves.—I am, etc.,

"A.M.O."

Obituary

ARNOLD CHAPLIN, M.D., F.R.C.P.

We regret to announce the death on Oct. 18 of Dr. Arnold Chaplin, a learned physician who was for many years Harveian Librarian of the Royal College of Physicians of London.

Thomas Hancock Arnold Chaplin was born at Fulbourn, in Cambridgeshire, on Aug. 30, 1864, the youngest son of A. T. Chaplin, a member of a Puritan and Nonconformist family which has been resident in that neighbourhood for more than two and a half centuries and has always been engaged in the occupations of farming and allied trades. In the time of the great Civil War many members (ten) of the family played their part as troopers in Cromwell's Ironsides. Arnold Chaplin was educated at Tottenhall College near Wolverhampton, and then in 1883 went to St. John's College, Cambridge. In 1886 he took his B.A. in the Natural Sciences Tripos, and went on to St. Bartholomew's Hospital to complete his medical studies, graduating in medicine in 1889. At Cambridge he had also paid considerable attention to literature, especially history and biography. In 1892 he took the M.R.C.P., and in 1893 the M.D. of Cambridge, and in 1902 was elected a Fellow of the Royal College of Physicians.

In 1889 Dr. Chaplin was appointed house-physician to the City of London Hospital for Diseases of the Chest, Victoria Park, and at the end of the year resident medical officer. He occupied this post until 1892, and was then appointed registrar and pathologist. Having decided to make a speciality of the study of chest disease, he was elected assistant physician in 1893. He became full physician and in 1922 consulting physician, after serving the hospital for thirty-three years. From 1893 to 1904 he held the post of assistant physician to the East London Hospital for Children, and he was also physician in London to the Ventnor Consumption Hospital and physician to the Metropolitan Dispensary for twenty years. It had always been his wish to use what medical skill he might possess for the benefit of great commercial concerns. With this end in view he began practice in the City of London in 1892, and in 1898 was elected physician to the Marine and

General Life Office, a position he held for more than thirty-three years. He was medical adviser to many banks and commercial firms in the City, of which the National Bank of India, the Mercantile Bank of India, the Imperial Bank of Persia, and the P. & O. Banking Corporation may be mentioned. All of these positions he held for more than thirty years. He was also physician to the Standard Life Office in London for more than twenty years, and physician to the Chinese Imperial Customs for fifteen years. But while he held these appointments his main interest in the City was the important position of medical inspector to the P. & O. Company. To this office he was appointed in 1903, and he held it for thirty-five years. Besides being responsible for the medical control of this great company he was also medical inspector to the New Zealand Shipping Company and the British India Steam Navigation Company. While he held these shipping appointments many improvements calculated to make medical service at sea more efficient were put into operation. He was also medical adviser to the Chamber of Shipping, and on two occasions was chairman of the committee set up by the Board of Trade for the revision of drugs to be carried on board ship.

In 1918 Dr. Chaplin was appointed Harveian Librarian to the Royal College of Physicians. In 1917-18 he was FitzPatrick Lecturer in the history of medicine, and in 1922 delivered the Harveian Oration. For two years he served on the Council. He was a close student of English and French literature, especially that belonging to the seventeenth and eighteenth centuries. In fact the whole of his leisure may be said to have been spent in the study of literature. He was much interested in medical history and had been President of the History of Medicine Section at the Royal Society of Medicine. For many years he was a persistent collector of the engraved portraits of British medical men, and from this fine collection he gave 250 portraits to the Royal College of Physicians and 350 to the Medical Society of London. He was three times called upon to address the social gatherings at the Royal Society of Medicine, and twice chose as the subject of his discourse the engraved portraits of medical men, and on the remaining occasion great figures in the world's history. Another favourite study was the St. Helena period of the career of Napoleon while a prisoner there. During the later years of his life Dr. Chaplin acted as informal adviser to the Royal College of Obstetricians and Gynaecology on matters connected with the library.

Arnold Chaplin's literary output was select rather than large. In his younger days several papers on diseases of the heart and lungs were followed by co-operation with Sir Andrew Clark and W. J. Hadley in writing a monograph on *Fibroid Diseases of the Lungs, including Fibroid Phthisis*. Chaplin wrote jointly with E. H. Colbeck in 1902 a small book on the *Science and Art of Prescribing* to give the student and practitioner some knowledge of the principles that underlie the administration of drugs. So much prescribing was done by means of stock hospital formulae that such information was of importance, and the book met with a demand, for a second edition was issued in four years. In 1913 he wrote a full account of the final illness of Napoleon I. This was read as a paper before the Historical Section of the International Congress of Medicine in London and was published, with some additions, in the same year as *The Illness and Death of Napoleon Bonaparte*. Besides reviewing the published accounts of the various doctors in attendance at St. Helena, he considered the illnesses which the Emperor had been subject to and which were attributed to epilepsy. Napoleon had an habitually slow pulse—rarely above 50 when well—and the vomiting, lethargy, and stupor (almost unconsciousness) which he suffered from after unusual strain and effort were, Chaplin thought, quite possibly due to some passing form of heart-block. Some of his military failures were attributed to this weakness. The final illness, as revealed at the post-mortem, was diagnosed as gastric ulcer and cancer of the stomach; in life it had been put down to tropical abscess, to liver disease, and (two weeks before death) to hypochondriasis; no one suspected the stomach. The FitzPatrick Lectures, privately printed for the author, were on *Medicine in England during the Reign of George III*. They conveyed a good deal of general information about medical affairs over the sixty years of the history, 1760-1820: medical education, hospitals, public health, the medical press, progress of knowledge, with personal notes on many of the leading physicians and surgeons of the time. An interesting section is that on the Royal College of Physicians and the prolonged struggle between its licentiates and Fellows which lasted close on a century. The subject of the Harveian Oration was "Medicine in the Century before Harvey." It had as its thesis the comparative dearth of scientific endeavour before the date of his work and the

stimulus scientific research received after its appearance. Interesting accounts are given of scholar-physicians before Harvey's time—Linacre, Caius, and others—who created a spirit of wide culture in the College of Physicians—and of those who followed his precepts or original research in the period immediately succeeding the appearance of his book—Glisson, Wharton, Willis, and Grew. The Oration concluded with a tribute to Sydenham's subsequent work of stressing the importance of clinical investigation in the treatment of disease.

Arnold Chaplin joined the B.M.A. in 1910. He held office as vice-president of the History of Medicine Section at the Annual Meeting of 1927 and as president of that Section in 1936. He was a member of the International Medical Sea Code Committee, of the Ship Surgeons Postgraduate Training Committee, and of the Ship Surgeons Subcommittee.

R. J. ROWLETTE, M.D., F.R.C.P.I.

We have to announce with regret the death on Oct. 14 of Dr. R. J. Rowlette, a distinguished Dublin physician who represented Dublin University in Dail Eireann for four years and had been President of the Royal College of Physicians of Ireland and of the Royal Academy of Medicine in Ireland.

Robert James Rowlette was born on Oct. 16, 1873, second son of Matthew Rowlette, of Carn Cash, Sligo. He was educated at Sligo School and at Trinity College, Dublin, where he graduated B.A. as Senior Moderator in Ethics and Logic in 1895. He took the M.B., B.Ch., and B.A.O. degrees in 1898, proceeded M.D. a year later, and was elected F.R.C.P.I. in 1913. Early in his career he was pathologist at Queen's College, Galway. Among the positions he held in Dublin were those of King's Professor of *Materia Medica* and Pharmacy at Trinity College, physician to Mercer's Hospital, and consulting physician to the Royal Hospital for Incurables, Donnybrook. During the last war he went to France with the rank of lieutenant-col., R.A.M.C., and was mentioned in despatches. He served on the Irish Public Health Council after returning to civil life and was professor of pharmacology at the Royal College of Surgeons in Ireland for five years. He was also a member of the Committee of Inquiry on National Health Insurance and the Public Medical Services.

Dr. Rowlette joined the B.M.A. in 1900 and represented his Division at two Annual Meetings; he was president of the Leinster Branch in 1922-4, and at the Annual Meeting in Dublin in 1933 presided over the Section of Pharmacology and Therapeutics. He was a past president of the Irish Medical Association and for many years acted as Irish editor of the *Medical Press and Circular*, whose history he wrote for its centenary in 1939; he also edited the *Journal of the Irish Free State Medical Union* and wrote memoirs of Irish physicians and surgeons for the *Dictionary of National Biography*.

From 1908 to 1920 he was president of the Irish Amateur Athletic Association and was always keenly interested in its work; he had been a famous athlete in his youth, and was honorary physician to the Irish Olympic teams that went to Antwerp in 1920, to Paris in 1924, and to Amsterdam in 1928.

Dr. ANDREW GRAHAM RITCHIE, who died in Edinburgh on Oct. 12, was born in that city on Sept. 3, 1884, and from Edinburgh Academy went to study medicine at the Universities of Edinburgh and Berlin. He took the B.Sc.Ed. in 1907, the M.B., Ch.B. in 1910, and was elected F.R.C.P.Ed. in 1920. For several years after qualifying Dr. Ritchie held resident posts at the Edinburgh Royal Infirmary, and then became clinical tutor. He was also for a time resident surgeon at the Royal Maternity Hospital and physician to the Livingstone Dispensary; later he became physician to the Cowgate Dispensary and to the Longmore Hospital for Incurables. During the last war he served in No. 8 Mobile Laboratory, B.E.F., with the rank of captain, R.A.M.C. He contributed papers to the *Journal of Pathology and Bacteriology* and the *Quarterly Journal of Medicine*. He joined the B.M.A. in 1922 and represented his Division at the last two Annual Representative Meetings in London. A colleague, in the course of a tribute published in the *Scotsman*, has written: "Those who remember his father recognize how much Andrew Ritchie derived from him—in particular the strong, almost stern, sense of duty and the realization of the 'high calling' of his professional work. His experience as a pathologist in the Army in the last war filled him with such a love of the scientific side of medicine that at the end of the war he was much tempted to devote himself to it, but he saw it to be his duty to take over the large family practice with

which his father's increasing years were making him unable to cope. How well he succeeded in that vocation is attested by the devotion of his many patients.

Dr NOEL F ROWSTON of Sunderland, who died on Sept 19, was born in Corunna Spain 74 years ago and educated at St. Bartholomew's Hospital, taking his M.B. degree at Durham University in 1893, and later his M.D. for which he was gold medallist. About 1899 he settled in Sunderland as a general practitioner. In the list war he served in Malta, and on his return was appointed V.D. medical officer in the Royal Infirmary, Sunderland, at which he practised to the day of his death. He was a member of the British Medical Association nearly all his professional career, and was founder of the West End Society—a subsidiary in the Sunderland Division of the B.M.A. A colleague writes: "Since 1912 this society has drawn its members into close collaboration, improved their scientific knowledge, and ameliorated conditions of work. The members admired the enthusiasm of our friend both in his profession and in our society, and feel in debt to his untiring efforts."

Dr. VICTOR JENNER BATESON of Ilford, who died on Sept 29, was for some years an active member of the B.M.A., representing the Stratford Division at nine Annual Meetings and serving as chairman of the Division in 1930-1, he had also been a vice-president of the Metropolitan Counties Branch. He was born in Mile End in 1867, the son of John Bateson, M.R.C.S. After seven years at University College School, London, he entered University College Hospital Medical School and qualified L.S.A. in 1894. During three years' service as temporary captain in the R.A.M.C. he held the post of sanitary officer at Malta. For a short time after returning to civil life he was assistant physician to the Queen's Hospital for Children, having served earlier as physician to the Plaistow Baby Clinic. Dr Bateson gave much time to lecturing for the St. John Ambulance Association which made him an honorary life member.

Dr Charles Vincent Mackay, F.R.A.C.P. writes from South Yarra Melbourne. In the obituary columns of the *Journal* of April 22 you published an appreciation of the late Sir HENRY MAUDSLEY by Sir Thomas Dunhill, his house physician at the Royal Melbourne Hospital in 1904. The memory picture which he has so clearly drawn of this great physician teaching neurology at the bedside, will recall many such scenes to those who enjoyed the same privilege as himself. Sir Thomas is however, not quite accurate in his dates. Sir Henry Maudsley was appointed directly to the in-patient staff of the Royal Melbourne Hospital on Aug 27 1903, and retired in 1919. Sir Richard Stawell was appointed to the out-patient staff on May 19 1903. He actually preceded Sir Henry Maudsley on the teaching staff of the hospital, and succeeded him as in-patient physician on April 25 1919. The praise which Sir Thomas Dunhill gives to these two great teachers of medicine is echoed back to him by all their students in Australia, who are so much indebted to them.

The Services

Major Gen. R. E. Barnsley, M.C., K.H.S. late R.A.M.C., has been appointed C.B. (Military Division) in recognition of distinguished services in connexion with the landings in Normandy.

The *London Gazette* has announced the following appointments, awards, and mentions in recognition of gallant and distinguished services in Burma and on the Eastern Frontier of India.

C.B.E. (Military Division)—Col (Temp) A. N. T. Meneces, R.A.M.C.

M.B.E. (Military Division)—Capt (Temp Major) D. B. Jamie, R.A.M.C. Capt (Temp Major) A. A. M. Nolan, I.A.M.C., Capt M. L. Sudan, I.A.M.C.

M.C.—Capt K. B. Fraser, R.A.M.C.

Mentioned in Despatches—Majors (Temp Lieut Cols) T. E. A. Carr and P. D. Johnson, Capts (Temp Majors) T. S. R. Fisher and A. D. Stoker, Capt A. G. H. Clay, R.A.M.C.; Capt (Temp Major) A. Lakshminarayana, Capts B. N. Blagran, J. W. A. Crabtree, S. N. Basu, M. K. Akhtar, S. K. Ghosh, F. M. Khan, and U. P. Mukherjee, I.A.M.C.

Major Gen. Sir P. S. Tomlinson, K.B.E., C.B., D.S.O., K.H.P., late R.A.M.C., has been mentioned in despatches in recognition of gallant and distinguished services in the Middle East.

Capt G. E. Wodehouse and Lieut L. Dallan, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in the field.

Capt (Temp Major) J. G. B. De Vine, R. W. Jones, and J. L. Nicol, Capt (acting Major) D. R. Sandison, Capts T. G. Grav, P. G. Griffiths, C. C. Laird, W. W. Marsden, and J. Thompson, and Lieut F. S. Cooper, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in NW Europe.

Temp Surg Lieut G. A. Gould, R.C.N.V.R., has been mentioned in despatches for good services to the survivors when H.M.C.S. *Regina* was lost.

CASUALTIES IN THE MEDICAL SERVICES

Fl Lieut A. J. Chiappa Sinclair, who died on Oct 2, was born in April, 1898, studied dental surgery and medicine at Middlesex hospital, qualifying L.D.S. in 1919, and M.R.C.S., L.R.C.P. in 1922. After holding appointments at the Dental Hospital, Great Portland Street, he entered general practice. He was commissioned in the Medical Branch of the R.A.F.V.R. on June 13, 1941. At the date of his death he was serving as medical officer at a mobile field hospital overseas.

Killed on active service—Capt Ernest Lawrence Holden Ellis, R.A.M.C.

Killed in action in NW Europe—Capt James Thorburn Doyle, R.A.M.C.

Died of wounds—War Subs Capt Hayter Arnett Wells, R.A.M.C. Previously reported missing now officially presumed killed—Surg Cmdr Humphrey de Bohun Kempthorne, R.N.

Reported missing (1 April)—Majors C. J. Longland and G. Riggby-Jones and Capts J. H. Keesey and J. E. Buck, R.A.M.C.

Reported missing—Capt R. E. Bonham Carter, R.A.M.C.

Reported missing in Holland—Capt P. Louis, R.A.M.C.

Reported missing believed prisoner of war—Capt C. C. M. James, R.A.M.C.

Missing in NW Europe believed prisoner of war—Lieut Col M. E. M. Herford, M.B.E., M.C., R.A.M.C.

Capted and missing in NW Europe believed prisoner of war—Capt G. F. H. Drayson R.A.M.C.

Wounded—War Subs Capts N. R. Carlson and J. R. Kyles, R.A.M.C.

Medical Notes in Parliament

Tuberculosis Treatment

In the House of Commons on Oct 10 Sir WALDRON SMITHERS called attention to the increase of tuberculosis in Kent and the lack of institutional accommodation for patients. It was reported that there were at present 350 patients awaiting institutional treatment and owing to the shortage of beds and staff, men could not be accommodated for at least three months and women and children for about five months. The incidence of tuberculosis went up in wartime. In reply to a question he had put to the Minister of Health on July 27, he was told that the rate per 1,000 went up from 0.704 in 1938 to 1.248 in 1941, 1.017 in 1942, and back to 0.984 in 1943. While realizing all the difficulties he had every possible step been taken to see that all available staff and accommodation were economically used? The Minister had tried to put as good a case as he could by saying that the number of deaths which was considered the truest guide to the incidence of the disease, showed only an increase of 0.1% over the same period. It was not a question of the number of deaths but of the terrible danger of the spread of infection. The admission of patients was strictly in accordance with the date of recommendation. Why should that be? Surely some consideration should be given to the state of health, age, and home surroundings of the patient.

The conditions at the clinic at Bromley, to which, although it was not in his constituency, his constituents had to go, was appalling. There were no beds, and the accommodation for patients and the dressing-rooms was most primitive. The tuberculosis officer for that clinic, to whom he paid a tribute, was a splendid man and was heartbroken at the distress around him and his inability to help. The medical officer of health for Kent had written him (Sir Waldron Smithers): "You will appreciate that the doctor at the clinic at Bromley is an officer on my staff, but as tuberculosis officer to the Bromley area he is not familiar with the questions of policy raised. In any event, as a subordinate officer on my staff, it would be improper for him to answer your questions." Here was a foretaste of a State-run medical service, a service run too much by people sitting in offices and tending to get out of touch with the realities of medical practice. The medical officer of health also complained that he (Sir W. Smithers) had shown a report of his to the wife of a tuberculous patient in his constituency.

The war boggy had been overdone. Tuberculosis was bad all over the country. The Minister had a very grave responsibility in this matter in trying to alleviate human agony and suffering, which might have been avoided in some degree had he been a stronger man and shown some foresight and courage.

SIR HENRY MORRIS-JONES said that Sir Waldron Smithers's remarks on what was said by the chief medical officer about his subordinate officer was characteristic of what was likely to happen in this country when we got a National Health Service under the State. There was a medical man who, when asked his opinion, was not allowed by his superior officer to give it. The thing would have been quite impossible in a voluntary hospital. The position in regard to institutional vacancies and to tuberculosis cases which were compelled to be in homes that were often overcrowded was very serious in this country. Conditions in Wales were growing more serious. It was time that the Minister of Labour released generally more women for domestic and institutional help.

MISS HORSBRUGH said that they all realized what difficulties the hospitals were facing at the present time. Patients who would benefit most from sanatorium treatment and rest had to be taken before other cases which, although distressing, would receive no real lasting benefit from treatment. She agreed that they should have sufficient beds and institutional accommodation for both kinds of cases. Even in wartime they had practically the same number of beds as they had before the war, but that was not enough. The real difficulty was the question of staff—nursing and domestic. The pool of trained nurses had at present to be drained for service all over the world. They were asked for more midwives, more mental nurses, more staff for sanatoria, more general nurses. The Minister of Labour had set up a National Advisory Council for the Recruitment and Distribution of Nurses and Midwives. But it was just as important to see that they had enough domestic workers. They had asked the Minister of Labour to do more about this.

The death rate from tuberculosis was down practically to the figure for 1938—there was a small increase in the number affected, but nowadays they were discovering the disease earlier. They must have buildings, and above all trained men and women to look after these people. The Ministry of Health and the local authorities were doing their best, and there was an economic use of our facilities at present. The facilities were not great enough, and she hoped when the war ended they would be able to get on with a bigger and better health service, which would have the approval of the House of Commons and the country as a whole.

Inoculation in the Forces

On Oct. 17 Mr. A. EDWARDS asked the Secretary of State for War if he would consider making a King's Regulation prohibiting the vaccination or inoculation by force of any member of H.M. Forces, and the imposition of any punishment or disability on men who exercised their right to object to these operations. Sir JAMES GRIGG said that King's Regulations laid down that inoculation against tetanus and the enteric group of fevers was voluntary, and the *Manual of Military Law* stated that a soldier could not be punished for disobedience of an order to be vaccinated or for refusing to be inoculated. This was well understood, and he was not aware of any need for further regulations.

Parliamentary Medical Group and Medicine in India

During his visit to India last winter Prof. A. V. Hill had special opportunities of learning about the present situation and needs of India in connexion with education and research in medicine and public health. On his return he discussed these with the Parliamentary Medical Group, which was keenly interested in some of the proposals and took steps to facilitate a project for providing postgraduate training in the United Kingdom of selected Indian medical graduates. These would be key men for future developments. More recently two members of the Parliamentary Medical Group discussed these and kindred matters with Lieut.-Gen. J. B. Hance, D.G.I.M.S., and Dr. C. G. Pandit, director of the King Institute of Preventive Medicine, Madras. The Group is keenly aware of the urgent need of India for great improvements in the fields of medicine and public health. It hopes to keep in close touch with developments, and will do what it can to facilitate cooperation with and help from the U.K.

Penicillin

Answering questions on Oct. 19, Mr. WILLINK said no facilities had been granted to Mr. Kendall, M.P., to obtain penicillin. Mr. Willink had no information as to the source of his supplies. The value of penicillin for the treatment of bacterial endocarditis had not been established. In view of the limited

amounts available for civilians he had not felt justified in recommending its use for this disease. He was not aware if civilians were being allowed to die because they were refused treatment with penicillin. For many diseases treatment with penicillin would be ineffective.

Mr. GEORGE GRIFFITHS asked whether Mr. Willink knew a discovery in a laboratory of the West Riding County Council where penicillin was being made. Had not permission been given to use this on West Riding patients? Mr. WILLINK said questions on the production of penicillin were not for the Department. His responsibility was to advise on the distribution and use of what was available for civilians. There was shortly to be a debate in the House on penicillin, during which he proposed to speak. Mr. KENDALL said larger quantities of this drug were now available.

Establishment of Married Women Doctors

Captain PRESCOTT on Oct. 19 asked the Minister of Health what disqualifications or disabilities attached to the establishment or promotion of married women doctors, either in the local government service or in the Ministry of Health, a whether he would consider recommending their removal. Mr. WILLINK replied that there was in all Government Departments a ban on the establishment of married women civil servants. This was removable in exceptional cases where was considered that the efficiency of the Department would suffer by the loss of the officer's services. When a woman doctor in his Department was retained after marriage there was no disqualification as regards promotion. The abolition of the ban in the Ministry of Health was a general service question within the province of the Treasury. There was no statutory bar to the employment by local authorities of married women medical officers. The question was one entirely within the discretion of local authorities. A similar rule to that applied in the Civil Service was commonly applied in local government but had been widely relaxed during the war.

Anaesthetic Cylinders

Mr. WILLINK told Mr. George Strauss on Oct. 19 that attention had been drawn to the recent death of a child at Bath during an operation as a result of the use of a badly marked nitrous oxide anaesthesia cylinder. The British Standards Institution had appointed a committee to consider what measures could be adopted to distinguish more readily than at present between the various medical gas cylinders used in the administration of anaesthetics for the purpose of avoiding repetition of such a tragedy. His Department was represented on this committee.

Battle Casualties

From the opening of the campaign in Western Europe up to the end of August the casualties sustained by the British Imperial Forces engaged totalled 103,842, of whom 20,795 were killed, 63,193 wounded, and 19,854 missing or taken prisoner.

Health of Miners

Replying to a debate on Oct. 18 about recruitment for the coal industry, Mr. TOM SMITH said the greatest wastage from the industry was through men who left it on medical certificate. That question was constantly under review. The fatal accident rate still showed a decline and progress had been made with rehabilitation in fracture cases. The rehabilitation centres were appreciated by patients who had been treated in them. Through the Home Office the Ministry of Fuel and Power had been able to do a little in regard to silicosis. No time had been lost in the efforts to prevent pneumoconiosis, which was wanted watching constantly. Some progress had been made.

Goodenough Report.—The recommendations of the Goodenough Report, including the wider admission of women to the medical schools, are under consideration, and Mr. Willink hopes to be able to make a statement soon.

Proprietary Medicines.—Mr. JOHN DUGDALE on Oct. 19 asked the Minister of Health to inquire into all proprietary medicines claimed to cure certain diseases with a view to warning the public against those found not to act in accordance with their claims. Mr. WILLINK did not think that action on these lines would be practicable. It was already unlawful to advertise any article for the treatment of certain diseases, including cancer, diabetes, tuberculosis, and venereal diseases.

Serum for Rheumatoid Arthritis.—On Oct. 19 Cmdr. LOCKE LAMPSON inquired whether particulars of the cure for rheumatoid arthritis announced in Russia had been secured. Mr. WILLINK said the Empire Rheumatism Council had carried out tests with a small supply of serum sent to them from Russia. The results obtained did not justify a favourable verdict. The Council proposed to make further investigations when war conditions permitted, but meanwhile were not prepared to recommend the use of this serum.

No. 40

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 7.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year for: (a) England and Wales (London included) (b) London (administrative county), (c) Scotland, (d) Eire (e) Northern Ireland.

Figures of Births and Deaths, and of

for: (a) The 125 great towns

(b) London (administrative county)

The 13 principal towns in Eire. (c)

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales during the week measles, acute pneumonia, scarlet fever, and dysentery continued to rise in incidence, notifications being respectively 477, 149, 94, and 39 higher than last week. There were 122 fewer cases of whooping-cough and 36 fewer of diphtheria.

Whooping-cough notifications fell most noticeably in the south-west and south midlands from 190 to 101. Lancashire reported 18 fewer cases of diphtheria than last week. Measles notifications are still mounting in the north; Lancashire had 328 more cases than last week, Cheshire 71, and Warwickshire 55; in Durham the total fell by 137.

In Scotland there was a general lowering of the incidence of infectious diseases. The decreases were scarlet fever 51, acute primary pneumonia 43, measles 28, dysentery 11, diphtheria 15; but the total for whooping-cough rose by 22. The largest returns for dysentery were Glasgow 64, and Edinburgh 32.

In Eire diphtheria notifications rose by 26 and measles by 8. The chief outbreak of measles was in Dublin North Rural district, which had 23 cases.

In Northern Ireland measles notifications rose by 15, but those for diphtheria fell by 6, and for scarlet fever by 8. There has been an outbreak of typhoid fever, involving 11 persons, with 2 deaths, in the village of Lisbellan, Co. Fermanagh.

Dysentery

In England and Wales during the present year dysentery notifications have been high, the weekly totals ranging between 127 and 622. In the past five weeks 2,108 cases have been notified. The total notifications for the first, second, and third quarters of this year are 9,178, compared with 1,174, 3,665, 1,368, 1,698, 4,487, 5,118, 5,453 for the corresponding periods of 1937-43. During the week reviewed the largest returns were Glamorganshire 54, Lancashire 52, Suffolk 43, London 42, Pembrokeshire 36, Essex 24, Northamptonshire 20, Surrey 18, Kent 11.

The age and sex distributions for the first quarter of the year are given in the recently published report for the June quarter. They are:

Ages	Civilians		Non-civilians	
	Male	Female	Male	Female
0-15	676	563	—	—
15+	440	843	115	21
Unknown	30	43	—	—
Total	1,146	1,464	115	21

Quarterly Returns for Eire

The birth rate during the June quarter was 23.6 per 1,000, which is 2.1 above the average of the five preceding second quarters. The infant mortality was 70 per 1,000 registered births—2 above the five-years average. The general death rate was 15.1 per 1,000, which is 0.5 above the average of the second quarters of 1939-43. 436 deaths were attributed to the principal epidemic diseases, compared with an average of 318. Increases over the June quarter of 1943 were as follows: measles 56; typhoid 6, diphtheria 5; there were 9 fewer cases of whooping-cough, 8 of scarlet fever, and 230 of diarrhoea and enteritis under 2 years than for the same period last year. The 222 deaths from the latter disease were, however, 63 above the five-years average. 871 deaths were due to respiratory tuberculosis, and 280 to other forms, the former being 107 below and the latter the same as in the corresponding quarter of last year.

Week Ending October 14

The returns of infectious diseases in England and Wales during the week included: scarlet fever 2,152, whooping-cough 897, diphtheria 567, measles 3,088, acute pneumonia 655, cerebrospinal fever 43, dysentery 358, paratyphoid 7, typhoid 9, poliomyelitis 24.

W. A. Blankenhorn (*Ann. intern. Med.*, 1944, 20, 423) records six cases of multiple peripheral neuritis which occurred among 600 patients treated with sulphonamides. In 5 the total dose was 50 g. or more; 6 g. a day was administered by mouth. The largest dose was 197 g. and the smallest 36 g. In several cases other factors may have contributed. Eight cases showed signs of neuritis before sulphonamide drugs were given.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Annual Meeting of Fellows and Members

The annual meeting of Fellows and Members will be held at the College on Thursday, Nov. 16, at 2.30 p.m. A good attendance is hoped for, because there will be important matters for consideration, such as the attitude of the profession to the White Paper, which was dealt with at the Fellows' meeting in May and reported on pages 14-17 of the annual report, copies of which may be had from the secretary of the College, Lincoln's Inn Fields, W.C.2, who will send also a copy of the agenda to any Fellow or Member applying for one. Other matters for discussion at the meeting are the implications of the report of the Goodenough Committee, and the attitude of the College in regard to the possibility of developing a conjoint building in which the three Royal Colleges and other academic bodies can be housed.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At the annual meeting of the College held on Oct. 18 the following officers were re-elected for the ensuing year: *President*, Prof. R. W. Johnstone. *Vice-President*, Mr. J. W. Struthers. *Secretary and Treasurer*, Mr. K. Paterson Brown. *Representative on General Medical Council*, Mr. Henry Wade. *Convener of Museum Committee*, Mr. W. Quarry Wood. *Librarian*, Dr. Douglas Guthrie. The following candidates were elected Fellows of the College, having passed the requisite examination:

H. H. Atkinson, P. H. Beales, H. M. MacCarthy, Mary Savory.

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council held on Oct. 13 a donation of £100 for cancer research was received from Mr. George I. Forster of Northwood, Middlesex, in memory of his father and mother.

The following academic staff appointments were made: Dr. I. F. S. Mackay, as lecturer in experimental physiology; Dr. H. R. Vickers, as honorary lecturer in dermatology; and Dr. D. P. Greaves and Miss E. M. Spedding, M.B., as temporary demonstrators in anatomy.

Medical News

Dr. Janet M. Vaughan, F.R.C.P., has been appointed a member of the Royal Commission on Equal Pay for Men and Women in the Public Services, in Industry, and in Other Fields of Employment.

The Society of Apothecaries of London announces that Col. Elliott C. Cutler, chief consultant in surgery, U.S. Army, European Theatre of Operations, will deliver a lecture on "Military Surgery in 1944" at Apothecaries' Hall, Black Friars Lane, Queen Victoria Street, E.C.4, on Friday, Nov. 3, at 2.30 p.m. Members of the medical profession and senior students will be welcomed. Later in the session Brig. L. E. H. Whitby will lecture on blood transfusion; Sir Howard Florey on penicillin; and Mr. Eardley Holland, F.R.C.O.G., on midwifery.

At a meeting of the Society of Public Analysts and Other Analytical Chemists to be held at 3 p.m. on Wednesday, Nov. 1, at the Chemical Society's Rooms, Burlington House, Piccadilly, W., the following papers will be presented and discussed: "Some Experiences of Microbiological Assays of Riboflavin, Nicotinic Acid and Other Nutrient Factors," by D. W. Kent-Jones, Ph.D., and M. Meiklejohn; "A New Method for the Estimation of Micro-quantities of Cyanide and Thiocyanate," by W. N. Aldridge. Guests introduced by members are welcomed at the meetings by the Council.

A Congress of Friendship and Co-operation with the U.S.S.R. will be held in London on Nov. 4 and 5, in the Central Hall, Westminster, and the Coliseum Theatre. The sponsors of the congress include Lord Horder, Sir Alfred Webb-Johnson, Sir Philip Manson-Bell, Sir Boyd Orr, Prof. F. Wood Jones, and Sir E. Rock. The aim of the congress is to survey the successes already achieved in the field of British-Soviet co-operation within the framework of the United Nations, and to consider ways and means of further extending such co-operation in the post-war period.

Dr. M. J. C. reports that a small quantity of DDT (dichlorodiphenyl trichlorethane), which has been produced by carbamate poisoning, and was used with telling effect. Samples has been placed at the disposal of the Salford Health Department for testing purposes, and will be applied to the disinfection of houses. Salford is the only authority outside London to be issued with the powder, because war needs in the Middle and Far East make it impossible for quantities to be made available in this country.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Atiology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Ammon. Chlor. for Soda-ash Burns

Q.—Is the 5% solution of ammonium chloride issued to firms for treating burns caused by soda ash to be used neat or diluted?

A.—If the bottle issued is labelled "5% solution" it should be used neat, to drench the affected tissues, and may be followed by bathing or irrigation with normal saline or plain water. (See *B.M.J.* 1943, 1, 756.)

Sero-fibrinous Pleurisy

Q.—What conditions in sero-fibrinous pleurisy would lead one to believe that the effusion is non-tuberculous?

A.—All recent work tends to show that in the vast majority of instances sero-fibrinous pleurisy is tuberculous in origin. All case of pleural effusion should be investigated thoroughly with a view to ascertaining the cause; a careful history, x-ray examination of the chest, and examination of the fluid are essential. Where there is no clear indication, such as the presence of a neoplasm, heart failure, acute rheumatism, or injury, to suggest that the condition is non-tuberculous, it should be assumed that tuberculosis is the cause. It must also be remembered that a persistent sterile effusion is a common sequel to pneumonia which has been treated with sulphonamides in inadequate doses.

Bed-sores

Q.—An enfeebled lady of 82 years of age with myocardial degeneration and anginal symptoms was admitted to hospital with a fractured neck of femur and Colles's fracture, the result of a fall. Within four days she developed two pressure sores, one on the buttock and one over the scapula. Is this attributable to careless nursing as is so often thought to be the case by the public? The pressure areas had been treated in the usual manner, but in spite of this the abrasions appeared and progressed. Is this inevitable, and if not how can it be avoided? The question is one of supreme importance to hospitals nursing this type of case.

A.—The occurrence of bed-sores in this case was by no means necessarily due to careless nursing. The measures taken to prevent such sores have each their special aim. The gentle rubbing during the process of cleansing with soap and water, the drying, and the powdering aim at improving the local blood supply; the application of spirit is meant to harden the skin so that it may be better withstand unavoidable pressure; the care taken to avoid rucks in the sheet and to distribute pressure by pads and rings aims at avoiding undue pressure or irritation on any one spot. In addition if the heart action be weak it may be advisable to stimulate it by appropriate drugs.

In the lady of 82 with double fracture and suffering from myocardial degeneration it would be difficult to maintain a good peripheral circulation by any means and bed-sores might be inevitable. It must be understood, however, that in the great majority of cases, even at that advanced age, the above precautions should suffice to prevent the occurrence of sores.

Indoor Ripening of Tomatoes

Q.—Is there any difference in the vitamin content of tomatoes that ripen on the bush and those that ripen indoors?

A.—Very little information on this subject is available, although published results suggest that tomatoes which have been picked green and ripened in storage contain not only less vitamin C but also less carotene than similar fruit allowed to ripen on the vine. Conditions of storage have their effect, however, and it has been found that if unripe tomatoes are exposed to sunshine after picking their vitamin C content is much higher than that of tomatoes stored in the dark. Other factors, such as season, variety, and soil also influence the vitamin value of fruits, and consequently indoor-ripened tomatoes may or may not be nutritionally inferior.

Workmen's Compensation

Q.—It has to be the procedure for a patient without means who does not belong to a trade union to apply for compensation? My patient suffers from disseminated sclerosis which has apparently been aggravated by a fracture sustained at work and he has only seven shillings a week for work.

A.—The workman should go to the county court nearest to his workplace and explain the position to the registrar or his deputy. He will be instructed how to make a claim, and if the registrar considers that he should have legal aid he will be directed to the secretary of the local Poor Persons Committee of the Law Society. The registrar will probably himself communicate with the secretary. County courts are used to poor litigants, and their officials are humane and helpful. If the workman is physically unable to go to the registrar's office, any friend may go in his place. The local Poor Man's Lawyer might have something useful to suggest. The police, or the Citizen's Advice Bureau, or the local social welfare society, or the town hall staff, will almost certainly know whether a P.M.L. is available in the district.

Boy or Girl?

Q.—I have recently been approached by a patient who has read an article in a periodical about the predetermination of sex and he now wishes to know whether there is any possibility of ensuring that a child of one sex should be born by taking the appropriate measures.

A.—Many fantastic theories have been advanced, but none of them are supported by evidence. The pH story continues to crop up at intervals, but it has no better support than other less probable hypotheses.

Motile Spermatozoa in the Vagina

Q.—I have been in the habit, when examining a couple for childlessness of examining microscopically a vaginal smear for motile spermatozoa as soon as possible after intercourse. This examination should determine whether ejaculation occurs into the vagina and whether the spermatozoa are capable of remaining motile in the vaginal secretions. Surprisingly enough however, I have seldom been able to detect active or even dead spermatozoa although the male partner usually turns out to have no abnormality of the genitalia. Is this test a misleading one and do spermatozoa in fact tend to disappear very soon from the vagina?

A.—The reaction of vaginal fluid is almost invariably acid, in a series of more than 400 electrical estimations of vaginal pH the range was 4.2 to 7.0 and was below 6.0 in more than 90% of cases. Sperms (even from a perfectly fertile man) that remain in the vagina are rapidly immobilized within 1 to 3 hours in most cases, though there are fairly wide variations from one couple to another, depending on such things as the volume and quality of the ejaculate, the volume and pH of the fluid present in the vagina prior to ejaculation, the occurrence of orgasm on the part of the female, and the phase in her menstrual cycle. Motile sperm have rarely been found in the vaginal vault up to 7 hours after intercourse (and once at an interval of 14 hours, and this vagina had a pH of 7.2), but unless the examination of vaginal contents is made within two hours of coitus little weight can be attached to the absence of motile sperm. On the other hand, with careful searching small numbers of immobilized sperm can frequently be found in vaginal fluid up to 24 hours after coitus—later than that they are only rarely found and then usually in a state of disintegration—e.g., tailless forms. Certainly a complete absence of sperm (motile or immotile) from a properly collected and examined sample of vaginal fluid obtained within 10 hours of coitus must cast grave doubts on the potency and/or fertility of the male. A more profitable and informative test, however, is the post-coital examination of adequate samples of mucus extracted from the cervical canal, in a satisfactory test it should be possible to find motile sperm in the cervix 40 hours or more after coitus during the second and third week of the cycle, whereas when the husband is inadequately fertile or impotent, or when the cervical mucus is hostile, motile sperms are not to be found even within a few hours of coitus.

The Injured Man's "Fag"

Q.—(1) Is nicotine volatile enough to disappear when a cigar or cigarette or pipe is lit? (2) If not, does it find its way into the lung? (3) Surely if that is the case a smoker must acquire some form of immunity? (4) Is it not likely that nicotine is drawn off when the tobacco is alight and that the ill effects of smoking are due to products of combustion (CO, CO₂, etc.)? (5) Should an injured man or woman be given his/her fag as treatment for shock? (6) Is it given as a sedative or stimulant, or both?

A.—The vapour of a cigarette, pipe, or cigar contains a considerable quantity of nicotine, which is absorbed through the mucous membrane of the upper respiratory tract and in the lungs. This causes a fall in pulse rate and skin temperature, and in excessive doses, nausea, vomiting, and diarrhoea. While a certain degree of

tolerance to the inhaled nicotine is acquired after the first few trials this tolerance is never absolute, and toxic effects are inevitable if the dose is large enough. The untoward effects of smoking are adequately explained by this absorption of nicotine, but there is no reason to withhold a cigarette from an injured man. Nicotine is a central stimulant but in small quantities is unlikely to have either a beneficial or a deleterious effect in traumatic shock.

A.T.S. for Minor Cuts

Q.—Are the three doses of 3 c.c.m. A.T.S. recommended for air-raid casualties necessary for uncomplicated minor cuts due to glass? If the three doses are not considered necessary, is it worth while to give a second dose to lessen the chance of sensitization?

A.—Is antitoxin necessary? That depends on one's interpretation of "necessary". The conditions predisposing to tetanus are fairly clearly understood. The bacillus or its spores must be present, also a suitable material in which it can grow and develop its deadly toxin. A severe compound fracture with lacerated and necrosed muscle deprived partly or entirely of oxygen-carrying blood, and fouled with tilled manured soil, provides a dangerously high chance of tetanus. That patient should receive at once two or three times the ordinary prophylactic dose of 3,000 international units, repeated seven and fourteen days later. At the extreme other end of the scale of danger come trifling injuries. The sewing housewife who pricks her finger and the man who nicks his face while shaving are not in danger of tetanus, and no one gives antitoxin. Where in the scale do we place "minor uncomplicated cuts due to glass"? It is improbable that anyone has ever found tetanus spores on window panes, and it is improbable that an "uncomplicated minor cut" would provide a nidus in which tetanus can grow. In private practice in pre-war days probably very few doctors would give antitoxin to such a patient. However, the opinion of the Ministry of Health is clear (*Monthly Bulletin*, Oct., 1943). "However trivial the wound may be" the doctor is to give 3 c.c.m. and repeat it twice at weekly intervals. The doctor may feel that this practice leans towards over insurance, and he may intensely dislike serum rashes, but when he complies he will feel that he has the weight of official responsibility behind him, and, after all, in the chaos of a raid he may have overlooked some other small but dangerous wound demanding antitoxin. If he makes certain that he is injecting modern enzyme treated ('refined') antitoxin, he will reduce the risk of serum reaction to a minimum. The average immunologist would not in these circumstances give a second dose.

Cleaning the Glans

Q.—It would be helpful to know whether the foreskin should be retracted and the glans cleansed in (1) the child, (2) the adolescent, and (3) the adult after intercourse and at other times.

A.—The less attention drawn to a child's genitalia the better, and special cleansing is not usually necessary before puberty. After puberty, and still more in adult life, the foreskin should be withdrawn and the coronal sulcus cleansed whenever necessary. How often this will be required will depend on the amount of smegma and other sexual secretions produced.

Arcus Senilis

Q.—Is this a record—the arcus senilis practically disappearing? A year ago mine was very noticeable quite a wide ring of yellow fatty deposit. Now nothing is left but a very narrow and grey ring.

A.—The arcus senilis, once definitely established, very rarely disappears. The distinctness with which an arcus is seen depends to some extent upon the colour of the iris which forms the background. Should the iris become lighter in shade, as sometimes happens, the arcus will be less noticeable.

Sterilizing Thermometers

Q.—What is the best way of sterilizing thermometers for taking temperatures by mouth in the surgery of a busy single handed practitioner?

A.—A clinical thermometer placed in the mouth or rectum may be contaminated with pathogenic bacteria and convey infection to another patient unless disinfected. Phenolic disinfectants of various kinds are efficient for this purpose, but tend to dissolve the markings on the thermometer, thus making it difficult to read. The disinfectant most commonly used is spirit, and this is satisfactory if certain precautions are observed. The thermometer must be wiped clean after use, so that no mucus or other material remains adherent to it. It should then be placed in 70% spirit, this being the optimum concentration for bactericidal action. Undiluted spirit is much less effective. Spirit in pocket cases should be renewed often enough to ensure that approximately this concentration is maintained. Harman, Gorton, and Parker (*Public Health Nursing*, 1939, 31, 23), who demonstrated the efficiency of this method by cultural tests, obtained somewhat better results when a few drops of liquid green soap were added to the spirit.

LETTERS, NOTES, ETC.

"Heel Reform"

Dr. PERCY TATCHELL writes: "She caught her heel in the carpet and fell." How often is that statement heard in the casualty department! On the stretcher lies an elderly woman, with a fairly obvious fracture of the neck of the femur, to judge by the position of the foot. Searching for the reason why people trip on carpets and fall downstairs, attention fixes on the sharp points at the sides of the heel, relics perhaps of days when we had to scramble up and down stony paths and really no longer essential under present conditions except for hill-climbing. Fig. 1 is an attempt to design an improved

A NON-TRIPPING HEEL

FIG. 1

form of heel. Gone are the points at the side, yet the vertical wall in front in the middle is retained as a safeguard against slipping. This heel has strong economic advantages too. Secured simply by six screws it could easily be replaced at home; also being twice as thick as the standard rubber heel, it should last a year, at a cost of about 10d. a pair. Contrast this with having to send shoes away every six months to have the heels rebuilt: generally a delay in execution of several weeks, and a bill of three or four shillings to pay.

RUBBER HEELS WILL TAKE THE CURVE OF THE WORN SURFACE

FIG 2

MAKING A COMFORTABLE WALKING SHOE

Fig. 2 suggests that the ordinary rubber heel sold in the cheap stores will take the curve of a worn leather heel, and give a reasonably finished appearance. To apply them they are first stuck on with rubber solution, and then nailed with the nails thoughtfully provided by the makers with each pair. To fix to the worn heel, after solutioning both surfaces, and when the solution is nearly dry, get the bend-up portion in position first, and secure with a brad or a small screw; afterwards press down the rest of the heel, drill out the holes, and knock the nails in with a punch. Finally, with a pocket knife pare away the angles in front, and so lessen the risk of tripping.

Ingrowing Toenail

Dr. EVA MCCALL (Sunninghill) writes: With reference to the answer in the *Journal* of Sept. 16 (p. 390), I have found powdered lead in rate packed round the nail very effective. Vaseline or lanolin rubbed into and round the nail is also useful. Most important, too, is the choice of footwear. Shoes or boots made with a raised toe, to obviate pressure on the nail, are a great comfort.

Brandy as an Anaesthetic

Dr. R. K. BROOKS (Chipping Sodbury) writes: A fortnight ago I was in attendance on a multipara and successfully delivered her of a female child with the use of instruments. Before cutting the cord I noticed an unusually large stump continuous with a protruding umbilicus. On close examination this was not mere jelly but what appeared to me to be mesentery. Under the unusual anaesthetic of brandy Miss Betty Fox of the Bristol Royal Infirmary operated in four later, and this child is alive to-day and should do well. The details of the findings at the operation and what was done have been supplied to me by Miss Fox. "The caecum, appendix, and some 8 in. of the terminal ileum was found to be protruding through the umbilicus along the side of the cord, and encased in a membrane and a coating of jelly. The umbilical ring was made slightly larger by a niche in the skin and the bowel returned to the abdomen; two purse-string catgut sutures were tied closely round

the peritoneal margin of the umbilical opening, and a pressure dressing applied. The child was returned to its mother the following morning, and the umbilicus on inspection about a fortnight later was soundly healed." I write to inquire as a point of interest if there is on record an account of any such or similar operation being performed on a baby an hour and a half old and under the influence of brandy.

Injections for Osteo-arthritis

Dr. LEOPOLD MANDEL (London, W.1) writes: In your issue of Sept. 2 under "Any Questions?" (p. 326), your correspondent asked if procaine injected into the hip-joint in cases of intractable painful osteo-arthritis had met with any success. In the answer it was stated it had met with but short-lived success. I quite agree. I have also tried it combined with histamine; this also gives transient relief. More recently I have been using a solution of acid potassium phosphate, with the addition of a small amount of procaine, with quite striking results. Relief from pain is practically instantaneous and in several cases has lasted for 2 months while under observation.

Pest of Flies

Mr. J. COSSEY (Leatherhead, Surrey) writes: In the *Journal* of Aug. 26 you published a communication from Lieut.-Col. R. M. Barron in which he writes: "Breeding places outside houses should be searched for and, if found, dealt with." How this is to be done is not stated. However, he does give some useful hints for dealing with the flies themselves. Undoubtedly the remedy lies in destruction of, or in rendering the breeding places incapable of supporting larval growth. It may interest your readers to know that powdered borax or boric acid, if used correctly, are most satisfactory for dealing with fly-breeding places, such as garbage stands or similar areas. The borax or boric acid should be dusted lightly at intervals over the surface as the pile of refuse builds up, or they may be dissolved in water (3% solution) and the solution sprinkled. About 5 lb. of borax or boric acid per ton of garbage or manure is considered sufficient. These recommendations come from the Vermont University Agricultural Experimental Station, U.S.A., where investigations were carried out in 1942, the report being published in the *Journal of the American Society of Agronomy*, September, 1943 which should be consulted for more detailed information. Supporting evidence of the efficacy of borax is provided by the issue of the U.S. Army of packages of borax which bear the following instructions: "In pit latrines apply in the ratio of 1 lb. per 8-hol latrine every 5 days. If the pit contents are moist, apply the dry powder directly by dusting it evenly over the surface. If the pit contents are dry, use just sufficient water to dissolve the borax and then spray pit contents. Do not use an excessive amount of water. If needed borax may be used in trench latrines in the same manner as in pit latrines. To control fly-breeding around garbage stand and similar areas powdered borax should be dusted lightly over the moist earth after each cleaning of the area. On compost piles use borax in the ratio of 1 lb. per 8 bushels of manure. The compost should be thoroughly wet when the borax is applied. *Caution* For external use only. Store away from food."

Cracked Fingers

Dr. W. MURRAY (Hessle, Yorks) writes: I wonder if the doctor who writes for advice about cracked fingers (Sept. 9, p. 361) has ever heard of a method of treatment which was old when I started practice 53 years ago and which I have used both personally and in my practice with unvarying success ever since. It consists simply in filling the cracks with cobbler's wax. You obtain a small lump of cobbler's wax, and to keep it from sticking to everything you put it in a very small chip ointment box without a lid. You draw the crack, using alcohol if you don't mind the momentary stinging pain. You heat a large-sized needle in the flame of a spirit lamp to a dull-red heat. With the hot needle you take off the surface of the wax as much as you can get on to the needle and coax it by manipulating it in the flame until a drop of liquid wax hangs from the point of the needle, just as a Chinese manipulates his pellet of opium before he transfers it to the bowl of his pipe. You then open the crack as wide as you can and lay the drop of molten wax along the crack, using the needle, which can be gently heated several times, to get the wax well into the crack. Then press the wax-filled crack into the warm palm of the opposite hand. The result is just as if a piece of old-fashioned black silk court-plaster had been applied. The pain goes immediately. If the wax gives way before the crack is quite healed, repeat the process. Celluloid dissolved in acetone and amyl acetate can be used in the same way. The consistency has to be that of a thick syrup. This takes a few minutes to dry.

Correction

We regret that a mistake crept into the note by Lieut.-Col. Orr Wilson (Oct. 14, p. 520) which made nonsense of his opening words. What he wrote was: "Another very good reason for cracks on the finger-tips, which are very painful and difficult to heal, is the use of methylated ether to cleanse the skin after the removal of plasters."

INFECTIVE HEPATITIS IN THE GARRISON OF MALTA*

BY

K. DAMODARAN, M.B., B.S., M.R.C.S., L.R.C.P.

Capt., R.A.M.C.

AND

S. J. HARTFALL, B.Sc., M.D. F.R.C.P.

- Lieut-Col., R.A.M.C.

This paper is based on the clinical observation of 450 cases admitted to a general hospital during 1941, 1942, and early part of 1943. The siege conditions prevailing in Malta at the time facilitated this investigation.

Epidemiological Consideration—The epidemic is practically confined to autumn and early winter, but sporadic cases are seen throughout the year. Over 65% of the cases occur in the peak months of October, November, and December, about 86% falling in the age group 20-29. Men over the age of 40 appear to be less susceptible to the disease. The majority of cases occur in the fourth week after exposure to infection, but there is considerable variation in the incubation period. Infectivity seems to be confined to the pre-icteric stage. There is a tendency for the cases to appear in series at intervals of about four weeks. The probable explanation is that the disease is infectious only for a short time, and the cases occur in series at intervals corresponding to the incubation period. It is probably airborne through infectious droplets, and overcrowding in barracks and quarters tends to its spread. About 6% of the cases occurred in the R.A.M.C., including medical orderlies of other units. This is a high figure considering the proportion of R.A.M.C. to the whole Army.

Clinical Types

Infective hepatitis may be described under four clinical types according to the mode of onset, signs and symptoms, and course of the disease: (i) gastro-intestinal, (ii) febrile; (iii) icteric, and (iv) the group without jaundice (hepatitis sine icterus).

(i) **Gastro-intestinal Type (52%)**—The onset is insidious. This type starts with malaise, nausea, anorexia, vomiting, constipation, or (rarely) mild diarrhoea. Epigastric pain or a feeling of discomfort or distension is present in most cases. After the lapse of three to five days the urine turns dark. Within an interval of 24 to 48 hours an icteric tinge appears in the conjunctivae. Frontal headache, retro-orbital pain, generalized muscular pain, pain in the loin, vague pain in the joints, and a feeling of chill and faintness have been noticed at the onset. Injection of conjunctival vessels, giving the appearance of radiating streaks from the corneal margin, was observed in a number of cases. Flushing of the face and a faint generalized erythematous rash were seen in a few very early cases. The signs, symptoms, and course of the disease in this type closely resemble the so-called catarrhal jaundice of civil life.

(ii) **Febrile Type (30%)**—All patients with marked pyrexia at the onset (100° F or higher) are included in this group. The temperature may rise to 105° F. The onset is more rapid than in the previous type. Usually the patient notices a sensation

of cold or chill, not amounting to a rigor, accompanied by frontal headache, retro-orbital pain, and sometimes generalized muscular pain. Rarely it begins with a rigor. Injection of conjunctival vessels and mild erythematous rash have been noted in some cases of this type too. The temperature after three or four days usually drops by rapid lysis. Within a day or two after lysis bile appears in the urine and 24 to 48 hours later there is an icteric tinge in the conjunctivae. Relative bradycardia is a noteworthy sign. Some typical cases were very closely observed, and four hourly pulse and temperature charts were maintained. The charts revealed Faget's sign in a number of cases. Symptoms usually subside soon after the onset of jaundice. The subsequent course of the disease is similar to that of the previous type. Post-influenzal jaundice has been recorded, especially towards the end of the last war. It is extremely doubtful whether influenza is responsible for jaundice at all. The fever resembles influenza very closely, but by tracing the source of infection we have been able to establish the fact that the febrile type may be the source of infection to a case of the gastro-intestinal type and vice versa. Besides in barracks and billets both types occur side by side.

(iii) **The Icteric (Ambulatory) Type (10%)**—No definite prodromal symptoms are observed in this group. Occasionally there may be a feeling of general malaise for two or three days. These patients report sick only if the icteric tinge of conjunctivae is pointed out to them by some other person or noticed in the looking glass by themselves. Teetotallers, patient over the age of 35, and Maltese usually belong to this group. The great majority feel quite well subjectively. Jaundice is no deep. Bradycardia is as frequent as in the other types.

(iv) **The Group without Jaundice (Hepatitis sine Icterus)**—We came to know about the existence of this group under the following circumstances. Eight officers were staying together in a billet. In the last week of Oct., 1941, one of them developed jaundice and was admitted to hospital. About five weeks later four others developed the same symptoms—fever, headache, nausea and slight epigastric pain—and were also removed to hospital, where three of them developed jaundice, but the fourth did not, though he had the same symptoms at the onset. On admission his liver was enlarged and tender. White cells: 5,200—polymorphs 44.5%, eosinophils nil, basophils 1.5%, lymphocytes 51.5%, monocytes 2.5%. Van den Bergh—direct and indirect, negative. The onset in this group is similar to that of the first two groups. One feature is the definite enlargement of the liver (often two fingerbreadths or more below the costal margin). The spleen may or may not be palpable. Relative lymphocytosis is more pronounced. The temperature settles down in less than a week; the liver returns to the normal size in a fortnight. Urine is normal throughout. Sometimes a trace of bile may be seen for a few hours only.

* Abridged specially for the B.M.J.

The main signs and symptoms are as follows:

Symptoms and Signs	Frequency %	Remarks
Anorexia, nausea, and general malaise	90	Usually appear at onset. Very mild in icteric type
Vomiting	46	Most marked in gastro-intestinal type. Not present in icteric type
Headache, retro-orbital pain, vague pain all over body	21	More severe in febrile type
Pruritus	10	May occur just before, during, or after appearance of jaundice
Fainting	2	At the onset
Bradycardia	75	Lowest pulse rate recorded 34. In febrile cases there is always a relative bradycardia
Icterus	All except group without jaundice	First appears in conjunctiva a day or two after urine turns dark; then spreads to trunk and limbs. Disappears in same order
Haemorrhagic signs:	Rare	The case with haematuria had <i>B. coli</i> infection of urinary tract complicating infective hepatitis
Epistaxis	One case	
Echymosis	" "	
Petechiae	" "	
Haematuria	" "	
Herpes labialis ..	3	In one case herpes appeared on forehead
Erythematous rash ..	5	Very faint generalized macular rash all over trunk. Face escapes. Seen only in very early cases. Easily missed
Flushing of face ..	4	Seen only in very early cases
Conjunctival congestion	10	Blood vessels dilated to show red radial striation. Some of these cases complained of photophobia
Urine		Mild amber to deep dark; acid. Bile pigments plus. Bile salts present only in about 3%. Bile free in about 12 days. Extremes: few hours and three months
Bowels:		
Constipated at onset	51	Stools usually light in colour, but may vary from almost normal to definite clay colour. Stercobilin present even in palest stools
Diarrhoea	9	
Loose bowels	12	
Normal	28	
Liver:		
Lower edge below rt. costal margin	15	Area of hepatic dullness increased in many patients when examined early enough, but soon shrinks after onset of jaundice. When hepatomegaly marked, jaundice usually mild. Gall-bladder not palpable
Enlargement of spleen	15	Splenomegaly may exist independently of hepatomegaly
Distension of rt. lateral thoracic vein ..	15	This vein becomes distended in some cases late in the disease. The flow is upwards. Liver dullness diminishes at same time. It is probably a sequel to intrahepatic obstruction to blood flow
B.S.R. (Westergren) (studied in 25 cases)		Within normal limits in uncomplicated cases. Slightly raised during pyrexial period and also if there is any lung complication
Leucocyte count (taken in 50 cases)		Slight leucopenia in most cases at onset of jaundice. Total W.B.C. may be as low as 2,550. Relative or absolute lymphocytosis usual. Leucopenia may be followed by slight leucocytosis
Van den Bergh test (qualitative) (made in 25 cases)		Direct reaction is either prompt positive or biphasic; becomes negative soon after urine is bile-free. Indirect reaction is positive a little longer
Van den Bergh (quantitative) (done in 10 cases)		Bilirubin content varied from 0.4 to 28 mg./100 c.cm., according to intensity of jaundice

Prothrombin Content of Blood.—Estimation of prothrombin content of blood was carried out in a group of 18 patients and two controls by one of us (S. J. H.). Quick's method of estimation as modified by Kark and Lozner was employed, using the stable thromboplastin preparation described by Souter and Kark. In seven of these patients, in whom a low prothrombin level was found, the estimation was repeated in four weeks to ascertain the progress of the case. The prothrombin percentage varied from 35 to 100, depending upon the severity of the case. There was considerable improvement after an interval of four weeks, but in severe cases the prothrombin level was still low (about 60%). Assuming that the liver was the source of prothrombin, it was seen that the liver function was deranged, at least so far as it affected the manufacture and release of prothrombin.

Complications

Acute Hepatic Necrosis (Icterus Gravis).—This is the most serious and fatal complication, and its possibility renders the disease potentially dangerous. Fortunately this complication is exceedingly rare. We have come across only one fatal case out of 450. A few days after onset of jaundice, mental irritability, vomiting, and stupor supervene. Cheyne-Stokes breathing, coma, and pyrexia supervene, and the patient usually dies in three days. Haemorrhagic manifestations such as haematemesis, epistaxis, or haematuria may occur. Urine contains bile, albumin, and casts. Either suppression of urine or anuria may occur. A marked diminution in liver dullness can be made out on percussion, and the right lateral thoracic vein may be very much distended. The clinical picture is that of cholaemia

(icterus gravis), and the necropsy findings are those of acute necrosis of liver.

Subacute Hepatic Necrosis.—This is a more frequent but less fatal complication. It is met with in all grades of severity. At the onset there is nothing to distinguish it from an ordinary case of jaundice, but gradually jaundice becomes deeper. Liver is tender and slightly enlarged in the beginning, but shrinks later. Nausea, vomiting, and constipation are more pronounced than in an average case of jaundice. The stay in hospital and convalescence are prolonged, but these cases have a fair chance of ultimate recovery.

Other complications are not worth mentioning here.

Second Attacks of Jaundice; Relapse

Apart from icterus neonatorum and relapse due to alcohol, second attacks of jaundice occurred in two cases—two years and five years after the first attack, respectively. In both cases the second attack was milder than the previous one.

Relapse.—True relapse, though rare, is occasionally met with. It appears to be favoured with too early convalescence or too early discharge from hospital. Bile reappears in the urine. The patient may develop a mild pyrexia and feel sick. The icteric tinge of skin and conjunctivae deepens and stools turn pale. The signs and symptoms clear up quicker during this type of relapse than during the original attack.

Relapse due to Alcohol.—The following case first made us realize the part played by alcohol in bringing about relapse of jaundice.

A corporal aged 25 was first admitted on Sept. 8, 1941, with jaundice of moderate intensity. There was tenderness in the hepatic area, but liver and spleen were not palpable. Urine bile-free on Sept. 16. Jaundice had cleared up well on discharge to unit on Sept. 26. Took 5 or 6 bottles of beer a day since the beginning of Nov., 1941. Took 18 bottles of beer on Nov. 19, 1941. Felt pain in the hepatic area on the 22nd. Vomited once in the night. Next day jaundice obvious. Readmitted on Nov. 24 with jaundice of moderate intensity. Lower edge of liver just palpable and tender. Urine contained both bile salts and pigments. Bile-free on Nov. 30.

We have come across eight more similar cases of relapse due to alcohol. The amount of alcohol taken in each case is quite considerable, and is the maximum consumed on any single day since leaving hospital. Beer, whisky, gin, sherry, champagne, all appear to be capable of bringing about relapse. Urine turns dark within 24 to 48 hours after taking alcohol in such cases, and jaundice is quite obvious in 3 or 4 days. The following case illustrates the facts mentioned above.

An officer had his first attack of jaundice two months previously. Took 10 oz. of sherry, 10 oz. of champagne, and 4 oz. of liqueur one day. Within two days developed jaundice again. Urine bile plus; hepatic tenderness plus; liver not palpable; spleen palpable. Total W.B.C., 2,550. Blood bilirubin, 20 mg./100 c.cm. Prothrombin content of blood, 40%; a month later increased to 60%. Urine bile-free a month after onset. Ever since, similar attack of jaundice occurred within 24 hours of taking any alcohol. Finally boarded out to U.K.

Alcohol sometimes produces a hepatitis without jaundice:

An officer attended a party four weeks after hospital treatment for infective hepatitis. Took 12 oz. of whisky. Within about 12 hours developed a mild rigor. Temperature 102° F.; liver enlarged 1 in. below costal margin; urine N.A.D. Temperature normal next morning. Liver appeared normal five days later.

Effect of Liver Poisons on Infective Hepatitis

1. **Alcohol.**—The effect of alcohol on infective hepatitis was studied in over 300 cases. Relapse due to alcohol has been discussed above. Apart from relapse, alcohol appears to precipitate jaundice in persons who are incubating the disease. If an appreciable amount is taken any time between three and six weeks after infection jaundice is very likely to be precipitated within from a few hours to three days. We have about 100 cases to illustrate this fact. The following is a typical example.

A sapper aged 22 had been in contact with a case of jaundice five weeks previously. Did not take any alcohol for three months previous to Oct. 17, 1942. That night he took two cocktails, two bottles of stout, and three glasses of imbecet (crude Maltese wine—alcoholic content 15%). Next day he had a good amount of rum and imbecet. Noticed dark urine within 48 hours. Deep jaundice on admission to hospital on Oct. 23.

The intensity of jaundice increases if alcohol is taken during the course of the disease.

Two oz. of brandy, 3 oz. of gin, 3 oz. of whisky, 10 oz. of imbecet, and three bottles of beer appear to have a more or less equal precipitating effect on jaundice. In all probability the factor responsible for the toxic action on the liver is the alcoholic content of the liquor and not any flavouring agent in it. A bottle of beer or an

equivalent quantity of wine or spirit does not seem to have any effect. It is also doubtful whether two bottles of beer would precipitate jaundice. But if in addition to two bottles of beer some other alcoholic beverage is taken within 24 hours there is a possibility of some effect on the intensity and onset of jaundice. In several instances jaundice has become manifest 24 to 72 hours after taking three bottles of beer. A fortnight's ration of three bottles of beer is usually issued on a single day. Men usually empty the three bottles at the same time, and two or three days later develop jaundice. Alcohol of all kinds was severely restricted in Malta during the latter part of 1942. There was an appreciable fall in the incidence of jaundice, especially among officers, during that period as compared with the previous year.

2. *Arsenic*.—There has been no general agreement as to the causation of jaundice occurring during and subsequent to the treatment of syphilis by arsenamine preparations. Though syphilis itself can cause jaundice, the fact that the latter often occurs after the serum reactions have been rendered negative proves that syphilis has very little to do with it. The incidence of jaundice due to arsenamine therapy has increased in recent years *pari passu* with "catarrhal jaundice" in the areas affected. A seasonal prevalence has also been noticed. The signs and symptoms closely resemble those of catarrhal jaundice or infective hepatitis. There is considerable evidence to support the view that the majority of cases of jaundice met with during and subsequent to arsenamine therapy are not due solely to arsenic, though that drug is a strong contributory factor. The incidence of jaundice is less in American clinics, where arsenamine is administered by continuous I.V. drip or by frequent I.V. injections during a short period of intensive treatment varying from 1 to 5 days. We have come across 14 cases of jaundice in syphilitic patients. The majority occurred during the season when infective hepatitis was prevalent. All were sero-negative when jaundice was manifested. There was no definite relation between the total amount of arsenic given and the onset of jaundice. Jaundice occurred in the beginning, middle, or towards the end of a course of injections or, in some cases, even long after the last injection. If an injection was given after the urine turned dark jaundice was precipitated within 48 hours. In such cases the jaundice was deep and the course of the disease prolonged. Jaundice which occurred a considerable interval after a course of injections was very mild when compared with that occurring during the course of injections. In all these respects the effect of arsenic is similar to that of alcohol, already discussed, but is more pronounced. Nine out of 14 cases arose in naval personnel. Two main reasons for this preponderance seem to be the daily issue of the rum ration and the I.V. administration of arsenic.

3. *Gold*.—In reviewing 900 cases of arthritis (rheumatoid) treated with gold at an arthritis clinic in Leeds one of us (S. J. H.) noticed a high incidence of jaundice after gold treatment. Among the first 100 cases (1935) there was no jaundice. In the second series, of 300 cases (1936), 3.5% developed jaundice, and in the third series (900 cases) 9.4%. The clinical picture was indistinguishable from the classical catarrhal jaundice. The van den Bergh test gave biphasic reactions, and in severe cases a transient positive direct reaction. There was a sparse outbreak of infective hepatitis (sporadic) for about eighteen months during 1936 and 1937 in the area from which most of the cases came. The proportion of cases of toxic jaundice among patients on gold treatment was much greater than could be accounted for by chance infection. Presumably the cause of jaundice was the temporary toxic effect of the gold salts on the liver cells, inducing a hepatitis which in some cases progressed to subacute necrosis. Gold is therefore brought into line with arsenic in producing similar toxic effects upon the liver. All evidence favours the view that gold was not entirely responsible for the jaundice, but was only accentuating the effect of the attack of ordinary infective hepatitis.

Discussion

The clinical findings, already discussed, indicate that the jaundice is, at least partly, obstructive in nature. The gall-bladder was not palpable in any of our cases. Our post-mortem cases showed no evidence of obstruction in the bile ducts, cystic duct, and bile canaliculi, but there was diffuse hepatitis with necrosis. The obstruction lies in the liver parenchyma, resulting from the swelling and compression of liver cells consequent upon direct damage to them.

Relationship with Catarrhal Jaundice.—Virchow, in 1864, first put forward the view that catarrhal jaundice was due to catarrhal swelling of the opening of the common bile duct the result of an acute gastro-intestinal disturbance. Later it was believed that the inflammation extended into the smaller ducts. Eppinger described obstruction of the ostium of the common bile duct by a mucous plug in his much-quoted post-mortem report of a jaundice patient who died by accident. Later, however, after following up his cases for over 18 years, he supported

the view "that acute catarrhal jaundice is merely acute yellow atrophy in miniature." Schrumph, in 1932, secured a piece of liver removed on the eighth day at an operation undertaken for a mistaken diagnosis, and described the changes as those of "acute yellow atrophy in miniature." Gaskell, in 1933, described a case of jaundice which ended fatally at an earlier stage (third day) from another cause, and the condition found in the liver was an acute inflammation with degeneration of the liver cells. The bile ducts were intact with normal epithelium, and appeared to be in no way involved in the inflammatory process. A M. Gilchrist recently published pathological reports upon material removed at operation from the liver of two patients with jaundice who were operated on because of "mistaken diagnosis." The finding in both was a subacute hepatitis with swelling and albuminous degeneration of the liver cells, accompanied with necrosis of a few liver cells in the centre of the lobules. Findley, in 1941, reviewing catarrhal jaundice, quoted post-mortem records of eight published cases in which were found degenerative changes in the liver cells and round-cell infiltration in the portal tracts with no change in the bile ducts or duodenum.

Clinically, it is impossible to separate catarrhal jaundice from infective hepatitis—especially the gastro-intestinal and icteric forms—the symptoms and signs of the two conditions are identical. There is usually leucopenia, the total W.B.C. reaching a figure as low as 2,000. There is a relative lymphocytosis, and primitive forms sometimes occur. The monocytes are increased. It also sometimes occurs in sporadic outbreaks. In fact, there is nothing to distinguish widespread catarrhal jaundice from infective hepatitis. It breaks out in epidemic form when conditions are favourable for its spread. During the epidemic in Malta the few cases admitted to the civil hospitals were diagnosed and treated as ordinary catarrhal jaundice. In the light of these facts the theory of catarrhal pathogenesis of jaundice is not tenable.

Aetiology

The long incubation period, the seasonal prevalence, the appreciable immunity after the first attack, and the high infectivity during the pre-icteric stage favour the view that it is a virus disease. We know very little about the nature and paths of entry of the virus. The prodromal malaise, the occasional generalized rash, and the early splenomegaly rather suggest a generalized blood-borne infection. The mode of infection is probably droplet, after brief exposures as in "speech contact," with a possibility of transmission by fomites. Since the period of infectivity is very limited, conditions in civil life are less favourable for its spread. Overcrowding in barracks and billets is an important factor for its epidemicity in the Army.

Alcohol is another contributory factor. It seems that two hepatotoxic factors—virus plus gold, virus plus N.A.B.—increase the liability of the patient to develop hepatitis. We have no doubt that the same explanation holds in relation to virus and alcohol. During the incubation period alcohol is capable of precipitating jaundice, and after the onset of jaundice it is capable of intensifying it. It is quite probable that alcohol precipitates jaundice in the group of hepatitis without jaundice. In civil life it is impossible to identify this group. Teetotallers appear to be less susceptible to jaundice. During the last war Indians serving in the Middle East were found to be much less susceptible to infective hepatitis. The mortality due to jaundice among the Indian force was less than half that among the other forces. During the present war the number of infective hepatitis cases treated in Indian hospitals in the Middle East is negligible when compared with that treated in British hospitals. The vast majority of Indians are teetotallers. The Mauritians serving in the Middle East are more susceptible to infective hepatitis, though the majority of them are descendants of Indians originally settled in Mauritius. The Mauritians are addicted to alcohol as much as anybody else.

Prophylaxis

Under war conditions the temptation to indulge in alcohol is great, and it is difficult to avoid overcrowding. But the disease is most prevalent in September to January, and restrictions are needed only during these months. A possibly useful preventive measure would be the reduction of consumption of alcohol to one bottle, or perhaps two bottles, of beer or an

equivalent amount of other alcoholic beverage for periods of three days during these months. Measures should also be taken to prevent overcrowding, so far as is possible, from the middle of August to the end of December.

One might ask how soon after discharge from hospital can a patient take alcohol or resume arsenic or gold therapy? We have come across cases in which a considerable amount of alcohol was taken a few weeks after discharge without any untoward effect. We know at least one patient who received a complete course of arsenic injections after an interval of only five weeks from the date of discharge without any toxic manifestation. It should be remembered that the normal liver can withstand large doses of all these drugs. The capacity of a damaged liver depends upon the amount of damage already done. Recovery is complete in a short time in mild cases, whereas in severe cases it may be months before the liver is capable of withstanding even small doses of these drugs. In a case of moderate severity a period of six months is a reasonable interval, after which the administration of these drugs can be resumed with safety. Great caution and longer intervals are needed in relapse cases. Evidence is accumulating to support the view that a weak liver poison such as alcohol may have a stimulant action on the fibrous tissue stroma of the liver while exerting a degenerative effect on the liver parenchyma, and the prolonged stimulant action may lead to cirrhosis in course of time. In all probability these properties of the drug hold good only if the liver is already damaged by a previous attack of hepatitis, with or without jaundice. If the stroma is as much damaged as the parenchyma, stimulation can produce no proliferation, and cirrhosis is unlikely in cases of moderate or severe jaundice except as replacement fibrosis in multiple nodular hyperplasia. This is rather speculative, but it is hoped that future work will confirm it.

Summary

A review is given of 450 cases of infective hepatitis treated in a general hospital in Malta. The epidemiology, clinical types, signs, symptoms, diagnosis, complications, and cause of relapse are discussed. The effect of liver poisons—alcohol, arsenic, and gold—is described. The pathogenesis of catarrhal jaundice is reviewed critically.

The clinical findings suggest that the jaundice is partly obstructive in nature.

We wish to express our gratitude to Col. Morrison and Col. Whalley for permission to carry on this investigation and publish this paper. Our thanks are also due to Lieut.-Col. McPherson, Major Kidson, Major Wilson, Major Shucksmith, Major Light, Capt Oakes, Sister Bevan, and Sister Nicholson.

HUMAN-MILK INTOXICATION DUE TO B₁ AVITAMINOSIS

BY

LYDIA FEHILY, M.D.

formerly LMO (Maternity and Infant Welfare), Hong Kong

For the first few months after the birth of their infants the Chinese women in Hong Kong live in constant dread of losing them. This anxiety is comprehensible, taking into consideration the infantile mortality, which amounted to 345 per 1,000 live births in 1939 (Hong Kong Annual Medical Report)—more than one-third of all infants born alive died within the first year of life. A certain proportion of deaths occur suddenly in apparently healthy, well-fed, and well-cared-for babies with a predilection for the male sex, thus giving rise to a belief among the Chinese that evil spirits, out of jealousy, snatch their infants, especially plump baby boys. Hence the rather pathetic efforts of the parents to protect their infants from such a fate: "joss" papers are pasted on the windows and "joss" sticks are burned before the entrance of their homes to prevent the incursion of evil spirits; the infants are disguised as animals by sewing fur ears on their caps; protective talismans are hung on their necks and chains on their ankles to fetter them, allegorically, to their homes. However, in spite of all these "precautions," a mother may find, to her

horror, that her infant has died, unobserved, during the night or while strapped to her back (the usual method of carrying infants in China). Sometimes the mothers observe that their infants suddenly become cyanotic and dyspnoeic and die, apparently of suffocation. In such cases women believe that suffocation is due to "wind" which drives mucus into the child's throat. Furthermore, they believe that this "wind" is transmitted to the infants through their own milk, which is considered to be "no good."

Aetiology

Actually the belief that their milk is not good has been scientifically proved. In 1888 Hirota, in Tokyo, was the first to observe a complex of symptoms in infants fed by beriberic women; and he called this complex "infantile beriberi"—thus connecting this disease with a condition later found to be B₁ avitaminosis. Since then a number of Japanese workers (Ito, 1911; Asakura, 1932; Takamatsu, 1934), and also I myself (Fehily, 1940), have suggested that the milk of B₁-avitaminotic women, besides being vitamin-deficient, contains some toxic substance or substances. We now know that in B₁ avitaminosis, owing to a reduction of certain co-enzymes, the intermediary products of incomplete carbohydrate oxidation accumulate in the tissues, organs, and body fluids, including human milk. These intermediary metabolites are believed to consist of lactic acid, aceto-acetic acid, glycuronic acid, glyceraldehyde, acetaldehyde, dihydroxy-acetone, methylglyoxal, and others. Most of these intermediary metabolites (lactic acid excluded) are estimated as "bisulphite binding substances" (B.B.S.), which are found to be increased threefold to fourfold over normal values in all body fluids in B₁-avitaminotic living beings. After the administration of vitamin B₁, the B.B.S. decrease almost immediately to the normal values. Although the correlation between the intermediary metabolites and B₁ avitaminosis has been definitely established, many workers (Haynes and Weiss, 1940, and others) have proved that these metabolites are not the causative factor in the development of the acute nervous and cardiac symptoms encountered in this condition.

One of these substances—methylglyoxal—has been shown to be actively toxic (Kermak, Lambie, and Slatter, 1927; Vogt-Moller, 1931), and as it is never found in the milk of healthy women it has been suggested that this product is the toxic factor in the milk of B₁-avitaminotic women. However, various authors have stated (not in connexion with infantile beriberi) that other intermediary products, if in excess, are toxic, and this seems to have been demonstrated by many experiments, including the following (Haynes and Weiss, 1940):

The administration of large doses of pyruvic acid or sodium pyruvate to normal and deficient rats was followed by death of the rats, both normal and deficient. Pyruvic acid in sublethal doses was especially irritating to the throat and had an injurious effect on the digestive and respiratory systems, whereas sodium pyruvate in sublethal doses produced diarrhoea. In the case of B₁-avitaminotic rats, the lethal dose of sodium pyruvate is smaller than that for normal rats, and the animals developed neurological symptoms shortly before death.

It would seem that the amount of pyruvic acid and sodium pyruvate in the milk of B₁-avitaminotic women is beyond the infantile tolerance, as one encounters all the above-mentioned symptoms as well as similar modes of death in infants fed on such a milk. It would seem also that besides methylglyoxal and pyruvates, other intermediary metabolites, in the amounts encountered in the milk, may take part in the intoxication, and their action would appear to be synergic and also cumulative, as even a few feeds may be fatal to an infant. This action is especially evident in acute cases, in which the intermediary metabolites may possibly give rise to acidosis similar to that of diabetic coma—an acute intoxication caused by the products of disordered carbohydrate and fat metabolism. In addition, it seems that the accumulation of intermediary metabolites alters the taste of the milk, as obviously hungry infants, after sucking greedily for a few moments, avert their heads protestingly and spill the milk (while water or cow's milk is taken without trouble).

Thus infantile beriberi differs considerably from the adult type, being primarily and mainly an intoxication, with acute

symptoms, short duration, and bad prognosis. Consequently the term 'infantile beriberi' would seem to be misleading and this may account for the non recognition of the disease in some countries until comparatively recently. A more suitable term is therefore desirable, in 1911 Ito suggested that the disease be called breast milk intoxication and recently I (Fehily, 1943) suggested the term 'human milk intoxication'.

Symptoms

Although infants fed on the milk of B₁ avitaminotic women may present a characteristic habitus or acquire some persistent symptoms, the disease generally manifests itself in the form of attacks which develop shortly after breast feeding. These attacks are characterized either by vomiting, abdominal pain (accompanied either by crying or by screaming), diarrhoea, and abdominal distension, or by vomiting, stiffness of the neck and extremities, and convulsions. In the most acute form the attack consists of dyspnoea, cyanosis, and running pulse. The attacks often end fatally, but in case of survival the infants pass into the chronic stage with symptoms of oedema, oliguria, aphonia, constipation, meteorism, neck retraction, enlargement of liver and right side of the heart, loss of weight, retarded growth, and narsismus. At the beginning of the intoxication the infants sometimes present a characteristic habitus, they are fat and flabby, pale and restless, and often have cough, which in some cases may be due to irritation by intermediary metabolites. The condition of the reflexes is variable, being normal, exaggerated, diminished, or absent. The temperature in uncomplicated cases is normal or subnormal. Probably as a result of the irritation and of the oedematous condition of the respiratory tract, intercurrent diseases, such as bronchitis and bronchopneumonia, are present in the majority of cases and these complications contribute greatly to the extremely high mortality, which amounts in untreated cases to approximately 95%. Before the main cause of this high infantile mortality was recognized, in infant welfare centres in Hong Kong cod-liver oil, iron and calcium mixtures were administered prophylactically as a routine, but without any noticeable effect on infantile morbidity or mortality.

The acuteness of milk intoxication is dependent on the amount of milk ingested, consequently overfed babies are more liable to acute attacks and to sudden death. These attacks, as well as other symptoms of the disease, disappear on the cessation of breast-feeding and its substitution even by foods such as diluted sweetened condensed milk or rice paste, which are deficient in vitamin B₁ and consist mainly of carbohydrates. With the resumption of breast-feeding the attacks reappear and eventually lead to death, unless the secretion of the mother's milk ceases or considerably diminishes. It would seem that infants born alive possess a reserve, however small, of vitamin B₁ and may progress satisfactorily until the accumulated intermediary products of carbohydrate metabolism are ingested in the milk of vitamin-B₁-deficient women. Thereafter the infants try to get rid of these intermediary metabolites by excretion through the kidneys (methylglyoxal can be found in the urine) and the lungs (the pungent smell of the breath often noted is probably due to pyruvic acid), but mainly by further oxidation of the metabolites to harmless end products, provided sufficient vitamin B₁ is available. Consequently infants succumb to intoxication when their vitamin reserves become depleted. In infants born with a low vitamin reserve or those fed previously on vitamin-B₁-deficient food the intoxication is greatly accelerated. I observed the symptoms of acute milk intoxication in a 3 months old poorly nourished infant, whose mother admitted, on close questioning, that until a week previously the child had been fed on sweetened condensed milk, she being a professional wet-nurse. (Incidentally during these five months she nursed two infants, both of whom succumbed to a disease similar to that of her own child.)

During the year 1939, of the infants brought to an infant welfare centre in Hong Kong, 18% showed manifest signs of milk intoxication, while 25% of the mothers complained of one or more of the following symptoms: weakness, numbness or oedema of the extremities, dyspnoea, palpitation, or meteorism (this latter condition often being an early sign of B₁ avitaminosis). The maternal beriberi and the milk intoxication in infants did not always correspond owing to the fact

that most of the women with manifest B₁ avitaminosis ceased to lactate, while those with good lactation were still in a latent stage.

Findings at Necropsy

In post mortem examinations the most striking feature of human milk intoxication (in uncomplicated cases) is the absence of any, or any significant, pathological lesions to account for death. The appearance of the infants, especially of those who died in an acute attack, is that of fat well cared for babies, sometimes cyanotic, but otherwise with normal organs and tissues. This absence of pathological lesions puzzled the medical profession in Hong Kong, and it was suggested that death might have been due to overlaying to asphyxiation from charcoal fumes or to accidental poisoning with native medicine. In some cases of milk intoxication oedema of the larynx was noted, in others hyperaemia of the intestines or enlargement of the right heart. In subacute cases one may find an internal varicella—namely, oedema of the brain, respiratory tract, right heart (cause of its enlargement), spleen, liver, gall-bladder, and kidneys as well as slight effusions into serous cavities. External oedema is comparatively rare, and if present is most likely to be seen in the form of a slight general puffiness or as a localized oedema—e.g. of the scrotum. This increased water retention may be due to acidosis (mainly lactic and pyruvic), as it has been pointed out (Fischer, 1921, Fliegerbaum, 1932) that acidosis of tissues and organs increases their affinity for water. Death from human milk intoxication, as in the acute cardiac beriberi of adults, is attributed to heart failure, caused through degeneration of the vagus nerve or loss of contractility of the heart muscle (owing to water retention). However, it is remarkable that no vagus degeneration has been reported in the case of infants who died of 'infantile beriberi' and, furthermore, death may occur before the appearance of any pathological cardiac lesions, such as hydrops. It is also remarkable that cardiac stimulants do not produce any effect on the symptoms, whereas administration of vitamin B₁ is followed by a dramatic improvement and eventually by a *restitutio ad integritatem*. These facts would suggest that death may be of central origin (probably due to a biochemical lesion).

Since human milk intoxication in infants is due to the ingestion of milk from B₁-avitaminotic women, one is inclined to seek an explanation for such widespread maternal B₁ avitaminosis.

Reason for Prevalence of Maternal B₁ Avitaminosis

It is generally accepted that the requirements of vitamin B₁ are in direct proportion to the intake of carbohydrates. In Hong Kong highly milled rice is the only staple food of the Chinese, and consequently B₁ avitaminosis is widespread. In the case of pregnant and lactating women this condition becomes aggravated and often manifests itself as beriberi because of (a) increased physiological requirements, (b) increased excretion of vitamin B₁ in milk, (c) increased appetite being satisfied mostly by highly milled rice, and (d) food prejudices. Thus they believe that fruit and vegetables are unhealthy because they give rise to wind, which is transmitted with their milk to their infants. Consequently, they abstain from fruit and vegetables for at least one month after delivery—in the case of male infants often during the whole period of nursing. This custom, as well as the fact that male infants are often overfed, explains the apparent predilection of milk intoxication for the male sex.

From the beginning of the war large stocks of milled rice were stored in Hong Kong. Even highly milled rice, if fresh, contains a certain amount of vitamin B₁, but this gradually disappears on storage. In the course of time rice which had been stored for longer periods than hitherto was distributed to the population, with the result that B₁ avitaminosis, followed by pellagra and arboflavinosis, increased tremendously and appeared even in institutions which up to then had been free of any deficiency diseases. Consequently, human milk intoxication among infants must have correspondingly increased (no statistics are available). Indeed, one could see on the streets a greater number of infants with the characteristic habitus or the symptoms of chronic intoxication, or with the incipient cyanosis and dyspnoea of an acute attack. After the Japanese

occupation of the colony this long-stored rice was severely rationed, so that individuals received approximately only one-third of the amount previously consumed. Consequently undernourishment was added to B₁ avitaminosis, with the result that the secretion of lactating women either considerably diminished or completely ceased. Thereafter one could see many undernourished infants with the symptoms of chronic milk intoxication, while acute milk intoxication had apparently disappeared. It may seem incongruous, but the fact remains that a high incidence of acute human-milk intoxication in infants indicates a certain degree of prosperity in the case of the native population. The observations of Bray (1929) on the island of Nauru support this statement. There the natives were given royalties for their phosphate deposits. As a result there was a distinct drop in their production of native foods, which were replaced by imported white flour and tinned meat. As palm toddy was prohibited they consumed large quantities of sugar-water instead. This change of diet resulted in the appearance of acute human-milk intoxication, and the infantile mortality rate rose to 40%.

Human-milk intoxication occurs whenever the staple foods of women are vitamin-B₁-deficient carbohydrates. Admittedly, in Great Britain such staple foods as the national loaf and potatoes have enough vitamin B₁ for their own metabolism; however, if the bulk of the diet consists of carbohydrates, some of them refined, the balance may be upset and result in deficiencies. In fact, deficiencies of other components of the vitamin B complex—such, for example, as riboflavin and nicotinic acid—have been reported recently in England (Slater, 1942; Duckworth, 1942; Clarke and Prescott, 1943; and others).

An apparently healthy mother with latent B₁ avitaminosis may produce milk containing intermediary metabolites just above the infant's tolerance, which would lead to predisposition to infantile complaints such as respiratory infections or persistent intestinal catarrhs. Even before the war Geiger and Rosenberg (1933), in Palestine, reported that Jewish sucklings suffering from persistent diarrhoea with toxic symptoms and excreting methylglyoxal in the urine, were cured after the administration of vitamin B₁. Popoviciu and Munteanu (1934) observed similar gastro-intestinal disturbances in Rumanian infants, which they also attributed to deficiency of vitamin B₁ in human milk. Occasionally in the paediatric wards in continental Europe and in the United States of America one encounters cases of sudden dyspnoea and cyanosis or learns of cases of sudden death in breast-fed infants. Where no pathological lesions are found to account for these occurrences, death is usually presumed to be due to status lymphaticus, laryngeal spasm, or oedema, to asphyxiation caused by blankets, pillows, or overlaying, or to strangulation with the strings of a jacket. May it not be possible that some, at least, of these puzzling and inadequately explained cases are due to human-milk intoxication?

Causes other than B₁ Avitaminosis

Furthermore, it is quite possible that accumulations of intermediary metabolites may also occur in other conditions in which there is a disordered carbohydrate metabolism, as in cases of glandular dysfunction—e.g., diabetes; or in other vitamin-deficiency diseases such as nicotinic acid and riboflavin deficiencies (the last two conditions most probably associated with B₁ avitaminosis).

It is conceivable that human milk intoxication occurs whenever BBS are increased in the human body; and their increase has been found in various conditions other than B₁ avitaminosis viz., acidosis, ketosis, anoxaemia, toxæmia, and uraemia (Wilkins, Taylor, and Weiss, 1937), as well as in diabetes, anaemia, epidemic dropsy, and splenomegaly (Wilson and Ghosh, 1937). However, the correlation between the nature and amount of intermediary metabolites in human milk and the symptoms in an infant fed on such a milk have yet to be definitely established. To the best of my knowledge such work has not yet been undertaken, my own investigations in this field having been curtailed after a short time.

It would seem that the statement that breast milk is the best food for an infant should be qualified by the proviso that it is secreted by a healthy woman.

Summary

It is suggested that the term "breast-milk intoxication" or "human-milk intoxication" be substituted for the term "infantile beriberi."

It is also suggested that in addition to methylglyoxal, hitherto considered to be the only toxic factor in the milk of B₁-avitaminotic women, other intermediary metabolites, in concentration encountered in the milk, may play an important part in human-milk intoxication.

The action of these intermediary metabolites appears to be synergic and cumulative.

The symptoms of human-milk intoxication are discussed.

It is pointed out that accumulation of intermediary metabolites in the milk of lactating women may be encountered in conditions other than B₁ avitaminosis and thus cause an intoxication.

ACUTE BRACHIAL RADICULITIS

BY

J. W. ALDREN TURNER, D.M., M.R.C.P.

T/Major, R.A.M.C.; Command Neurologist

Spillane (1943) has drawn attention to the comparative frequency of cases of neuritis of the nerves around the shoulder girdle in his experience with the M.E.F. Cases also occur in which the incidence is predominantly on the roots of the brachial plexus rather than on the peripheral nerves, and combinations of these conditions are seen in other patients. This paper is based on 36 cases—24 personally observed in various stages of the disease and 12 seen by Major Philip Buckley, R.A.M.C.

The essential clinical picture is a simple one: severe pain starts across the back of the shoulder and radiates down the outer side of the arm and sometimes on to the upper part of the chest; the pain remains severe for a few days and then weakness of the shoulder develops, sometimes accompanied by numbness. As the paralysis appears the severe pain usually passes off and is replaced by a dull ache, the paralysis persisting.

Illustrative Case History

An R.A.F. corporal aged 33 was admitted to hospital on Sept. 15, 1942, with the history that six weeks previously he had developed very severe pain across the back of both shoulder-blades, which radiated down the outer side of the right arm and forearm; the severe pain persisted for about five days and was then replaced by a dull ache. On the third day of the severe pain he noted considerable weakness of both arms, but especially the right, and this weakness had persisted unchanged. There were no general symptoms of malaise or fever at the onset of the illness, and his past history was uneventful except for attacks of migraine.

On examination he had winging of the left scapula due to paralysis of the serratus magnus. In the right arm there was considerable wasting of the spinati, deltoid, biceps, supinator longus, and the clavicular head of the pectoralis major. There was minimal voluntary power in the supinator longus, while the other wasted muscles were weak; the biceps and supinator jerks were absent, and the triceps jerk just present. On sensory testing there was impairment of cutaneous sensibility down the outer side of the right arm

and forearm in the distribution of C.5 and 6 segments. There were no other abnormal neurological signs. The W.R. was negative. The C.S.F. was under pressure of 150 mm. and there was no block on jugular compression; it contained 1 lymphocyte per c.mm. and the protein was 30 mg. per 100 c.cm.

He was treated with massage and exercises. In the course of two months there had been considerable improvement in the right arm; the biceps and deltoid were of normal power, the spinati and supinator longus moderately weak. The biceps jerk was feeble and the supinator jerk still absent: the sensory impairment was still present, but over a smaller area than previously. The left serratus magnus remained paralysed.

Anatomical Distribution of the Lesions in the Series

(a) *Cases Confined to a Single Peripheral Nerve.*—The peripheral nerve most commonly involved was the long thoracic nerve, with resultant winging of the scapula and difficulty in raising the affected arm above a right-angle. Isolated palsies of this nerve have been recognized for many years, and Richardson, in 1942, drew attention to their comparative frequency. The reason for including the isolated non-traumatic cases in this series is because in 4 instances paralysis of the serratus magnus has occurred on one side with involvement of other muscles in the other arm, while in 6 cases other muscles on the same side have been involved, together with the serratus magnus. There have also been 11 examples of isolated serratus magnus palsy. It has been found that if the paralysis of this muscle first occurs while the patient is in bed with some other complaint he may not notice the muscle weakness himself; it is usually first noted when he tries to stretch up to take something off a high shelf. The suprascapular nerve has been involved alone in two cases with paralysis of supra- and infra-spinatus and weakness of external rotation of the arm. It was noticeable in one case, seen some months after the onset of the disability, that the two muscles were involved in very different degrees, the infraspinatus being considerably weaker and more wasted than the supraspinatus. There were two examples of isolated circumflex palsies with paralysis of the deltoid and sensory impairment over the nerve distribution. In one case the musculo-cutaneous was the only nerve involved, with loss of power of the biceps and sensory impairment in the distribution of the lateral cutaneous nerve of the forearm. The disability was relatively slight, as good flexion of the elbow was carried out by the supinator longus, the main weakness being in supination.

(b) *Cases of Root Involvement.*—There were 5 examples of involvement of C.5 and 6 roots, of which the case described above is one. In these cases the muscles affected were the spinati, deltoid, biceps, supinator longus, and sometimes the clavicular head of the pectoralis major; and there was impairment or absence of the biceps and supinator jerks, with sensory impairment on the outer side of the arm and forearm. In one case the C.7 root was affected in addition to C.5 and 6, as shown by weakness of the triceps and extensors of the wrist and fingers as well as of the muscles just mentioned.

(c) *Muscle Involvement Not Explicable in Above Groups.*—In a number the muscle weakness was not explicable on the basis of involvement of a single peripheral nerve or in terms of root distribution, as in the following cases: spinati and serratus magnus on one side (2 cases); deltoid and spinati (7 cases); deltoid and biceps (1 case); spinati and serratus magnus on both sides (2 cases); sterno-mastoid, trapezius, deltoid, spinati, and serratus magnus (1 case); while in another case there was widespread bilateral involvement affecting the spinati, deltoid, and triceps on one side, with the spinati, biceps, triceps, and extensors of the wrist and fingers on the other; in this patient, sensory impairment was found over the lateral side of both forearms. In these cases there is often a different degree of involvement of the various muscles affected. It is possible that the distribution is explicable on the basis of involvement of more than one peripheral nerve—for instance, the long thoracic and suprascapular in the serratus and spinati cases—or by partial involvement of one or more spinal roots.

(d) *Bilateral Cases.*—In 9 of the 36 cases there has been bilateral involvement, usually asymmetrical. In 7 cases the two sides were affected at the same time or with an interval of one or two days, but in the remaining 2 cases there was a longer interval: in one, three weeks elapsed before the second

arm was involved; and, in the other, six months between paralysis of the serratus magnus on one side and the spinati on the other.

Other Features of the Disease

Precipitating Causes.—The age incidence has been 16 to 54, and all the cases have been in males; this is probably on account of the selected Service personnel seen. The geographical incidence of the disorder appears to be wide; in this series the onset has occurred in the United Kingdom, Iceland, the Middle East, Tunisia, Italy, Uganda, Nigeria, India, and in one case at sea off the West African coast. In a number of the cases a possible precipitating factor has been found. In no fewer than 9 cases the onset has followed closely on a surgical operation: in 8 of them herniotomy, and in the other excision of a pilonidal cyst. The anaesthetics were varied—spinal in 4 cases, general in 3, spinal in combination with a general anaesthetic in 1, and intravenous in the last. The time interval between the operation and the presenting pain of the radiculitis has been from 2 to 4 days in 6 cases, 6 to 7 days in 2 cases, and 10 days in 1 case. This time interval rules out as the causative factor trauma during the operation from pressure against the side of the table or other accident of that type. Eight cases were related to infections, the onset of the radiculitis usually being during the period of convalescence: malaria in 2, influenza in 2, and pneumonia, glandular fever, dysentery, and an axillary abscess in 1 case each. In this last case the disorder was bilateral and so could not have been the direct result of the abscess. Two cases followed a week after a fall on the shoulder; although pain and muscular weakness in each case developed on the same side as the fall, the trauma was slight and there was a complete absence of symptoms in the week immediately after the fall. One man developed the presenting symptoms of pain during a period of severe exposure to cold and rain while escaping from a P.O.W. camp. Two cases followed diagnostic procedures—one 10 days after a lumbar encephalogram for a suspected cerebral tumour, and one on the day after a lumbar puncture. (This was done on account of a prolapsed lumbo-sacral intervertebral disk.)

The question of prophylactic inoculations in the possible aetiology of these cases has been raised, but it is difficult to draw any conclusions from this series. One patient had an anti-typhus inoculation three days previously and 1 two weeks previously, while 3 patients had had T.A.B., the interval between inoculation and onset of symptoms being 18 days, 4 weeks, and 5 weeks. Another man had had A.T.T. three weeks previously, while in the remaining cases no recent inoculations had been given.

Onset of the Disorder

The absence of general symptoms of fever and malaise is remarkable; in only two cases was there slight malaise when the pain started. The presenting symptom is always pain; it is across the back of the shoulder and down the outer side of the arm; in bilateral cases it spreads to both shoulders and arms, and in cases in which the C.6 or C.7 root is affected it spreads to the outer side of the forearm. The pain is continuous and is usually of considerable severity; in only 3 of the cases was it described as slight.

The duration of the severe pain before muscle weakness first appeared has varied from a few hours to two weeks or possibly slightly longer, the usual length of time being three to four days. The severe pain tends to pass off as the weakness develops, and may be replaced by a dull ache; but in some cases severe pain has lasted for two to three weeks, although the paralysis has occurred within a few days of the onset of the pain. The onset of weakness in the majority of cases is sudden, with a maximum at the onset, but 4 patients said that the weakness had progressed over the course of two to three days.

Sensory Changes

No sensory impairment was found when a motor nerve, such as the long thoracic or suprascapular, was alone involved; in the cases of involvement of the circumflex and musculo-cutaneous there was cutaneous impairment to all forms of sensation in the area expected, and in 5 cases in which C.5

and 6 roots were affected there was impairment down the lateral side of the arm and forearm. Of the mixed cases only two (in which the deltoid was involved) showed some sensory impairment over the skin on the outer side of the arm, and the case previously mentioned in which there was impairment over the lateral side of both forearms. In the other patients no sensory impairment could be found.

Special Investigations

As many of these cases have been seen some time after the onset, detailed investigations in the acute stage have been infrequent, but when they have been possible the C.S.F., blood count, and E.S.R. have been normal, and Spillane also found this in his cases. The only exception was the finding of 10 lymphocytes per c.mm. in the C.S.F. in the case of glandular fever with radicular involvement.

Prognosis is difficult to determine in view of the varying times after the onset at which these cases have been examined. The prognosis in the serratus magnus palsies is on the whole poor: of the 21 cases in which this muscle has been involved 3 were partial from the beginning, and of these one had shown definite improvement after three months, while the other two were apparently stationary in the same period. Of the complete cases, 1 recovered completely in four months, while 5 had shown partial recovery in periods ranging from three to seven months; the remaining cases still had complete palsies when last examined at periods ranging from three to eighteen months after the onset.

Once marked atrophy has occurred in a muscle the prospect of recovery is poor; when localized atrophy is only slight, considerable and even complete recovery may occur, though the onset of recovery may be delayed for as long as six months and possibly more. In a few cases recovery has started within three to four weeks and has progressed rapidly.

Pathogenesis

There has as yet been no pathological material available from cases of this disorder; it appears, on clinical grounds, that the condition can affect single peripheral nerves, nerve roots, or combinations of these. Riddoch (1944) has suggested that the anterior horn cells may be involved in some cases, basing this view on the rapid muscular wasting which may be present and on the scattered nature of the muscular involvement which is occasionally seen. No exactly comparable condition seems to occur in the lower limbs.

The best name for the disorder is uncertain in the absence of a known aetiology or pathology. Acute brachial neuritis is already used for a different clinical syndrome, and the name applied by Spillane of "localized neuritis around the shoulder girdle" is hardly comprehensive enough. For these reasons the term "acute brachial radiculitis" has been applied to it for the time being till more is known about its aetiology.

The differential points from anterior poliomyelitis, to which it bears some clinical resemblance, have been admirably summarized by Spillane, the main ones being: the absence of signs of general disturbance in the acute stage; the normal C.S.F. when this has been examined early in the illness; the sensory impairment in a number of the cases; and the occurrence of these cases in the absence of typical cases of poliomyelitis in the same district at the same time. To these may be added the fact that it may occur at the age of 50—a most unusual happening with poliomyelitis.

The aetiology of the condition is still speculative, and the somewhat mixed group of apparently precipitating causes has not helped on this point. It has been suggested that a virus infection is the cause, the main point against this is the absence of fever or other signs of general infection and the normal C.S.F. findings. In most diseases due to neurotropic viruses—even in zoster, in which the main incidence of the infection is on the posterior root ganglia—an increase of cells is found in the C.S.F.

There is one condition which has a very close clinical resemblance to it, and that is serum neuritis (Kennedy, 1929; Young, 1932). This may occur after the injection of any form of serum, usually about the seventh to ninth day; there are frequently the usual symptoms of serum sickness, followed

within a day or two by severe pain in the region of the shoulder and upper arm; muscle weakness shows within the next few days, and when this happens the severe pain passes off. The paralysis which may be accompanied by sensory changes is most often in the distribution of the fifth and sixth roots or the circumflex nerve, but at times paralysis of the serratus magnus may arise. The exact cause of these cases is uncertain, but it is thought that oedema of the affected nerves occurs as a reaction to the foreign protein in the serum. I think that the possibility of some, as yet uncertain, aetiological relationship between serum neuritis and acute brachial radiculitis must be considered before assuming that neurotropic virus is the causative agent.

With the lack of knowledge of the aetiology, treatment can be only palliative—analgesics for the pain in the acute stage, support for paralysed muscles to prevent stretching, and active and passive exercises and electrical stimulation of the affected muscles when the painful stage has passed.

Summary

The syndrome of pain around the shoulder, followed in the course of a few days by muscular weakness and wasting and times sensory changes, is described.

The anatomical distribution of the weakness can be a single peripheral nerve, two or more spinal roots, or combinations of these.

A number of apparent precipitating factors are mentioned, the most outstanding being operation for hernia in 8 of the 36 cases.

The possible aetiology is discussed and an analogy drawn between this condition of acute brachial radiculitis and serum neuritis.

My thanks are due to Major-Gen. Mitchiner, C.B.E., for permission to publish this paper; to Brig. Riddoch for help in its production; and to Major P. S. Buckley, R.A.M.C., for the use of notes of cases under his care.

THE TRANSNASAL INTRAGASTRIC RYLE'S TUBE IN TROPICAL PRACTICE

A LIFE-SAVING MEASURE

BY

G. A. RANSOME
Lieut.-Col., I.A.M.C.

L. M. GUPTA
Capt., I.A.M.C.

AND

J. C. S. PATERSON
Capt., R.A.M.C.

Ryle's tubes have been used by us in a series of 355 acute medical cases during the past year. So far as can be ascertained, this represents the first extensive trial, in tropical practice, in which the method has been applied to the problems of hydration and alimentation presented by such acute cases. Its use was introduced, in the first place, to meet the special problem of the dehydrated patient who would not or could not drink that amount of fluid considered necessary for him. Dehydration, among coolies especially, was seen on a scale rarely encountered in civil practice, and in many cases was so gross as to resemble that of cholera. Marriott's (1943) teaching of the fatuity of what he calls "the homoeopathic dosage of a pint or two" is wasted unless we realize that in gross dehydration the fluid loss is to be measured in gallons. Furthermore, some of these patients refused to drink, and spat out the water or saline offered to them. In a series of 30 of our cases this symptom was found to be associated with a low serum chloride figure, and possibly represents a vicarious form of water intoxication. In the more robust patients this can be corrected by the intravenous injection of one or more pints of hypertonic (2 N) saline solution, after which the previously non-drinking dehydrated patient will drink avidly. Other patients, however, are often so enfeebled by disease on admission to hospital that for them to drink is too much effort. It is in such cases that the tube becomes a life-saving instrument, since by its use the body fluid may be restored in a few hours.

About five pints of normal saline solution can be given to these patients by slow intravenous drip in a 24 hour period, but this represents only a fraction of the fluid loss. To give more by the intravenous route, which has been tried, exposes the patient to the very grave risk of pulmonary oedema, particularly if there is any central circulatory weakness and if the serum proteins are low. On the other hand, a large quantity of fluid can safely be absorbed from the alimentary canal when administered through the Ryle's tube.

Appreciation of the advantage of this method after a short trial led to the extension of its use to include practically every type of case whose state of hydration was in any respect inadequate or in which fluids required to be forced. Such were the following cases: malaria and blackwater fever, cerebral malaria (over 100 cases), cerebrospinal meningitis (65 cases), enteric fever and typhus, pneumonia, psychoses, and coma due to other causes—e.g., head injuries.

Advantages of the Nasal Route

1 When *in situ* Ryle's intragastric tube is comfortable—indeed, not felt.

2 Food, fluids, and drugs may be given as necessary, independently of the patient's desires. Unpleasant-tasting drugs such as quinine and paraldehyde may be given without distress, and are retained.

3 In lung cases the respiration is not embarrassed.

4 Adequate fluid intake can be ensured, and its quantity accurately measured and recorded. The quantity given may be large and yet without the risk of producing pulmonary oedema. In gross dehydration the fluid required may be as much as 10 to 15 pints. In relation to this it is worthy of note that, although water absorbed from the alimentary canal is followed by a speedy diuresis, physiological saline does not have this effect. Further, saline absorbed from the alimentary canal is better retained and produces a less immediate diuresis than does saline given direct into the blood stream (Wright, 1940).

Technique of Passing the Tube

Cases may be divided into three groups: (1) those with a swallowing reflex even in the presence of coma, (2) those without a swallowing reflex—i.e., cases in deep coma, (3) refractory patients—e.g., maniacal and cerebral irritation cases. The first essential is to test the tube for patency and leaks by syringing a little water through it. Lubrication of the tube is all-important, and the best means is with liquid paraffin, although vaseline or olive oil may be used. With apprehensive or non-cooperative patients analgesia of the nose and soft palate may be induced by 5% percaine nasal spray, but this has not been necessary in military practice. It is desirable to sit up the patient and then proceed as follows:

Group 1—Pass the tube into the nostril, choosing the one which is the more patent, and gently push it backwards along the floor of the nasopharynx. The passage past the turbinates is assisted by tilting up the tip of the nose with the finger. Now pass 6 to 8 in. of the tube, when the patient will cough, wait until the inevitable retching occurs, followed by a swallow, which will draw the tube into the oesophagus; after this it may be rapidly pushed down to the third mark on the tube. Swallowing may be aided by instructions to the patient, by water to drink, or by placing something palatable on the tongue. There is no danger of getting the tube into the larynx if the act of swallowing is awaited before passing it onward.

Group 2—Prop up the patient and lean him forward. Put two fingers into the mouth and the posterior pharynx, using a mouth gag if necessary. Pass the tube through the nostril and into the pharynx as before, and use the fingers to guide it behind the epiglottis into the oesophagus. It is then pushed onward as before. A tube passed into the trachea speaks for itself. Prove that the tube is *in situ* by aspirating a little of the gastric contents.

Group 3—Refractory patients may be dealt with by either of two methods. One is to anaesthetize with an intravenous barbiturate (evipan sodium) just short of abolishing the swallowing reflex. If this is abolished, wait until it returns and then proceed as in Group 1. When the tube is in the stomach put in a dose of potassium bromide gr 40, chloral hydrate gr 20, with or without tinct. opii mm 20, or paraldehyde drs 2. The alternative method is to produce twilight sleep with intramuscular sodium luminal or subcutaneous scopolamine morphine before attempting to pass the tube. By employing these methods with judgment unseemly struggles are avoided.

With a little practice it is very easy to become really proficient at passing an intragastric Ryle's tube. Three or four successes make anyone confident. It is important to train as many as possible to do this. Our nursing officers and trained nursing *épouys* soon do it with ease.

Fixation of the Tube

Bring the free end alongside the nose and up to the forehead between the eyes and fix it with strapping. When not in use the free end should be tied or be closed with a clip. Some patients, especially psychotics, tend to pull out the tube at first. This may be overcome by splinting the arms to prevent flexion of the elbow and tying to the bed if necessary, and/or giving sedatives through the tube. Patients, however, soon become accustomed to it, and are scarcely aware of its presence. Recently a Chinese patient with a delightfully indolent attitude towards life became extremely annoyed when his tube was removed and he once more had to rouse himself for food and drink.

The period during which the tube is *in situ* is governed by the condition and progress of the patient. It varies between 12 hours and three or four days. One of our patients a psychotic had a tube in place for three weeks without ill effect or fouling of the tube. Fluids and feeds may be given either as a continuous drip, using a graduated flask and Murphy drip apparatus or by means of a funnel without drip connexion. The former method is preferable in cases of coma, since the rate of absorption proceeds *pari passu* with the rate of drip, and regurgitation is thus avoided.

Possible Drawbacks

In discussing this method with Brig H L. Marnott, Consulting Physician, India Command, and Col G F Taylor, Consulting Physician, Eastern Army, two possible objections to its use were raised—namely, the possibility of ulceration of the laryngopharynx, and the danger of bronchopneumonia arising from the aspiration of gastric contents regurgitated alongside the tube. Consequently in 19 cases treated by this method which ultimately came to necropsy these ill effects were sought, but were never found. In coma the method of dripping-in fluid minimizes the risk of regurgitation.

Serum proteins have been estimated in some 300 cases of varying type coming under our care, and in an alarming proportion of these low albumin figures have been observed, especially among coolie personnel. Care must be taken not to force the fluid to excess in these, as in a few instances a generalized anasarca has resulted. Constant reference to a "fluid intake-output chart," which we always keep in our wards, forms a valuable guide to the fluid balance.

Discussion

Although this method has been employed previously in surgical practice for continuous gastric drainage and in head injuries (McAlpine, 1944), and in medical practice for the continuous duodenal drip feeding in peptic ulceration and recently during the Bengal famine (Indian Research Fund Association, 1944), its value is by no means so well known as it deserves to be. Recent graduates from the medical schools of Bombay, Madras, Calcutta, Patna, and Lahore are unfamiliar with its application to acute medicine, and as these have been interns, we can only assume that either the method is not used in the teaching institutions of India or its use has been sporadic.

One of us with five years' postgraduate experience of acute medicine in teaching hospitals in London and four in Singapore, regards the full application of this method, forced on him by the exigencies of war, as a considerable advance in treatment, and, had he only been earlier aware of its full possibilities, believes that certain patients who died in the Medical College Hospital in Singapore would have been saved by its bold use. Particularly has it solved the problem of hydration in malarial coma, in which, owing to the reduction of serum albumin brought about by the disease itself, and frequently a pre-existing condition as well, the risk of pulmonary and secondary cerebral oedema following intravenous saline infusion is very real, as has been widely appreciated in the past (Thomas and Svidenstricker, 1940).

A most important lesson we have learnt is that no patient is too ill to have a tube passed. Even seemingly moribund dehydrated cases of pneumonia and meningococcal meningitis have been saved by this method. These patients were so ill that had one not had previous experience of the intragastric drip one would not have dared to pass a tube. Brinton (1941) draws attention to severe dehydration developing during cerebrospinal fever, and mentions the method of giving fluid by means of a nasal catheter, but does not convey to the reader that an intragastric tube is used, and states that an adult should take 2 to 3 pints of fluid every 24 hours. This demonstrates the difference in tropical practice, in which, in the same disease, a fluid intake limited to 3 pints a day would lead to disaster not only from dehydration but commonly in the form of sulphapyridine haematuria. We have in these cases used Ryle's tube with such complete success for the administration of large quantities of fluid, and also sulphapyridine, that to pass a tube in cerebrospinal fever is now our routine procedure.

It was with some trepidation that this method was first employed in acute pulmonary disease, but the need for fluid was so great that it was attempted, the intravenous route being out of the question and the rectal "not satisfyingly certain" (Bailey, 1939). It was not found appreciably to embarrass respiration—rather less so than do many forms of oxygen apparatus in common use. An especial advantage is that hydration proceeds during sleep.

The attitude of our nursing staff, drawn from all parts of the British Commonwealth, has been one of unqualified approval, since it saves much of their time spent in repeatedly requesting the patient to drink. The tube achieves what may only otherwise be done by special day and night sisters under nursing-home conditions.

It is realized that this practice is not as familiar as it should be, and we are certain that an extension of its use and emphasis on the quantity of fluid needed will be found to save the lives of many people whom one would ordinarily expect to die in a few hours.

Our thanks are due to Col. F. R. Cawthorn, I.A.M.C., for the facilities given to us in developing this technique and for permission to publish this article. We also wish to acknowledge the valuable and willing co-operation of many nursing and medical officers.

SUPRARENAL HAEMORRHAGE

REPORT OF A CASE

BY

C. J. WILLIAMS, M.B., Ch.B.

AND

RONALD ELLIS, M.D., M.R.C.P.

Asst. Physician, Royal Liverpool United Hospital

We report a case of suprarenal haemorrhage diagnosed by necropsy. The clinical data are best presented as day-to-day

Case History

Monday. Onset of malaise, slight sore throat, short dry cough, and one attack of vomiting.

Sunday. Main complaint now was of "feeling cold." The throat was still sore, but there was in addition a complaint of pain in the lumbar region. This pain was never severe, and was not referred to the region of the loins. The symptom she stressed especially was the persistent feeling of cold.

Monday.—She called in one of us, and was seen for the first time at 3 p.m. The story of the preceding days was elicited, and in addition she complained of frontal headache, and was found to be menstruating. The menstrual period was to time, but the loss was excessive. The symptoms of the previous day were still present, but were no worse. On examination temperature 100°; pulse 84, with fair volume, regular and apparently normal tension; fauces and pharynx injected, but no gross clinical tonsillitis and no exudate. There was no cervical adenopathy or coryza. The heart, lungs, and abdomen presented no abnormality. There were no signs of meningeal irritation, and no change in the optic fundi or drum heads. The skin did not show any rash and there was no sweating.

Tuesday.—During the early hours of the morning the patient complained of intense cold and a feeling of profound fatigue. She was seen by C. J. W. again at 6 p.m. The whole picture was now in marked contrast with that of the previous evening. The woman was restless and had an anxious look. She was intensely cyanosed especially in the face and lips, hands and forearms, feet, and leg up to the knees. The temperature was 96° and there was a profuse cold sweat. The pulse rate was 120, regular, but of poor volume respirations 30, with frequent sighings. Examination of lungs, heart and abdomen revealed nothing further. Central nervous system. Mentally clear and co-operative; cranial nerves normal, optic fund normal, pupils dilated but reacting normally; knee- and ankle-jerk absent; arm-jerks present but weak; plantar response flexor. The arms and legs could be moved only with difficulty. Light touch, pin-prick, heat, and cold were blunted over the extremities, but deep sensation was normal.

At 8 p.m. the same day the woman's condition was obviously worse. The cyanosis was deeper, and there was no pulse at the wrist; she was mentally apathetic but rational, and was still sweating profusely.

At 11 p.m. she was seen in consultation. The main findings were as above: the heart rate was now about 160 or over, and the clinical state was obviously deteriorating rapidly. At this stage a tentative diagnosis of suprarenal haemorrhage was made, and adrenaline, pituitrin, strophanthin, etc., were administered. No cortical extract was immediately available. The patient died three hours later, at 2 a.m. on the Wednesday morning, after an illness lasting about four days.

Post-mortem Examination.—The right adrenal was completely disrupted by haemorrhage, which had burst through the capsule of the gland. The left adrenal showed discrete haemorrhagic areas throughout its substance. The other organs were macroscopically normal. There was no haemorrhage into serous membranes or any splenic enlargement. The necropsy was performed under difficulties, but was reasonably complete.

Discussion

This case presented great diagnostic difficulties. As mentioned previously, it occurred at the height of an influenza epidemic, with fresh cases of influenza being seen hourly, and not unnaturally the diagnosis when first seen was influenza—a diagnosis which may have been correct. But the striking change for the worse which occurred between the first and second visits of C. J. W. obviously called for a further diagnosis. The clinical picture was one of profound circulatory collapse, the cause of which an examination failed to reveal.

The unusually heavy menstrual period suggested the possibility of an abortion, and the question of poisoning by some drug taken to procure abortion was discussed. Hospital investigation was out of the question; the patient lived in a lonely farmhouse, and the weather was so foggy that she could be visited only with the greatest difficulty. At the mid-night consultation it seemed that the only diagnosis which would account for the profound asthenia was acute suprarenal failure. This very tentative diagnosis was confirmed by the necropsy.

The literature of acute suprarenal haemorrhage has become quite extensive, though the number of recorded cases, so far as we have been able to discover, does not exceed about 60: owing to wartime difficulties our search of the literature has not been as complete as we would wish, and we are open to correction on this point. By far the greater number of recorded cases and discussions concern the now well-recognized Waterhouse-Friderichsen syndrome, due in the majority of cases to meningococcal septicaemia, the symptomatology being characterized by sudden onset, malaise, restlessness, often vomiting and diarrhoea, followed by cardiovascular collapse with intense cyanosis, often a striking purpuric eruption, and death within 24 hours. But deviations from the syndrome have been recorded by many writers, and

classifications have been attempted based on the presenting or dominating symptoms. Thus we have the well-recognized "peritoneal" type, simulating the acute abdomen, a "nervous" type, presenting with convulsions and delirium; and a third variety simulating a severe purpura. An "asthenic" type was described by Arnaud as early as 1900, but the original reference is not available, and we know of no case-description, except the one recorded above, which typifies this asthenic group of Arnaud.

Conclusion

The features of the above case which seem to deserve emphasis are: (1) The insidious onset, but ultimately rapid collapse due to apparently causeless circulatory failure. (2) The absence of abdominal pain, which if present would have been of real diagnostic help, and this despite the severe haemorrhage into the right suprarenal; the same applies to the absence of petechiae. (3) It has been suggested that the purpura, when it occurs, is merely a manifestation of severe septicaemia: our case would support this belief. (4) The diagnostic value of the intense cyanosis associated with cardiovascular collapse. The cyanosis is much more striking than in any ordinary variety of acute heart failure, such as that due to a coronary thrombosis. (5) Was the patient really suffering from influenza and, if so, was the influenza responsible for the suprarenal failure? At no time did the case suggest a septicaemic state.

Summary

A case of suprarenal haemorrhage of the so-called "asthenic" type is described. The diagnostic difficulties are discussed. It was possible to suspect the diagnosis during life as the only explanation of the profound cardiovascular collapse.

Medical Memoranda

Acute Appendicitis, treated with Penicillin

I would like to bring forward the following case record to show the dramatic effect of penicillin in what would otherwise have been a hopeless case of acute appendicitis, with perforation, gangrene, and general peritonitis.

CASE HISTORY

A male aged 4 years 11 months was admitted to this hospital on Aug. 16, 1944, at 2.20 p.m. The previous day he had been ill with vomiting, and when seen by his own doctor had shown all the classic signs of acute appendicitis. On admission he had a tender and rigid abdomen, with pain more pronounced in the right iliac fossa. The knees were drawn up, he was restless, and he looked very ill. Temperature 101.8°, pulse 136.

Operation was performed at 3.5 p.m. under open ether—right pararectal incision. The abdomen contained thin greenish foul-smelling fluid, with gas. The appendix was found to be retrocaecal, coiled up on the caecum, with the thickened omentum wrapped over it. The omentum was separated and a small gangrenous portion removed. The appendix was perforated about the middle, and was also gangrenous in this area. The neighbouring bowel was covered with soft greenish fibrin over a wide area. The appendix was removed, the R.F.F. well swabbed out, a drainage tube inserted, and the wound closed.

A specimen of the fluid in the abdomen was sent to the pathologist at St. John's Hospital, and he reported the presence of *Str. haemolyticus*, staphylococci, and a Gram negative diplococcus.

Immediately after operation 12 c.c.m. of nukehamide (coramine) and 1 c.c.m. of staphylococcus antitoxin were injected. Sodium sulphapyridine 3 c.c.m.—i.e., 1 g.—was injected 4-hourly, also transpulmin 1 c.c.m. b.d. The child's condition was very poor, temperature 99°, pulse 164, vomiting brown fluid, very restless, and delirious. 1 c.c.m. of camphor in oil was injected during the night. Next day his condition had not improved, temperature 97.8°, pulse 153, delirium, vomiting, and restlessness continued; sedatives had no effect.

At 6.15 on this day treatment with penicillin was begun, and the sulphapyridine was stopped. The method of administration was to run in 15,000 units, in a strength of 2,500 units per c.c.m., through a catheter and pass it into the abdomen through the drainage-tube. The catheter was clipped to keep the penicillin within the abdomen. This procedure was repeated every three hours, but before each fresh injection the fluid in the abdomen was withdrawn through the catheter by means of a syringe. Pathological tests were taken of each syringeful of fluid so withdrawn. This treatment was carried out as stated every three hours for the next 48 hours, making 14 injections in all and employing 200,000 units of penicillin.

The child made little progress for the first 24 hours, but was quieter, with temperature 98.4° and pulse 136, and the report on the abdominal fluid showed that the growth of streptococci was

inhibited, while the Gram negative bacilli were still present, and were mostly coliforms.

After the first 24 hours the child began to make a striking recovery. The restlessness, vomiting, and delirium ceased, the temperature was 98.4° and pulse 132. He began to take fluids, and he had a good bowel action. On the third and fourth days after the operation penicillin was employed twice daily, morning and evening, in the form of an irrigation of the abdomen, with 20,000 units in the same strength as before, but it was not now retained in the abdomen, the catheter was not clipped, and a smaller drainage tube was inserted. A pathological report showed no growth of streptococci.

At the end of the fourth day the drainage tube was removed, there was no discharge, the wound was clean and healthy, and the child was quite well, taking food by mouth and sleeping normally. His subsequent progress has been uneventful.

COMMENT

The above case shows that the abdominal cavity can be sterilized by repeated aspirations of exudate and replacement with penicillin and that the toxic condition is thereby relieved. Penicillin eliminated the infection so that the patient's resistance was raised and his general condition improved; this contrasted strikingly with his previous very toxic state, in which subnormal temperature, rapid pulse, vomiting, and delirium were all present, indicating a very poor prognosis.

A total of 200,000 units of penicillin was left in the abdominal cavity in the first 48 hours, and in the subsequent 48 hours 80,000 units were used for irrigation.

I wish to record my great thanks to the American Ambulance Unit of Great Britain who so kindly and promptly sent a supply of penicillin in one of their cars. They must be proud to know that they have saved the life of this child. I would also like to thank the pathologist for his interest and co-operation in carrying out the pathological investigations and the medical superintendent—Mr. G. Richardson—for helping me to write this report. I am very grateful that I have had this opportunity of treatment with penicillin for I can now spread the light of this experience in my own country when I return there after the war.

MARIE KALISOVA, M.D. BRNO.

South Eastern Hospital for Children

Agranulocytosis after Use of Thiouracil

The following case is indicative of a complication of thiouracil therapy which seems to occur with rather variable quantities of the drug. In view of the early stage in experience of the complication this record may merit publication.

CASE HISTORY

The patient was a married woman aged 61. In 1907, at the age of 24, she developed a localized enlargement of the left lobe of the thyroid gland with marked toxic symptoms. She underwent an operation for the removal of the left lobe. There were no further symptoms and she remained entirely fit until three years ago, when mild thyrotoxicosis recurred—sweating, nervousness, and slight tremor being the only symptoms. Owing to an exacerbation of symptoms, and a severe tachycardia having supervened, she was admitted to another hospital in Jan., 1944, for thiouracil therapy.

She was given five 0.2 g. tablets daily for one month, and by the end of that time had lost all her toxic symptoms and felt well. She was kept on a maintenance dose of one 0.2 g. tablet a day, and returned home three weeks later still taking this dose. At the end of March after about 10 weeks' treatment, she was told to have a white cell count done as an out-patient. She omitted to do this, and still continued to take 0.2 g. of thiouracil daily.

At the beginning of May, after three months and one week's treatment, she had an acute febrile attack with some ulceration of the mouth and sore throat, which were untreated but cleared up entirely within six days. On May 27, having had exactly four months of continuous thiouracil, she had an identical though very much more severe febrile attack, and was admitted on June 3, in an acutely ill state, to St. Bartholomew's Hospital at Hill End.

On admission the following positive findings were recorded: T 103°, P 108, R 24. Restless, skin hot and dry. There was much conjunctivitis of the left eye, with cellulitis spreading in the infra-orbital tissue. There was severe inflammation of the tonsils and fauces, the tonsils almost met in the midline, and spots of purulent exudate covered much of the oral and pharyngeal mucosa. The neck glands were bilaterally enlarged and tender. The thyroid was enlarged by an adenoma of the right lower pole about 3/4 in. in diameter. There were no eye signs and only slight tremor. Several petechiae were present over the chest and arms. The lungs and heart were normal. The spleen was enlarged to one inch below the costal margin, it was slightly tender. The urine had a trace of albumin, but was normal to other ward tests, it was acid, with a sp. gr. of 1.010.

The day before admission a white cell count of 1,200 had been recorded, it was mainly lymphocytic, with an occasional degenerate polymorph. 10 c.c.m. of pentnucleotide had been given. Shortly after admission a further 10 c.c.m. of pentnucleotide was given intramuscularly and a pint of blood, warm from the donor, was rapidly transfused, 500 mg. of ascorbic acid was also given intravenously, and oral glucose and copious fluid were encouraged.

On June 4 the general condition seemed slightly improved; the left eye was frankly purulent. Large doses of ascorbic acid, 500 mg.

598 Nov. 4, 1944

MEDICAL MEMORANDA

BRITISH
MEDICAL JOURNAL

i.d.s., and 150 mg. of hesperidin were continued. A second pint of perfectly fresh blood was again rapidly transfused. The white cells at this stage numbered 1,500; a sternal marrow film showed marked hypoplasia with arrest of the granulocytic elements at the myelocyte stage.

On the third day, June 5, the pentnucleotide was increased to 20 c.cm. twice daily. The white cells had risen to 1,860, 149 of which were neutrophils. The fourth day saw the advent of moist sounds in the chest with some cough, but the patient herself felt much improved. A third pint of fresh blood was given. On the sixth day, June 8, there was less swelling of the neck glands, but still some rales at both bases, and the spleen had increased in size to 2 in. below the costal margin. The white cell count was then 6,700, of which 4,320 were neutrophils. A catheter specimen of urine was entirely normal microscopically and sterile. A fourth pint of fresh blood was again given. The 40 c.cm. of pentnucleotide was being maintained, though the injections gave pain and a feeling of severe malaise and anxiety of temporary nature; it was discontinued the next day, a total of 220 c.cm. having been given in seven days.

On June 13, the eleventh day, the chart was normal, the eye had almost entirely healed, and the throat was rapidly healing. The lungs were clear and the patient felt quite well. The white cells numbered 10,700. On the twenty-first day after admission the white cell count was 16,000; the spleen was easily palpable at over 2 in. below the costal margin.

Convalescence proceeded apace, and, though there was no further soreness of the throat, some considerable tonsillar enlargement remained. The patient was discharged feeling extremely well on July 12, 39 days after admission, the white cells on the last day totalling 8,100—neutrophils 65%, lymphocytes 29%, eosinophils 2%, basophils 1%, monocytes 3%.

This case had continuous thiouracil therapy for four months, with a dosage of 1 g. daily for one month and 0.2 g. daily subsequently. The neutropenia developed after three months and one week from the beginning of treatment, when the patient had taken a total of approximately 44 g. The total intake up to the second occurrence of symptoms was approximately 48 g.

Recovery was rapid after the cessation of thiouracil, and was probably due chiefly to this, although transfusion of fresh blood was no doubt of great benefit in maintaining a barrier to further spread of infection while the bone-marrow recovered its function.

I wish to express my thanks to Dr. Geoffrey Bourne for permission to publish this record for his encouragement.

DUNCAN LINSELL, M.B., B.S.

An Unusual Case of Acute Pancreatitis

The following case is considered worth reporting because of the unusual features it presented.

CASE RECORD

A healthy, well-built, and well-nourished Indian soldier, aged 27, complained of a sudden and acute onset of pain in the abdomen on the night of March 22, 1944, about four hours after his evening meal. There was a rapidly progressive collapse, and he expired before the unit M.O., who was sent for, could arrive—a matter of about 20 minutes. Death was judged to be due to heart failure, but the body was sent to the field laboratory for necropsy. There was no suspicion of foul play or poisoning, and previous to this attack he was known to be a perfectly healthy man, not addicted to any drug or alcohol and with no history of any gastro-intestinal trouble.

At the necropsy, performed a few hours after death, the paracolic gutters contained about 4 oz. of sour-smelling haemorrhagic fluid, and the lesser sac showed small scattered areas of haemorrhage. The omental fat was stained red, but did not present any areas of necrosis. The pancreas was much enlarged—length 26 cm., weight 145 g.—and the whole of it was a dark purplish black; it was very friable and adherent at places. A search for biliary and pancreatic calculi yielded negative results. The solar sympathetic plexus and the suprarenals were swollen, red, and congested. The brain had few pin-point haemorrhages scattered throughout the cortex andulla. The rest of the necropsy, which was a complete one, called nothing abnormal. Heart-blood culture and Kahn test were negative. Histological examination, carried out at the Central Pathological Laboratory, M.F., showed the pancreas riddled with foci of acute necrosis. The immediate cause of death seems to have been a sudden and severe shock to the sympathetic system and the suprarenals.

COMMENT

The unusual features in this case were: (i) Extremely rapid fatal termination—in fact, within 20 minutes of the onset of the first attack in a previously healthy man: usually the time taken is hours or days. (ii) Absence of calculi or inspissated bile usually the commonest cause. (iii) Absence of septicaemia, the next commonest cause—though in the lack of any other evidence this must be assumed to have been responsible, the negative blood culture notwithstanding. (iv) Absence of the diagnostic foci of fat necrosis, probably due to the very short duration of the illness.

M. HATANGDI, M.B., B.S., D.T.M.
Capt. I.M.C.

Reviews

FOLLOWING UP THE HOSPITAL PATIENT

Medical Care of the Discharged Hospital Patient. By F. Jensen, M.D., H. G. Weskotten, M.D., and M. A. Thomas, M.A. (Pp. 94; \$1.00 or 6s.) New York: The Commonwealth Fund; London: Oxford University Press, 1944.

This is an American experiment from the University Hospital of Syracuse. It should be remembered that the American hospital system is different from the British and that a number of the poorer in-patients have no family doctor who can carry on the treatment begun in hospital. It is reckoned that a considerable State economy is effected by this experiment, since the chronic case is not allowed to slip back and his subsequent period of stay in hospital is materially shortened.

An extramural medical resident was appointed with requisite nursing and social worker auxiliaries, and his duties were to follow up all cases discharged from hospital. In addition to the economic saving effected and the obvious benefit to the patient from a proper continuity of medical treatment, the teaching of the students was much enhanced by the chance afforded of following into their own homes the patients they had studied in hospital. Of all patients admitted to the medical wards of the hospital 84.1% were suffering from chronic disease, and about one-third of these had chronic degenerative cardiovascular disease. The resident extramural medical officer worked in close conjunction with the patient's private doctor when such existed. It was found that only 59.3% discharged to such a practitioner ever reported to him, and only 23.2% of those discharged to the free dispensary ever got there until the follow-up was instituted.

It is obvious that such a service is very necessary when there is poor liaison between the hospital and the practitioners of the district who use the hospital, or where the hospital is not acting in a consultative capacity so that the patient short-circuits his own doctor; but if all "played the game according to the rules" such a service should not be needed except perhaps from the statistical scientific standpoint of a personal follow-up of the results of hospital treatment. Even this, however, should not be necessary in a well-regulated and closely knit medical service.

ARTIFICIAL PNEUMOTHORAX

Artificial Pneumothorax in Pulmonary Tuberculosis. By T. G. Heaton, M.B. With an Introduction by Dr. C. D. Parfitt. (Pp. 217.) Canada: The Macmillan Company of Canada, Ltd.

In the first part of this book the author sets out the history of pneumothorax treatment, and follows this with a study of intrathoracic dynamics, the pathology and physiology of the collapsed lung, and, finally, the complications of artificial pneumothorax therapy. The information contained in these chapters is most useful, and they will be of interest to all who are engaged in treating pulmonary tuberculosis. The author has spent much time in searching the literature, and has collected valuable statistics on such subjects as the incidence of complications and the results of treatment. It is a pity, however, that most of the references quoted are at least ten years old.

The second part of the book, dealing with the indications for treatment and the technique and management of artificial pneumothorax, does not attain the same standard as the early chapters. The subject is controversial, and it would be difficult to please everyone, but this book does not give enough detailed instruction to help a novice faced with the practical problems which constantly occur in pneumothorax treatment. For instance, the management of effusions and empyema is dismissed in three short paragraphs, and it is doubtful whether the author's enthusiasm for oleothorax will be shared in this country. He also fails to point some of the morals which may be drawn from the collected statistics, so well presented in the earlier chapters: the clear demonstration that persistent adhesions carry a bad prognosis, and that such adhesions are present in more than 40% of cases, does not tally with the subsequent statement that not more than 3% of patients with pneumothorax will require adhesion section.

Of the more modern methods of treatment extrapleural pneumothorax gets only the briefest mention while pneumoperitonum is described merely as a rare complication of pneumothorax. In conclusion, it is impossible not to comment on the statement that "it is possible to manage a pneumothorax fairly well without x-ray control" surely this is putting the clock back twenty years at least?

ORGANIC CHEMISTRY

Principles of Organic Chemistry By SYLVANUS J. SMITH M.A. (Pp 569 15s) London: Macmillan and Co 1944

This new book on organic chemistry gives an introduction to the subject in an acceptable form. It is intended for the student who requires a manual that will serve him adequately during his three years' academic course. In this aim the author has fulfilled every reasonable expectation. Using a method which is the result of a gifted teacher's study he conveys the greatest measure of information in the smallest compass without incurring the risk of oversight on the part of the reader and without the ambiguity that may attend a paucity of words.

Chemical reactions and reactivities form the foundation of organic chemistry, and the book quite properly gives to these the chief prominence. The description of physical and other properties of substances, with remarks on their economic or industrial importance and other general information, is aptly included in the general text. A particular feature of value consists in the copious references to other pages on which is to be found supplementary information relating to the matter under consideration. Very helpful too is the revision exercise appended to every chapter. The revision exercise includes questions and problems the solutions to which are provided at the end of the book. The scheme of nomenclature applied to organic compounds is also fully explained, and the more recent development of theory connecting chemical properties with electronic arrangement is adequately treated. The book is a very serviceable students' manual and is also good as a general work of reference.

Notes on Books

Dr. J. S. Surgical Handcraft, a favourite with house surgeons and junior practitioners for 60 years, has reached its 14th edition. Mr. HAMILTON BAILEY is responsible for the book, as he has been since he succeeded the late H. W. Carson as editor in 1938. There are many new pictures, and Mr. Bailey and his team of 45 collaborators have earned the gratitude of a new generation of readers for keeping this manual not only alive but in very good form. The publishers are still John Wright and Sons, Ltd., and the price is 25s.

The Board of Registration of Medical Auxiliaries has published the first *Register of Dietitians*, which contains the names of some 140 members of the British Dietetic Association. Dietetics is defined herein as the interpretation and application of the scientific principles of nutrition in health and disease. Registered dietitians, however, have agreed in cases of disease not to undertake the dietetic treatment of any condition except under the direction and control of a registered medical practitioner. The names are arranged in geographical order and then regrouped in an alphabetical list, followed by a special list of hospitals, etc., employing dietitians. Copies of the *Register* can be had free on application to the Secretary, Board of Registration of Medical Auxiliaries, B.M.A. House, Tavistock Square, London, W.C.1.

Nearly a dozen years ago Dr. JOSEPH GARLAND of Boston wrote a charming and instructive book on *The Youngest of the Family*, which he has now revised (Oxford University Press, 11s. 6d.). It is a sound guide to be put in the hands of a mother or expectant mother, and medical practitioners could also read it with benefit, or it is full of facts, attractively presented and linked by common sense. At a time when "popular" books on babies seem to be the fashion this volume of Dr. Garland's could well serve as a model.

The National Association for the Prevention of Tuberculosis has issued four new leaflets which in form and material are a departure from what has been done in this way before. The titles are *Learning to Live*, a word of encouragement for the tuberculous patient, *Good Luck*, a practical guide for the ex-sanatorium patient, *Child-*

hood Tuberculosis a word for the health visitor, and *Dust Diseases Their Cause and Care* giving the essential facts for all connected with the dust-producing industries. Specimen copies of these leaflets can be had free, from the N.A.P.T., Tavistock House North, Tavistock Square W.C.1.

Preparations and Appliances

ILLUMINATED RETRACTOR FOR PENETRATING MISSILE WOUNDS OF THE BRAIN

Captain F. J. GILLINGHAM, M.B., B.S., R.A.M.C., writes from a neuro-surgical unit in Italy.

The problem of careful and complete debridement of penetrating missile wounds of the brain is that of visualizing all dead tissue and indurated foreign matter within the track. If inadequate surgery is carried out, resulting in incomplete removal of bone fragments and of necrotic brain tissue, the nidus for early or late abscess formation remains.

The present methods of debridement—removal of bone fragments with forceps, irrigation, partial visualization by means of suction and good spot-lighting—may tend to leave one only too often in doubt as to the complete success of the operation. Missile tracks occur at many angles and defeat the best of lighting (spot-lights, and cumbersome headlights or mirrors). To meet this problem a malleable illuminated brain retractor was improvised and later perfected. It had to be of such small dimensions that even small wounds could be explored easily under direct vision, and without further destroying valuable brain tissue. Simple construction, reliability and facility in use, and ease of sterilization were the essentials. The diagram illustrates the retractor that is being used with considerable satisfaction and success.

By means of thin rubber bands it can be changed quickly from a smaller to a larger retractor, as is required. A small rubber catheter (size 4) is often attached with the light to provide suction as well as lighting. This removes any blood or fluid debris, visibility is increased, and a hand is freed which can be usefully employed removing bone fragments etc. The instrument is easily sterilized in antiseptic fluid or by boiling, and can be cleaned without difficulty.

A number of cases have been dealt with by this method, and results are gratifying. In a series of 30 consecutive brain wounds operated on in the forward area post-operative check x-rays revealed no remaining bone fragments in 29 cases, and in two cases deep seated metal foreign bodies which previously would probably have been left were removed without difficulty.

Straightforward penetrating brain wounds can be sucked quite clean of all debris often to their complete depth, unless across the midline. Bone fragments are easy to find once the necrotic brain and blood clot are sucked away. They are seen as white broken bone fragments, tiny and large and often covered in part by necrotic brain or a few hairs. Gradually the normal brain forming the walls and depth of the track is seen, and all tags of dead brain sucked away until at last the track is seen to be quite clean. It is practically never necessary to enlarge the dural opening.

Abscesses presenting on the surface can be evacuated completely and explored to their depths. The collapsed lobulated walls fall together and prevent the insertion of a tube to the bottom but direct vision makes this a simple procedure. Orbital wounds involving the globe and the temporal or frontal lobes of the brain are often subjected to inadequate debridement owing to the difficulties of exposure but a track in the temporal lobe explored through the orbit was thoroughly cleared of its necrotic brain and indurated bone, and metal foreign body without difficulty. Ventricular wounds with metal foreign bodies in the walls of the ventricle can be cleaned out and the foreign bodies removed.

It is early yet to say whether there will be any diminution in the abscess rate in this series.

I owe my gratitude to R.E.M.E. in this theatre of war, and particularly to Lieut. Ward, R.A.S.C., for their enthusiasm and help in constructing the instrument. I am also indebted to Brig. Hugh Cairns, Consultant Neurosurgeon, for his encouragement and advice.

FUTURE OF ROYAL SOCIETY OF MEDICINE

Appeal for Building Fund

The house of the Royal Society of Medicine at the south-east corner of Wimpole Street was considered palatial when it was opened by King George V in 1912. The Society since those days has trebled its membership and multiplied its services, and the number of its sections has risen to twenty-four. At many meetings, even during the wartime dispersion, its larger hall has been crowded out, and other rooms fully taxed. The larger of the two meeting rooms holds only 350.

A recent special meeting of Fellows unanimously decided to open a building fund of £50,000 for the enlargement and re-equipment of the house to meet present and future requirements. The recommended alterations will provide a new top floor to contain a large room fully equipped for the examination of clinical cases. A third meeting room is also proposed, as well as new common-room and committee-room accommodation. These developments, of course, will not be possible until there is a large release of labour, but it is hoped that the fund may reach workable proportions even before reconstruction is begun.

The Society now serves its membership in ways not dreamed of thirty years ago, when its *Proceedings* was the only means of contact with those of its members who did not live in the Harley Street neighbourhood. It has been quick to take advantage of the photostat, the microfilm, and the precision enlarger, so that instead of the student having to visit the library, the material he is in need of goes to him. The microfilm, which has proved of immense value in the recording of documents, has been taken up by the Society, and eleven "film readers" have been lent to the medical branches of H.M. Forces over-seas and two to the American medical Forces, so that medical officers on any of the war fronts have an opportunity of keeping abreast of medical literature. The microfilm is more convenient than the photostat, but the photostat is most useful where there is no access to a "film reader," and this is to be augmented by a special camera which will serve for making book records.

Another development in which the Society has taken part, in co-operation with the Scientific Film Association and other bodies, is the establishment of a library of medical films.

MEDICAL SERVICE CONDITIONS IN TRINIDAD

The Legislative Council of Trinidad and Tobago has passed a resolution for the appointment of a committee to review the medical and health policy of the colony and to consider the reorganization of the health services. Mr. Gerald Wight, member for Port of Spain, in proposing the resolution, traced the past history of medical services and outlined the causes of present dissatisfaction. In his view no satisfactory service could emerge so long as the administration was on a purely Civil Service pattern, which in medical affairs meant an undesirable dictatorship. In Trinidad, he said, the authority in medical and health matters was concentrated in the Colonial Secretary, and below him in the Director of Medical Services. Out of 47 recommendations made by a Medical Reorganization Committee in 1934, only 22 had been completely implemented. An advisory council to the Surgeon-General was proposed and was actually set up in 1935, only to be abolished in the following year. Effect had not been given to recommendations for the enlargement of hospitals and the establishment of out-patient departments and for the making of staff appointments. Proposals for the establishment of blood transfusion centres, for the treatment of paying patients at general hospitals by private practitioners, for the appointment of part-time practitioners to carry out all forms of district work, and for the restaffing of district hospitals had not been carried out. Dissatisfaction in the service was such that there had been a number of resignations of medical and nursing staff. Mr. Wight also commented that Government policy concerning health insurance was ill-considered and ill conceived, as was illustrated by the appointment of an insurance committee without a single general practitioner among its members. Nothing had been done to implement the recommendations of the Royal Commission for better facilities for medical treatment in rural areas. Another member said that the district hospitals were small useless buildings, that there were no hospitals for infectious diseases, that patients with pneumonia had to be treated at home, and cases of diphtheria and poliomyelitis were treated in the ordinary wards of hospitals. The staff at the two general hospitals, San Fernando and Port of Spain, were said to be overworked. A reply was made by Mr. dos Santos, Acting Colonial Secretary, who pointed out that the expenditure on medical services had increased from 733,000 dollars in 1934 to over two million dollars in the present year's provision. He pleaded that owing to the war it had been difficult to obtain hospital personnel and equipment. Plans for a sanatorium were under consideration. Arrangements for clinics had been reviewed year after year and

readjusted to meet the needs of the population. Trinidad and Jamaica had the highest salary scales for medical officers in the West Indies, but the smaller colonies could not afford to pay the same scales, and there must be a levelling of salaries in any unified service. Another supporter of the administration pointed out that the death rate in Trinidad, which was 27.5 at the beginning of the century, had fallen to 17.5 by 1932, though since then it had remained stationary. It was announced on behalf of the Government that while it accepted the resolution the committee could not be appointed until a qualified person from abroad was available to act as its chairman.

MEDICAL LICENCES IN THE 16th AND 17th CENTURIES

In these days of Governmental proposals to regiment the doctors for the benefit of the State, it is interesting to learn in John H. Raach's "English Medical Licensing in the Early Seventeenth Century" that in 1421 the profession itself petitioned for some measure of State control and definition of its duties. The lack of a corporate spirit in medicine in the Middle Ages, as compared with the elaborate organization of the crafts with their guilds, and the stable edifices of the Church and the Law, made some such step sooner or later inevitable. The petition, which is here for the first time published, had but little effect, and in the early years of the reign of Henry VIII the State took the initiative and passed two effective statutes. The first of these (1511) placed the regulation of the profession, both in London and throughout the country, in the hands of the bishops, while the second (1522) was concerned with London and the surrounding districts. The article is concerned mainly with the first of these statutes.

The power of the Church in medical licensing (and it retained this authority, in theory at least, until the creation of the General Medical Council in 1858) may seem anomalous, but the author goes to some pains to justify the choice of the bishops, and makes a good case for their stewardship. In an attempt to rid the country of quacks the Tudor Government, as was its wont, made use of an established institution; and its choice of the Church for this work was by no means unhappy. The two universities retained their licensing powers and although the soon-to-be-incorporated College of Physicians quickly obtained a monopoly of licensing in London, its attempt to replace the bishops as a licensing body in the country never became effective. The Church was, in practice, by far the most important licensing authority, and two-thirds of the licensed doctors in the early seventeenth century received their licences at its hands. The bishops were advised by a committee of "expert persons," usually local physicians, who could, after examination, testify to the candidate's ability. Stress was laid by the examiners upon knowledge rather than qualifications and licensees with medical degrees seem to have been in the minority. The area in which the ecclesiastical licence was valid was circumscribed and may have depended upon the fee paid, whereas a university licence cost more and permitted practice anywhere in England.

This informative and well-documented study reveals the early consciousness of the Government of some responsibility for the public health and its attempt to legislate for it in the statute of 1511, which resulted on the whole in an efficient system of medical supervision in England. Medical licensing occupies a small but important niche in English social history, and well deserves this careful elucidation of its early evolution.

J. Biol. Med., 1944, 16, 267.

H. Derron and E. W. Le Hew (*Amer. J. med. Sci.*, 1944, 208, 240) record an epidemic of 129 cases of mumps in a small Tank force. The total days lost by hospitalization were 2,657, which, though a large figure, agrees with previous experience with mumps in the army. There was an evident correlation between inclement weather and crowded living conditions and the incidence of mumps. Thirty-five per cent. developed orchitis. Leukopenia with relative lymphocytosis was present in most cases. Sulphathiazole was given to eight patients without affecting the course of the disease.

New Potency Liver Extract

1 cc. now standard dose

The new 'Examen' in 1 cc. ampoules, which now replaces the old (in 2 cc. ampoules), offers the antianaemic factor of liver in the highest degree of concentration and purity yet achieved on a manufacturing scale.

The greatly increased retention in the new 'Examen' of the antianaemic activity of liver is such that an injection of 1 cc., in place of the former 3-4 cc., produces erythrocyte and reticulocyte responses which satisfy the most exacting of published criteria^{1 2}

The 1 cc. injection, at the same cost as the original 2 cc., and with the considerably increased potency, makes the treatment of pernicious anaemia still easier and less expensive for the patient

PETHIDINE HYDROCHLORIDE

— BOOTS —

ANALGESIC AND ANTISPASMODIC

Pethidine Hydrochloride is a new synthetic compound of proved value as an analgesic in neurological conditions and for the relief of pain associated with spasm. Recent clinical results show that it is a useful obstetric analgesic when administered orally during the early stages of labour or by injection either alone or with scopolamine during labour.

DIPHENAN B.D.H.

A Highly Active Non-toxic Oxyuricide

Diphenan is the most active anthelmintic against threadworms so far introduced. It quickly eliminates the parasites, and, provided adequate precautions are taken against re-infestation from the ingestion of eggs towards the end of a course, treatment is effective.

Diphenan B.D.H. is an exceptionally pure product, and, despite its great activity, it is virtually non-toxic.

Treatment with Diphenan B.D.H. is characterised by the following advantages :—

- 1 The drug employed is colourless and practically tasteless.
- 2 No nausea, vomiting or visual disturbances are to be anticipated.
- 3 Treatment is of relatively short duration.

ALUMINIUM DUST FOR SILICOSIS

Assuming that silica exerts its injurious effect upon animal tissue through a slow transformation into silicic acid, Denny, Robson, and Irwin^{1,2,3} thought that if the solubility of siliceous material retained in the lungs could be sufficiently reduced the usual fibrotic response could be diminished or prevented. They discovered that aluminium powder rendered siliceous material insoluble *in vitro* by coating the silica particle with a thin film of gelatinous hydrated alumina, which on drying formed crystalline alpha aluminium monohydrate. The presence of this adsorbed layer on the surface of the quartz was shown by staining it with aurin. That metallic aluminium dust produced no fibrosis in the lungs was demonstrated by dust-inhalation experiments on eight rabbits. Attempts were therefore made to prevent silicosis by mixing quartz with metallic aluminium dust. Animals exposed to quartz dust developed typical silicosis in about 5 months, but the addition of 1% aluminium powder prevented this even after exposure had been lengthened up to 22 months provided the aluminium powder was of a particle size below $5\ \mu$. This year Crombie, Blaisdell, and MacPherson⁴ have reported the treatment of 34 silicotic miners by the daily inhalation of fine aluminium powder freshly ground from small aluminium pellets in a specially constructed mill. Daily treatment began with five-minute inhalations, which were gradually increased to 30 minutes. Some of the men received 300 treatments, but the majority only 200. Out of the 34 cases thus treated clinical improvement in 19 was manifested by lessening or disappearance of shortness of breath, of cough, of pain in the chest, and of fatigue. In 15 cases the condition became stationary and remained so in spite of continuous employment in silica dust throughout the treatment. The progress of the disease was assessed by means of tests for respiratory function repeated at three-monthly intervals. Obviously this treatment cannot be regarded as a cure for silicosis, since it cannot restore lung tissue which has undergone fibrotic change; but Crombie and his colleagues believe that the inhalation of finely particulate aluminium powder offers every prospect of preventing the development of human silicosis.

In view of these findings it is surprising that repeated papers by Goralewski^{5,6,7,8,9} from Germany describe

various types of lung disease attributed to aluminium dust and press for them to be scheduled under the Workmen's Compensation Act in that country. Seven hundred workers were investigated. They were making, probably by a stamping process, aluminium powder containing about 4 milliards of particles of dust per grain, and are reported as complaining of dry cough with pain on breathing, shortness of breath, poor appetite, and gnawing abdominal pain. Spontaneous pneumothorax developed in four workers. No abnormal physical signs are described. Blood counts showed a relative lymphocytosis with an eosinophilia up to 10%. The sedimentation rate was within normal limits in 78% of the cases, but the vital capacity was decreased in 27 instances. Radiographs showed focal shadows in the apical region with an increase of normal bronchial markings in the upper and middle thirds of the lung, giving a reticular appearance which at a later stage tended to increase and become confluent. The development of the illness was rapid and appeared to bear no relation to the length of exposure to aluminium. Histological examination of the lung of one patient who died revealed coarse, branching, hyaline, collagenous fibres, which enclosed phagocytes containing fine and coarsely granular particles distinguished by their jagged outline from carbon particles. Jäger and Jäger¹⁰ suggested that, while aluminium powder is highly resistant to aerial oxidation, it is freely soluble in sodium chloride solution, giving sodium aluminate and aluminium chloride in equilibrium. A colloidal aluminium hydroxide complex results if the sodium and chloride ions are allowed to diffuse away, and if protein is also present it is co-precipitated round the partly dissolved aluminium particles. Jäger and Jäger think it is this complex which causes the lung changes. Koelsch,¹¹ however, believes that mechanical factors were responsible and that the disease is a consequence of the unsatisfactory ventilation of workrooms resulting from the black-out.

Aluminium powder is used in incendiary mixtures and in paints and inks. It can be made by two processes: either it can be blown, when the particles will be covered with a thin film of alumina; or it can be stamped, when they are covered with a thin film of stearine. Crombie, Blaisdell, and MacPherson⁴ investigated 125 workers employed in the Pittsburgh stamp mills of the Aluminium Company of America. The workers here had been exposed to aluminium dust for periods ranging from 6 to 23 years; their health was found to be better than that of the 3,000 other workers employed in the plant. X-ray films of the chests of all the men taken each year for three years showed no abnormalities which could be attributed to the inhalation of dust. In the current number of the *British Journal of Industrial Medicine* Donald Hunter and his colleagues¹² report an investigation into the effect of aluminium and alumina on the lungs of grinders of duralumin aeroplane propellers. The workers were exposed to a mixture of aluminium dust arising from the propeller and alumina from the alundum grinding wheels. The average concentration of aluminium dust close to the operator's mouth was found to be 3 mg. per cubic metre of air, of which the

particle size in 1 mg. was between 2 and 7 μ , the remaining 2 mg. consisting of larger particles. The alumina particles were mostly of less than 1 μ diameter. The health of these workers, as shown by the number of sicknesses during the preceding year, was better than that of those in a machine shop belonging to the same company. None gave any history of spontaneous pneumothorax, and no abnormality was found in their blood counts. Radiographs of 92 workers showed no evidence of lung disease which could be attributed to aluminium. Observations at factories where aluminium powder is made by the blowing process do not suggest that workers there suffer from a high incidence of pulmonary disease. The recent findings in Germany therefore remain a mystery; but reliable investigations in this country and in Canada and the U.S.A. now show that aluminium dust has no injurious effect on the lungs.

HOMOLOGOUS SERUM JAUNDICE

Jaundice is one of the few diseases which have shown an increased incidence during the present war. Epidemics of what used to be called "catarrhal jaundice," but which from recent pathological work is more correctly termed "infective hepatitis," have been common in both civil and Service communities. Among the former the epidemiological pattern has for the most part been that of a droplet-spread infection with a three to five weeks' incubation period,¹ but in the Services² the disease has displayed some unusual epidemiological features. Besides this epidemic infective hepatitis, jaundice has occurred as a sequel to injection of pooled human serum such as is used in yellow fever vaccine or for protection against measles and mumps or in transfusion.³ The rarity of jaundice after transfusions of whole blood or even pooled plasma and serum may be related to the so-called "dilution phenomenon," whereby neutral mixtures of virus and immune serum become reactivated when diluted.⁴ Thus a hypothetical icterogenic virus would be held in check by the large doses of antibody given in transfusions, but would be liberated after injection of the very small doses of hepatotoxic serum which produces jaundice. Jaundice among patients under arsenical treatment for syphilis has long been regarded as evidence of toxicity of the drug, but recent work indicates that this form of jaundice is also due to the transfer of some noxious substance from the blood of one patient to another owing to improper sterilization of syringes and needles used for intravenous injections.⁵ Both this post-arsphenamine jaundice and the homologous serum jaundice have a long incubation period of two to four months, but are accompanied by liver damage indistinguishable in kind and severity from that which occurs with infective hepatitis.^{6,7} Apart from the incubation period, the main point which

distinguishes infective hepatitis from homologous serum jaundice—a term we may conveniently use to include both the pooled serum and the post-arsphenamine jaundice—is the apparent lack of infectivity of the latter disease. In addition Hawley and his colleagues,⁸ in describing an outbreak of jaundice after use of convalescent mump serum, have drawn attention to the greater incidence of certain clinical phenomena—e.g., arthralgia, skin rashes of allergic (urticarial) type, and enlarged liver and spleen—among patients with homologous serum jaundice. Persistent vomiting was more common in the infective hepatitis series.

The problem which still remains unsolved is the relation of infective hepatitis to homologous serum jaundice. Are they one and the same? So far attempts to isolate a virus from either type of disease by inoculation of material—whole blood, bile, nasopharyngeal washings, liver and spleen from fatal cases—into a wide variety of experimental animals have been wholly unsuccessful. Attempts to infect human volunteers by injection of blood from patients with infective hepatitis⁹ or by nasal instillation of nasopharyngeal washings from cases of homologous serum jaundice¹⁰ have been rather more successful. Interesting data on the infectivity of serum from patients with homologous serum jaundice or of pooled serum that was known to be icterogenic have lately been provided by both American and British workers.^{11,12} Thus an injection of 0.1 to 0.5 c.cm. of an icterogenic serum produces the hepatitis syndrome in varying degrees of severity in 30 to 40% of volunteers. The active principle is filtrable; it survives drying *in vacuo* for more than a year and storage at 4° C. for long periods; it resists heating for one hour at 56° C., but may be neutralized by ultra-violet irradiation. There is even evidence that it may be capable of multiplying in tissue culture. It is present in the blood during the pre-icteric and icteric stages of the disease, but disappears after two months. But, again, it may be present in pooled serum from individuals who at no time showed any symptoms suggestive of infective hepatitis.¹³ Sheehan¹⁴ has discussed the possibility that infective hepatitis is transmitted by a biting insect, and this new point of view may explain some anomalous findings in the epidemiology of the disease among troops in the Middle East. He suggests that infective hepatitis and homologous serum jaundice are due to the same agent, presumably a virus, and that the incubation period in both may be around three months. Epidemiological evidence about infective hepatitis does not support this argument, nor is it easy to reconcile it with the apparent lack of immunity to infective hepatitis which victims of homologous serum jaundice show, although Findlay and others¹⁵ have lately brought forward fresh evidence about cross-immunity which leads them to believe in a common antigenicity. For the final answer we must await the discovery of the causal agent of one or both diseases.

THE END OF PATULIN

Most of us would be more grateful for a real cold cure than for many a therapeutic discovery in connexion with more serious diseases: hence the sensation a year ago when it was announced¹ that a substance extracted from cultures of *Penicillium patulum* Bainier had proved its worth for this purpose in what appeared to be an adequate field trial. Patulin belongs to a class of antibacterial substances formed by moulds which differ from penicillin in having a lower order but a wider range of antibacterial activity and a considerable degree of toxicity. As was pointed out in these columns,² the toxicity of patulin, and the narrow margin between the concentration used for nasal spraying and the minimum required for bacteriostatic action, made it difficult to account for therapeutic effect on a simple antiseptic basis, even assuming that any action on ordinary bacteria will influence the early stages of a cold. The original report was followed shortly by the account³ of another field trial with negative results, and since these conflicting findings derived respectively from the Navy and the Army we were left for the time being to speculate on possible differences in the nasal flora of the two Services.

Patulin is much easier to make than penicillin, and adequate supplies were evidently soon forthcoming for further trials. Two accounts of further work which have now appeared are wholly discouraging, and it must be concluded that patulin has not the action originally claimed for it. J. M. Stansfeld, A. E. Francis, and C. H. Stuart-Harris⁴ have made both a laboratory and a clinical study of its properties, the former including observations on its toxicity and a demonstration of its failure to influence infection by either influenza virus A or *Bact. typhosum* (an organism fully sensitive to it) in mice. Their clinical trial was conducted on the same lines as that on a much larger scale described in a succeeding paper⁵ by the Patulin Clinical Trials Committee of the Medical Research Council. The subjects were respectively 100 soldiers and 1,343 office and factory employees and public-school boys. Half the cases in each series were treated with patulin in phosphate buffer solution and half with buffer solution alone, the nature of the solutions being unknown not only to the patient but even to those responsible for administering it and observing the effects. Various methods of application were used, including precisely that of the original naval trials, and one which appears to be an improvement on it—instillation in the head-low position. Ample precautions were taken to ensure and to demonstrate the activity of the preparations used. The proportion of patients relieved at different stages or professing that the treatment had been of benefit to them is almost identical in the test and control series of both studies. All the authors are at one in testifying to the difficulty of assessing therapeutic effect in a condition of which the manifestations are largely subjective. How, despite this difficulty, to explain the conflicting results of the original and subsequent trials remains a problem which no one can positively solve on the basis of published information. There seems to be no further need to study patulin for its own sake, but if further study could throw any light on this discrepancy it might expunge a disturbing question-mark from our records of this form of investigation.

A LISTER MEMORIAL LECTURE

The first Lister Memorial Lecture of the Society of Chemical Industry will be given by Sir Alexander Fleming, F.R.S., in the Anatomy Lecture Theatre of Edinburgh University on Thursday, Nov. 9, at 5.30 p.m. The subject of his address is "Antiseptics," and the chair will be taken by Sir John Fraser, Principal of the University. Under the auspices of the Society of Chemical Industry endowed memorial lectures have recently been founded in different parts of the country to perpetuate the memory of scientists and industrialists whose work has assisted in building up our great chemical industry. The name of Lord Lister has been chosen for commemoration in the Edinburgh and East of Scotland Section of the Society on account of his connexion with Edinburgh and because of the stimulating effect his revolutionary medical methods had on the growth of the fine chemical industry in that country. The endowment has been the gift of two Edinburgh pharmaceutical chemical manufacturers, J. F. Macfarlan and Co. and T. and H. Smith, Ltd. The lecture will be delivered every four or five years in Edinburgh, Aberdeen, or St. Andrews.

PRENATAL DIET AND THE INFANT

Much of the recent field work in nutrition recalls the retort of the professor in Bernard Shaw's *Black Girl*: "The fact was known, of course, to every child; but it has never been proved experimentally in the laboratory; and therefore it was not scientifically known at all. It reached me as an unskilled conjecture: I handed it on as science." It is accepted by the layman that a high nutritional standard during pregnancy is necessary for both mother and child. The reports of Ebbs, Tisdall, and Scott¹ and of the People's League of Health,² which produced evidence of the beneficial effect on the mother of supplementary feeding, have received a good deal of criticism. Nevertheless, the results cannot be entirely discounted, and it must be accepted that diet is an important factor affecting maternal health. As regards the effect of the maternal diet on the infant, the position is still more interesting. There must be few mothers who do not believe that what they eat profoundly affects their unborn child. Scientific opinion, however, has tended to minimize the effect of prenatal diet on the infant, and the general opinion at the Nutrition Society's meeting³ in February, 1943, was that the child was unaffected except by gross deficiencies in the mother's diet. Nevertheless, Ebbs, Tisdall, and Scott showed that dietary supplements to the mother appreciably lowered the incidence of illness in infants up to 6 months of age. For example, 31% of the infants of mothers on ordinary diets suffered from some respiratory affection, compared with 8% of the infants of the mothers on supplemented diets. Similarly, 25% of the former were anaemic, compared with 10% of the latter. In addition to this experimental type of evidence a recent study⁴ has been reported of the "field" type, in which the health of infants in the first two weeks of life has been correlated with the ordinary diet of the mothers. The infants were placed in four groups depending on their physical condition—superior, good, fair, and poorest. The diets of the mothers were classified into three groups—good or excellent, fair, and poor to very poor. The correlation between the physical condition of the infant and the prenatal diet was very high. For example, of the superior children, 56% were of mothers whose diet was good or excellent, and 9% of

¹ *Lancet*, 1943, 2, 625.² *British Medical Journal*, 1943, 2, 633.³ *Lancet*, 1943, 2, 634.⁴ *Ibid.*, 1944, 2, 370.⁵ *Ibid.*, p. 371.¹ *J. Nutr.*, 1941, 22, 515. See also *British Medical Journal*, 1943, 1, 16, and correspondence, *British Medical Journal*, 1943, 1, 144, 204, 231, 263, 301, 353, 460.² People's League of Health Interim Report, 1942, *Lancet*, 2, 10.³ *British Medical Journal*, 1943, 1, 297.⁴ *Brites*, B. S., et al., *J. Nutr.*, 1943, 28, 569.

mothers whose diet was poor to very poor. Of the poorest children the figures were 3% and 79% respectively. Similarly, of the mothers whose diet was good or excellent, 94% of the infants were superior or good and 3% poorest; of mothers whose diet was poor to very poor the figures were 8% and 67%. Further, there was a close relation between the prenatal diets and the height and weight of the infants at birth. Infants from mothers on good or excellent diets were 51.8 cm. and 8.5 lb. at birth; infants from mothers on poor to very poor diets were 47.2 cm. and 5.8 lb. All the stillborn infants, all but one of those who died within a few days, and all the premature infants were born to mothers whose diets during pregnancy were very inadequate.

One would like to see many more such studies, covering many more individuals, and observed for much longer periods; for the importance of these observations cannot be over-emphasized if "positive health" is to be more than a new slogan for politicians.

PLASTIC SURGERY IN WAR

The war of 1914-18 saw the birth of plastic surgery as a specialty, and in those years the foundations for further advance were laid. The relatively short interval of peace enabled the lessons learned to be applied to the treatment of injuries and deformities arising from accident, disease, and congenital defect. Improvements in technique and advances in knowledge altered the prognosis of many conditions, and the scope of the specialty gradually increased to embrace most soft-tissue deformities or losses. With the onset of this war there was created within both the E.M.S. and the Ministry of Pensions a service designed to deal with civilian and battle casualties. Units staffed by plastic surgeons and their dental colleagues were established throughout the country. During the first few months they continued to draw their patients from hospital waiting-lists, and in this time the opportunity was taken to co-operate in the training of personnel for service in our own Navy, Army, and Air Force, as well as those of some of the Dominions. Dunkirk, the Battle of Britain, and the subsequent bombing of London and the larger cities brought casualties suffering from all types of soft-tissue injuries and burns. Some of the lessons of peacetime were found to have been based on faulty premisses, and that was particularly true of burns. The coagulation technique, which had been considered invaluable, was found to be fraught with serious dangers. There is so little in common between the lesion acquired by upsetting a kettle of boiling water and that inflicted by exposure to burning petrol fanned by a 300-m.p.h. gale that it is hardly reasonable to expect one method of treatment to be equally applicable to both. Indeed, it becomes increasingly obvious that any one method is not only inapplicable to all burns but is not suitable for all phases of the treatment of any one

This is well illustrated in a recent symposium on surgery,¹ and even here only a few aspects of the problems of control of infection first by the sulphonomide drugs and now by penicillin. These have been or are being worked out. There is little indication of the amount of thought and labour devoted to the burned hand—to the question of restoring not only the skin but also the functions of muscle and joint. There seems to be little awareness of the advances in the treatment of fractures of the jaw. In spite of these omissions, it is of interest to note that the contributors to the symposium are concerned with the evaluation of different methods of treatment. This is a sign that the specialty has become mature and is no

longer concerned with the elucidation of basic principles. These are already accepted; but it must not be thought that new and better applications do not remain to be found. A case in point is the recent modification of the process of free skin-grafting by the introduction of coagulum-contact methods. This represents not an entirely new development but an elaboration of technique which has the advantage of simplicity.

And so progress is made. In common with the other interdependent specialties, plastic surgery is meeting the needs of the moment in providing the resources necessary for the repair of battle and civilian casualties.

EDITORSHIP OF THE "LANCET"

The proprietors of the *Lancet* announce this week with much regret the retirement of Dr. Egbert Morland from the editorial chair. Dr. Morland joined the staff in 1915 and has been Editor since 1937. He is succeeded by Dr. T. F. Fox, with Dr. F. Clayton-Jones as assistant editor. As brother medical journalists we can appreciate better perhaps than others the skill and devotion with which Dr. Morland has served our profession through the columns of the *Lancet* during the past 29 years. His unremitting work for the advancement of medical science and practice, and for the maintenance of the traditions of medicine, has been done for the most part in the background, but both the Royal College of Physicians and the Royal College of Surgeons have recognized it publicly by admitting him to their Fellowship. The *Lancet* is fortunate in having Dr. Fox to succeed him, and we offer every good wish to the new Editor, who has already given long and valuable service to our contemporary.

KING'S FUND HOSPITAL MAPS

King Edward's Hospital Fund for London has prepared two large maps, one covering the Metropolitan Police District, and the other (in two sections, eastern and western) the Home Counties. Both maps are printed on the Ordnance Survey and thus show all roads, railway stations, etc. Voluntary hospitals are shown in red and municipal hospitals in blue, and the various sizes and types of each are denoted by different-shaped signs. No large-scale hospital maps of this kind have ever appeared before, and their publication is timely in view of the present emphasis on hospital planning. During the autumn the King's Fund hopes to make available to the medical profession and others interested in these matters a limited number of copies of the maps. Requests have already been received for over 300. Those who desire a copy should notify the secretary of the Fund at 10, Old Jewry, E.C.2. To enable those concerned with hospital planning to gain a more detailed knowledge of existing accommodation the King's Fund is also issuing a booklet which gives the addresses and bed complements, both E.M.S. and normal, of every hospital shown in each map. These booklets embrace mental hospitals, sanatoria, and public assistance institutions as well as general and special hospitals. The prices are 7s. 6d. for the Metropolitan Police District map and booklet, and 10s. for the Home Counties.

We regret to announce the death, at the age of 72, of Mr. Ernest W. Hey Groves, M.S., F.R.C.S., emeritus professor of surgery in the University of Bristol, and for many years surgeon to the Bristol General Hospital. He held many high positions in the Royal College of Surgeons of England, had been president of the Association of Surgeons of Great Britain and Ireland and of the British Orthopaedic Association, and edited the *British Journal of Surgery* from the time of its foundation.

STATEMENT ON DEMOBILIZATION BY THE CENTRAL MEDICAL WAR COMMITTEE

Some considerable time ago, at the request of the Ministry of Health, a special subcommittee of the Central Medical War Committee, known as the Demobilization Committee, was appointed to advise on the problems connected with the post-war release of medical practitioners serving with H.M. Forces. The Government had announced that the main considerations which would determine priority of release would be age and length of service, and the task of the committee was to consider what detailed procedures under this general plan would best combine justice to the serving doctors and satisfaction of the more urgent needs of the depleted civilian medical services. Most of the recommendations made by the committee were accepted by the Ministry of Health, though in some instances with modifications. The Government's proposals have now been published in a White Paper.¹ A brief account of the plan follows, with special reference to medical practitioners, whom the White Paper does not specifically mention.

SUMMARY OF GOVERNMENT'S PLAN

1. General demobilization must await the total defeat of the Axis Powers. All that is contemplated at present is the re-allocation of man-power between the Forces and civilian employment when Germany has been defeated and while the war with Japan is still in progress.

2. As there can be no break in the war effort military requirements will override all other considerations. The requisite control of civilian labour will be maintained, and compulsory recruitment for the Forces will be continued. At the same time it will be possible to "bring relief to the men who have served for long periods" and, through continued recruitment, to "enable more of them to return to their homes." This re-allocation of man-power will be "on a substantial scale," but "the rate of re-allocation must differ as between the three Services."

3. The plan provides for two separate methods of selecting men for return from the Forces. The larger group, designated Class A, will be selected for release according to age and length of service. In addition there will be a limited provision for the transfer from the Forces of men who are qualified for "urgent reconstruction work." This smaller group, designated Class B, will be required mainly to supplement the labour force available for building houses, but will include "a limited number of individual specialists, for whose transfer application may be made through Government Departments in accordance with existing arrangements." So far as doctors are concerned, the description "specialist" is not used here in its professional sense but is applicable to all medical officers.

4. Although the Services will make every effort to release men in their turn in accordance with the plan in whatever theatre of war they may be serving, no man will be released or transferred if his retention is considered necessary on military grounds; nor will any man be released or transferred if he prefers to volunteer for a further period of service. In short, there will be no compulsory return to civilian employment, but there may be compulsory retention in the Services of men due for such return, either in Class A or in Class B.

Class A

5. Within Class A there will be special priority for men of 50 years of age and over, who will be released before other men if they so wish. Otherwise, men in Class A will be released by release groups determined by a combination of age and length of war service on the basis that two months of service are equivalent to one additional year of age. For example, a man of 22 with four years' service will be in the same release group as a man of 40 with one year's service. "In general, war service means whole-time service in the armed Forces since the 3rd September, 1939, which counts for Service pay."

6. The release of men in Class A will begin as soon as practicable after the defeat of Germany, but there will necessarily be a pause to enable the Services to identify the men who are to be released first and to arrange for the return to this country of those who are over-seas. The number of releases in Class A will depend on the reduction that is found to be possible in the strength of the Forces and also on the number of new recruits called up.

7. To assist in resettlement, men in Class A will receive on release eight weeks' leave with full pay and certain allowances, and additional leave and pay will be given in respect of foreign service. When the period of leave has expired these men will be placed to a special class of Reserve, from which they would be recalled only in an extreme emergency. They will be able, on release, to exercise their right of reinstatement in their former civilian employment, and, while receiving regular Service payments, they will not be regarded by the Employment Exchanges as "subject to any powers of direction which are otherwise generally operative." The benefits received by men in Class A will be available also to men discharged on medical grounds. The present arrangements for release on compassionate grounds will be continued.

Class B

8. Transfers in Class B will be small in number in proportion to releases in Class A and will not begin until a start has been made with the release. The actual numbers for transfer will be determined from time to time by the immediate requirements of the "reconstruction employments" and the extent to which these requirements will be met by releases in Class A and by transfer from other civilian work. So far as possible, the selection of the required number of men from a particular occupational class for transfer in Class B will be based on the principle of age and length of war service.

9. Men transferred in Class B, since they will leave the Forces out of their turn, will not be entitled to the same benefits as those released in Class A. They will be given only three weeks' leave before being placed to the Reserve, and payments due in respect of foreign service will be held in suspense until after the end of the war. Men in Class B will be under direction and will be liable to be recalled to the Forces if they discontinue the civilian work for which they were transferred. If this is not the work in which they were formerly engaged, their reinstatement rights will be preserved.

10. A man will not be transferred in Class B against his wish if he prefers to await his turn for release in Class A. "Once, however, a man has been transferred in Class B he will not subsequently be eligible to apply for inclusion in Class A."

11. Both Class A men and Class B men may, immediately on release or transfer, apply for a pension for disablement due to war service. A scheme of war gratuities by way of reward for service will be announced later.

12. The general arrangements described above will apply to women as well as to men, "with the addition that married women will have priority over all others if they so desire."

Special Position of Medical Officers

As has been stated above, medical officers are not specifically mentioned in the White Paper. The general arrangements proposed will, of course, apply to them as to other members of the Forces. So far as Class B is concerned, they are within the category of "specialists" who will be transferred, not in groups, but individually on application made through a Government Department. In practice, the recommendations for transfer will be made by the Central Medical War Committee after consideration of applications submitted through the Local Medical War Committees, or, in appropriate cases in the London area, through the Committees of Reference. In short, the machinery set up for the recruitment of medical practitioners will "go into reverse" for the purpose of the re-allocation procedure.

The total number of transfers in Class B will be limited, and it is not to be expected that any particular group of "specialists" will be allowed a disproportionate share of such transfers. It is probable, therefore, that the strengthening of the hard-pressed civilian medical services will depend mainly on releases in Class A, and the question arises whether the

¹ Re-allocation of Man-power between the Armed Forces and Civilian Employment during any Interim Period between the Defeat of Germany and the Defeat of Japan (Cmd. 6548.)

numbers of medical officers whom the Services will be able to release will be such as to meet the urgent civilian needs and to ensure equality of treatment in respect of release between medical officers and other members of the Forces.

It is clear that the requirements of the Services in respect of medical officers will continue to be heavy after the defeat of Germany, both because of the high incidence of sickness in the Far East and because the resources of the Emergency Medical Service will not be available here. Moreover, some considerable time may elapse after the fighting has ceased in Europe before medical officers can be made available in sufficient numbers for service in the Far Eastern theatre. It may well be, therefore, that the requirements of the Services at the end of the European war will be such as to make it impossible to allow the medical profession its proportionate share of releases in Class A under the general re-allocation scheme.

It appears that the number of releases of medical officers will be determined largely by the number of civilian practitioners available for recruitment, and this in turn will depend on the Government's decision as to the limit of age for continued recruitment after hostilities in Europe have ceased. On this matter the White Paper gives no definite information, but merely states that "in order to increase the releases in Class A and to compensate for the transfers in Class B, numbers of young men at present deferred, particularly in the munitions industries, will be called up for the Forces."

The Demobilization Committee recommended the continued recruitment of young medical practitioners who are within five years of qualification or are below the age of 28, and this recommendation was accepted by the Ministry of Health. But, in view of later information as to the probable needs of the Services, it now appears that the continued recruitment of doctors will be desirable up to a somewhat higher age, perhaps in the region of 35, even if this age should be above that fixed by the Government for recruitment generally. The Central Medical War Committee has decided to recommend accordingly through the Ministry of Health.

A special consideration which has influenced the committee is the impossibility of recruiting, from practitioners within five years of qualification, the specialists—the word is used here in its professional sense—who will be required to replace those who are due for release in Class A and those whose transfer in Class B will be recommended. Apart from this, it is clearly important that the practitioners available for recruitment should be sufficient in number to enable serving officers generally to be released in their turn under the Government's scheme in order that their future prospects in civilian practice may not be unfairly prejudiced.

The committee has in mind the fact that the needs of the medical schools and associated hospitals, both in respect of the teaching of undergraduates and in respect of the postgraduate instruction of medical officers returning from the Forces, will be likely to give rise to applications for Class B transfers. Every effort will be made to deal justly with such applications in the light of exact information to be obtained from the schools regarding their comparative needs, and with due regard to the fair distribution of the permitted number of Class B transfers among the various spheres of professional work.

Reference has been made to the postgraduate instruction of practitioners returning from the Forces. It may not be generally known that, some years ago, the British Medical Association saw this need and urged the Government to prepare arrangements. The matter is now in the hands of the Central Medical War Committee, and discussions are proceeding with the Ministry of Health. The aim is to ensure not only that refresher courses and clinical appointments are available but also that appropriate financial arrangements are made in order that no man who is in need of professional rehabilitation, and no suitable candidate who wishes to continue his interrupted education with a view to specialization, will be unable to find the opportunity he seeks through lack of means.

L. N. Pearlman and R. G. Bell (*Arch. Pediat.*, 1944, 61, 75) record a fatal case of *B. coli* meningitis in a male infant aged 1 month. The case was treated with sulphonamides but without spinal drainage.

Correspondence

Administration of Pitocin and Ergometrine during and after Labour

SIR,—Conflicting opinions are expressed by Drs. O'Meara and Gaskell (Sept. 9, p. 353; Oct. 14, p. 511) concerning the propriety of administering pituitary extract during labour. On this much-discussed subject a firmer stand can, I believe, now be taken (*J. Obstet. Gynaec. Brit. Emp.*, 1944, 51, 247).

Careful clinical experiments led Burn and Bourne (1927) to the conclusion that two units of posterior pituitary extract given by intramuscular injection provide a useful means of stimulating a sluggish uterus without appreciable risk of foetal asphyxia or uterine rupture. The pros and cons have been more recently discussed at a symposium organized by the American Medical Association. There is no doubt that pituitary extract (like ergometrine) is highly dangerous if incautiously used. Nothing useful is gained by speeding normal labour; and to stimulate an already active uterus is certainly a rash venture ("A stream-lined labour," said DeLee, "is as safe as a stream-lined parachute!"). On the other hand, if the uterus is sluggish, if the head is low on the perineum, and if there is no mechanical hindrance to easy delivery—e.g. occipito-posterior position of the head—there is, I believe, good reason to give two units of the extract by intramuscular injection. For the next 15 minutes careful watch should be kept in order that excessive contractions—should they occur, which is unlikely—may be controlled by inhalations of chloroform. I have had no reason to regret this practice, and, like others, have found that it sometimes avoids the need of a forceps operation.

Ergometrine, on the other hand, should never be given before the birth of the head: for the foetus it is still the "pulvis ad mortem" that the parent drug was termed. But when labour is over it is safe; and it has, I believe, virtually banished the hot intra-uterine douche and other clumsy methods of controlling post-partum haemorrhage. To be fully effective in these urgent cases it must be correctly administered. Intravenous injection of 0.25 mg. (1/2 ampoule) gives excellent results. Injection into the uterus via the abdominal wall is even simpler and more effective. For the latter method there are three requisites: (1) the bladder must be empty; (2) the syringe and needle must be sterilized by boiling, and the needle should be of stainless steel to lessen any risk of snapping; (3) the uterus must be easily felt and capable of being manipulated to lie against the abdominal wall. The injection is made through an area of sterilized skin 2 in. below the umbilicus; 0.5 mg. (1 ampoule) should be given.

The administration of oxytocic drugs before the birth of the placenta has been much disputed, and personally I dislike the routine use of such methods. If, however, after half an hour or more the placenta cannot be expressed by Credé's manoeuvre, and if the uterus is flabby, I have on many occasions injected 5 units of pitocin into the fundus as described above. In 45 seconds the fundus and body become firmly contracted; placental expression is then often successful, and the operation of manual removal thus avoided. If the placenta still refuses to come away, haemorrhage from the uterine cavity will at least be arrested; and half an hour later, when the effect of the pitocin is spent, manual removal may be more safely performed. Ergometrine may also be used; but because it is more persistent in action a later manual removal (if necessary) is likely to be a more difficult operation.

Recently, several American obstetricians have reported the routine use in more than 1,000 cases of an intravenous injection of 0.2 mg. of ergonovine (ergometrine) given simultaneously with the birth of the anterior shoulder of the foetus. The placenta quickly separates and follows almost at once after expulsion of the foetus. Post-partum haemorrhage is greatly lessened. By this method of administration it is claimed that the risk of incarceration of the placenta by uterine spasm is negligible. I can corroborate these statements, but believe that the method has inherent risks and should not be used outside hospital practice.—I am, etc.,

Radclyffe Infirmary, Oxford.

CHASSAR MOIR.

Fracture of the Carpal Bones

SIR.—Your contributor H A Harris, in his article on fracture of the carpal bones (Sept 16, p 381) has raised a number of points concerning the paper which Wilkins and I wrote for *he Journal* of May 20, 1944.

He criticized our statement that more cases returned to full duty than were passed as having the fractured scaphoid united. We endeavoured to make it clear that although most cases of ununited fracture of the scaphoid develop osteoarthritis, in some the giving rise to symptoms may be long delayed. When one is dealing with large numbers of traumatic lesions it is by no means uncommon to come across an old fracture of the scaphoid of which the patient is unaware and which is giving rise to little or no disability. In these cases it is probable that there has been good fibrous union without destruction of the bone.

In giving the scope of the analysis we stated that the remaining fifty eight cases were Colles's fractures only. More over, a concluding section briefly described those cases in which multiple carpal injuries had occurred. Dr Harris's observations on the comparative and developmental anatomy of the scaphoid were very interesting. I feel certain that many of the so-called accessory and bipartite scaphoids that have been described by anatomists and radiologists are, in reality, overlooked ununited fractures. Their radiological appearances compare very strongly with those of known old lesions.

That skate fractures of the os magnum and cuneiform occur is undoubted. In my experience they require plaster immobilization just as much as the fractured scaphoid. This is largely for symptomatic reasons, although their presence implies considerable disruption of the ligamentary structure of the carpus—I am, etc.,

J M ROBERTSON

Ariboflavinosis

SIR.—Dr Hugh S Stannus in the Lumleian Lectures on riboflavin and allied deficiencies (*Journal* July 22 and 29, 1944) failed to make any reference to my work, "Eye Disease due to Vitamin Deficiency in Trinidad." While he says that "full references will perforce be omitted," it is difficult to understand how he could have published the table on page 104 in the July 22 number and omit Trinidad and my name. He must have known of my work, previous references to it are as follows: (a) *Amer J Ophthalmol*, Nov., 1941, leading article; (b) *Lancet* April 11, 1942, annotation; (c) *Trop Dis Bull* June, 1942, p 403; (d) "The Ariboflavinosis Syndrome," *British Medical Journal*, July 24, 1943, leading article; (e) *Brit J Ophthalmol* July, 1943; (f) *ibid*, Sept., 1943.

With respect to the observations made in the leading article in the *Journal* of July 29 1944, that "it is a sad reflection on our colonial administration that these studies should have been made in one of our colonies in the days of prosperity before the last war..." it should be pointed out that we have the pellagristologists to blame for a good deal of the administrative inactivity that followed, because of the fervid attempts made by them to keep a large number of vitamin deficiency diseases defined within the symptomatology of pellagra. In that way, and because of the terms "pellagra sine pellagra," "pellagra fruste" and "pre pellagra" the annual report of a colony could continue to repeat the formula, "the general health of the colony remained satisfactory," pellagra being regarded as nothing new. Fitzgerald Moore has pointed out that much of the research which has been undertaken in the Tropics has been of an individual nature, and the individual assertiveness that was needed to gain recognition has been the cause of harsh treatment being meted out to some medical officers. It was, however, with some dismay that I saw Fitzgerald Moore drawn into the camp of the pellagristologists, for in 1939 he published "Retrolbulbar Neuritis and Pellagra in Nigeria" (*J trop Med Hyg* 1939 42, 109). I prefer the term "tropical nutritional myopia." He also stated in 1939 that "gan, a dry, parched, mucous food was associated with the incidence of pellagrinous retrolbulbar neuritis" and that belief showed the influence of the work of Alfred Clarke. In Trinidad the latter was called "Tani" Clarke because he thought that the toxic principles which occurred in certain underground

foods, tania in particular, were responsible for nutritional disturbances which produced nephritis. A large amount of tania is still consumed in the British West Indies.

A recent article, "Malaria and Nephritis in the British West Indies" (P Granville Edge, *Caribb med J* 1944, 6, No 1, 32), provides interesting study by way of contrast. Edge begins by pointing out that "so far as health conditions in the Tropics are concerned perhaps the importance of diseases distinguished by exotic names has been unduly exaggerated, and the deadliness or disabling effects of some of the more familiar titles in the nomenclature underestimated. Plague, cholera, yellow fever, malaria and sleeping sickness are among some of the exotic models which appear to dominate the mortality pictures of life in remote places, for the menace to health and life created by the presence of these diseases has a permanent news and interest value."

With the establishment of U.S. naval and military bases in Trinidad the purchasing power of the people rose to great heights, a tremendous sum of money being spent on skilled and unskilled labour. One result of that is that vitamin deficiency conditions affecting the eye have largely disappeared, patients becoming fewer since 1942. Angular stomatitis is no longer seen, nor burning feet complained of at the eye clinics. There are, however, many problems remaining for research. For instance, there is the failure of drainage operations in many coloured persons, for the darker the patient the less likely is a corneo scleral trephine to succeed. Also, mild outbreaks of the nummular and macular type of superficial punctate keratitis occur repeatedly among Trinidad-born East Indian sugar estate labourers, while other members of the community in the same areas remain unaffected—I am, etc.,

Port-of-Spain Trinidad

VIVIAN M. METIVIER.

Prevention of Industrial Dermatitis

SIR.—The correspondence between Drs Bourne and Mummery on the value of various preventive measures in connexion with dermatitis has raised many interesting points, and would seem to show that there is a great deal to be learnt on this subject by all of us.

I myself have used the sulphonated castor oil which Dr Mummery advocates, and have found it extremely valuable. Apart from its preventive aspect it is ideal as a cleansing agent in established eczematoid rashes of all types, and popular with patients who try it owing to its re-fattening properties. Dr Bourne's personal experience with a barrier protective cream and metol dermatitis is just that sort of experience which is wanted to establish the value or otherwise of these substances. There has been far too much unscientific acceptance of these creams, which are often backed by an extremely ingenious advertising campaign from the vendors. This much has already been established to my mind that for a short exposure, such as developing a film or temporary handling of irritants (especially by intelligent users), these creams do protect to some extent. But it is quite another matter when their use is translated into everyday factory work among a mass of employees working for, say, an 8 hour shift. It is indeed difficult to decide their value because so many factors are involved: the experience of the operators, the nature of the oils, the quality of the foremanship, and many other factors. In an article in the *Lancet* in 1943 I pointed out that while some oils are innocuous others tend to produce much dermatitis. Working on these lines the factory doctor should be able to produce valuable results, and the old bogey of the workman neglecting to wash or use creams or take any other safety measure is relegated to its proper place.

American workers have produced many barrier substances of all types for all hazards, but Schwartz, in many of his publications, does not by any means give them pride of place in his category of preventive measures. I myself have seen factories where practically no barrier cream was used and yet very little dermatitis occurred, although cutting oils of every type were seen. Conversely, in factories where much barrier cream is used there may be many cases of dermatitis. Where supervision is bad in a factory no amount of barrier cream will retrieve the position. My own feeling is that good supervision by foremen who are welfare-minded is a very great factor in controlling dermatitis, and that in many cases

this factor is considerably enhanced if the medical and welfare staffs see that washing facilities are adequate. Dr. Bourne is probably right when he insists on protection of every possible kind (including barrier creams), but the relative value of these various protective measures is still a matter of opinion and may differ according to the hazard in question.

There is one other point. As the war progresses the experience of the workers increases, and this makes for less dermatitis in factories. This fact alone makes comparison of dermatitis figures from one year to the next fallacious. Finally, it seems to me strange that some dermatologists, instead of collecting rare and relatively unimportant skin diseases for exhibition at learned society meetings, have not long before taken more interest in workaday medicine and gone into the factories to learn something useful. The academic attitude of some English dermatologists has been a great blow to the value of dermatology to the nation, and the dermatitis of these war years has consequently fallen very heavily on the factory medical staffs, who have largely had to depend on their own initiative for their results.—I am, etc.,

Cowley, Oxford.

G. P. B. WHITWELL.

Intravenous Anaesthesia

SIR,—I heartily agree with Dr. H. B. Alcock over most of the points she raises in her letter (Oct. 14, p. 511). A substantial drawback to using the simple technique that she describes is that unless constant attention is paid to the needle it becomes blocked with clotted blood. I should like to mention one small point of technique, which requires no more apparatus but considerably lessens the risk of a blocked needle. In practice I cannot claim that it rules this out completely, but I have found it very helpful and it may appeal as worthy of trial to those who are not enthusiasts for "cumbersome" apparatus.

If a short-bevel needle, or one which is not too hollow ground, is used, it can be so arranged that it rests against the inner wall of the vein and prevents blood entering the needle and clotting. To do this I place the needle, bevel facing upwards, on an eccentric nozzle syringe. When the needle has been introduced into the vein I fix the syringe to the arm in such a position that the tip of the needle presses gently skinwards against the superficial wall of the vein. This usually just allows the outline of the needle to be seen for its full length by a slight raise in the skin. Before injecting further doses of anaesthetic solution I generally depress the point of the needle to lie in the centre of the vein, letting it fall back to its original position before relaxing pressure on the plunger after injection.

I cannot claim that this method is perfect, for occasionally the needle does block, due presumably to movement or faulty placing, but intervals between injection have often exceeded half an hour. On one occasion a needle was left untouched during the latter two hours of an operation, and found to be patent at the termination. Whether this technique harms the vein I cannot say, but thrombosis seems to occur at a rate no higher than when 5% pentothal is used by other methods.

I disagree with Dr. Alcock over one point—namely, that I use a 17 short-bevel needle for preference.—I am, etc.,

Aylesbury, Bucks

J. MORLAND SMITH, D.A.

Heredity and Tuberculosis

SIR—It may well be that in showing, as Stocks remarked, a tendency to ignore the evidence about heredity in tuberculosis the profession has also shown shrewd common sense. Although it is true as Barbara Burks pointed out, that there are certain directions in which this knowledge may be immediately applied, it does not alter the fact that environmental factors are the ones about which we as a profession can do something.

It is surely the fact that the husband or wife of the patient is five times as likely to develop clinical tuberculosis as an ordinary person that is important for the doctor and sociologist. The marital partner shares an overcrowded room with the patient; she shares his low wages and unsatisfactory diet. These are social problems which can be tackled now. Good houses can be built as labour and materials become available.

An application to peace of the lessons learnt in war can ensure that an adequate share of the nation's food is available to all. Even in the period of unstable economic equilibrium between the wars the tuberculosis figures improved slowly. During the war this trend has been reversed. It is plain, both to the profession and to the public, that a low tuberculosis rate is an index of prosperity, and vice versa. By comparison with these obvious facts the painstaking observations of Kallmann and Reisner are of little more than academic interest at present to the general practitioner and sociologist.

Advice such as that given by Barbara Burks as to choice of relative to nurse the sick patient may be sound, but how many working-class families are in a position to pick and choose in this matter? The problem is still the old one of the provision of adequate sanatorium beds.

In almost all disease there is a constitutional factor, great or small, but it is the environmental factor which is capable of modification. Prompt action now may avert a tragic increase in tuberculosis in the London area as a result of wanton Nazi destruction of homes and consequent overcrowding. Sensible planning of the nation's resources may reduce tuberculosis to a minimal level in one generation. How many generations would be needed to select a tuberculosis-resistant population?—I am, etc.,

St Mary Cray, Kent.

BRIAN H. KIRMAN.

Atmospheric Pressure and Migraine

SIR,—Though emotional factors are important in the aetiology of migraine they should not be overstressed. The observations described here may be of interest.

For a period of six months three of my patients had their attacks of migraine secretly recorded by relations. At the end of this period I compared the records with the barometric chart for the same period. It was observed that many attacks occurred when the barometer was rising or falling steeply, and some such happened in the small hours of the night waking the patients from sleep.

I am not prepared to assert that atmospheric pressure is the whole explanation in these cases. But in a seemingly unrelated field—the rheumatic—we note that changes in weather may provoke symptoms. These do not seem to result merely from alterations in humidity or temperature, and pressure change may be part of the explanation. Some Continental workers have suggested that changes in the ionization of the atmosphere, associated with and essential to changes of weather, affect the sensitive subject. I have yet to meet a convincing explanation of the ache in an old wound in bad weather.

Physiologists have here, I think, an interesting field of inquiry. And could they tell us if thunder weather causes any characteristic variations in encephalograms?—I am, etc.,

G. C. PETHIER.

London Medicine

SIR,—Brevity, though in these times doubtless the supreme recommendation to an editor, sometimes defeats itself. It does so when it sacrifices full clarity, as in the case of Mr. Twistington Higgins's kind reply to my letter. I should like, on behalf not only of myself but also of your many readers who must be interested in the profoundly important issue of London postgraduate medicine, to ask Mr. Higgins to expand a little some of the things he said. Thus, speaking of the proposed Institute of Child Health, Mr. Higgins said: "The conception in the minds of its originators has always been just as comprehensive as Dr. Rowland Hill suggests it should be." What I suggested it should be (and this principle applies to any comparable institutes in other special subjects) is fundamentally a full, fair, and equal partnership from the word "go" between all voluntary children's hospitals in the London area, with Great Ormond Street asking for no special privilege or power on the ground of its greater size *vis-à-vis* the others. I ask Mr. Higgins very respectfully to tell us if this is what he and his colleagues want. If so, I and many others will feel much relieved.

Mr. Higgins tells us that the plan for an Institute of Child Health emanated from Great Ormond Street, and that "we are proud of the fact." It is good to know that it came from his hospital. Mr. Higgins, I feel sure, will agree that additional fruitful ideas may originate from time to time in any other

of the children's hospitals, great or small, and will not desire to claim that his own has any monopoly of enterprise or originality. The marriage idea, for example, resulting in the recent formation of the splendid and promising Queen Elizabeth Hospital, was also one of which the hospitals concerned may well "be proud." Perhaps in the end it may prove as fine and productive a one as the "institute" idea. Let us welcome all these ideas in a mood of mutual respect and appreciation; and, in keeping with the open tradition which is the glory of English medicine (or should be), let us place them unreservedly in the common pool for the good of humanity and without thought of notoriety or reward for any particular institution. I feel we may well leave pride out of these altruistic matters unless it is a general pride in the achievements of English medicine as a whole.

I am particularly apprehensive and puzzled when Mr. Higgins goes on to say the "present collaboration between the University of London, the L.C.C., the Postgraduate Medical School, and the Hospital for Sick Children would seem to assure an adequate breadth of vision, which certainly aims at embracing in the future every paediatric activity in and around London." (The italics are mine.) As these words stand (I hope I am wrong, and my deep apology is formulated ready for instant utterance if I am) they convey to me a disquieting meaning. Why is Great Ormond Street the only children's hospital mentioned by name as collaborating with those bodies of presumably growing importance under the altered medical regime which we all anticipate after the war—the University of London, the L.C.C., and others? If I were a paediatrician setting to work to build up a London Institute of Paediatrics, I would (from a sense of right and justice) first approach my colleagues in all the other children's hospitals. Only after a strong and friendly alliance had been made would I, on behalf of metropolitan paediatrics as a whole, approach public and official bodies like the University of London and the L.C.C. I hope this is what was done, and that Mr. Higgins will reassure me.

I shall be really grateful to him if he will banish the fears I feel over his phrase: "Aims at embracing . . . every paediatric activity." Does he mean that his institute, composed of the institutions he has named, will grow so strong and large that it will eat up all London paediatrics (with the aid of the Nuffield windfall), so that all the other children's hospitals will have little to do, will not count for much, and will only continue a nominal existence, if at all, on terms dictated to them? Or does he mean—and I truly hope he does—that they will all freely enter his institute as equal partners, with equal rights of suggestion and decision, and equal benefit from the windfall from the very start? I venture to prophesy that any institute not based on this last principle of sense and justice will have a deservedly distorted, disappointing, and stunted career.

Of the three initial institutes mentioned in the Goodenough report, I understand that that of ophthalmology promises most clearly, by steps already generously and spontaneously taken by the parties concerned, to base itself on the foundation of equal partnership and combination between all the London voluntary hospitals in the specialty, and in this spirit, good fortune to the enterprise! On the other hand, so far not the faintest zephyr of a whisper of this spirit has yet been felt in the exclusive aristocratic world of the specialty with which I am concerned; but perhaps this is only the calm before a supremely constructive storm. Let us hope so.

Finally, repeating my respects and apologies held ready in advance, let us hope that an atmosphere of growing confidence can be assisted by Mr. Higgins's further reassurance.—I am, etc.,

London, W.1.

T. ROWLAND HILL.

Drugs and the Doctor

SIR.—Regarding the leading article "Drugs and the Doctor" in your issue of Oct. 21, I agree with almost everything you say except that the Pharmacy and Medicines Act, 1941, was a cartel agreement between the pharmaceutical profession and the proprietary medicine industry, which divided the retail market for drugs.

As my organization was primarily responsible for those negotiations with the proprietary medicine manufacturers, your

readers may be interested in the facts of the matter. We were informed that the Chancellor of the Exchequer proposed repealing the Medicine Stamp Duty. In reply to our protest against the freedom from control involved in the repeal the Chancellor said that if the manufacturers and retailers put forward any reasonable proposals to replace the Medicine Stamp Duty and obviate the evils we foresaw he would consider those proposals. The result was a fight between the pharmaceutical profession and the proprietary medicine industry; we never got complete agreement, and my organization fought the Bill in the House of Commons, receiving an unmerited castigation from the Minister of Health because he said he had the support of the Pharmaceutical Society. The Bill contained clauses on other matters which the society desired.

May I add that the pharmaceutical profession as a whole would welcome any reasonable controlling of the sale of medicines in the public interest?—I am, etc.,

G. A. MALLINSON,
Secretary.

The National Pharmaceutical Union.

SIR.—Your leading article on drugs and the doctor (Oct. 21, p. 535) is very instructive and timely. (1) We are informed by you that the patent medicine industry spends £3 m. on a year on advertisements, has a capital of £100 million, sells £20 million worth of drugs to a quarter of the population of the country "without medical advice and to the detriment of their health." (2) You are not sure whether a National Health Service is compatible with the advertisements of pharmacopoeial drugs. (3) You mention that sulphanilamide (to name only one drug) is being bought from a common source and sold under fifty-odd proprietary names at 300% profit. (4) You state that although the effects of patent medicines on personal and social health are harmful no Government has had the strength or courage to control it. (5) Your remedy for all this robbery, exploitation, and harm is that the individual doctor or patient must be supplied with unbiased information. (6) Lastly, you cite the example of the Americans, who "manage things much better than we do."

In this article you have no doubt made out a very strong case against the continued existence of the patent medicine industry, but you, like the Government, have not had the strength or courage to suggest the only remedy that can put an end to the nefarious practices of this industry—i.e., State control at a cost of £100 million of public money—and this sum is less than what we are spending in a week on war. When shall we learn to face the problem squarely, to hit the nail on the head, and to uproot the evil completely instead of applying palliative measures? No doubt the patent medicine industry will tell us all about the virtues of private enterprise and lack of initiative and individuality under State control, but if our municipal corporations and such huge enterprises as gas, water, and electrical industries can be run efficiently under State control, surely we can abolish the profit-grabbing patent medicine industry and hand over the pharmacological research to the Government at a cost of perhaps less than £3 million per annum, which is the sum that is being spent annually on advertisements of patent medicines. Sir, will you have the courage to advocate this policy?—I am, etc.,

Manchester.

M. R. SONI.

"Dissident Doctors"

SIR.—Your annotation suggests two questions. Why are there any dissident doctors and into what groups do they fall? By whom, when, and why were the proposed National Health Services identified in politics?

The answer to the first question is conditioned to some extent by that to the latter. Except for a small minority, surely all practising doctors were agreed upon the "medical policy" of the B.M.A. from the Dawson report to the publication of the draft Interim Report of the Medical Planning Commission. All of the recommendations lacked "political" complexion. When, however, the White Paper was published—as if the Government was too impatient to wait for any final report of the M.P.C.—medical services came to be discussed in Parliament. Various opinions reflecting party differences were expressed and debated; in particular, questions of organization and control. How else could it be? Thus the Government

itself introduced medicine into politics. Now, the B.M.A. does not openly refer to party issues, and a majority of its members deplore their intrusion. On the other hand, the S.M.A. exists to spread a knowledge of Socialism within the profession. Since Socialism has identified itself with the Labour Party, the S.M.A. has thus introduced party politics into medicine. Is the B.M.A. wise any longer to ignore the activities of this group of dissidents?

There is yet a second group of dissidents identified in the recently formed M.P.A.—who foresaw the cloud, anticipated the dictum of Gordon Malet with which you end your annotation, and sought and still seeks to counter party politics. The "reactionary M.P.A." evolved, together with certain Divisions of the B.M.A., as a reaction to the revolutionary movement of a vociferous minority which so many regret and so few understand. Over all the B.M.A. tries to survey the scene with a statesman-like demeanour, but presently it must see the challenge of the politicians.

A movement with national organization as its objective and bureaucratic control its consequence threatens to engulf us while our soldiers (the better part of our population) are away fighting (at any rate in *their* opinion) against this same atavism which exists abroad. The ordinary man, especially the scientifically trained man, is at a bad disadvantage in this sort of conflict. First, of course, he is obliged by his necessities or his conscience (or, happily, both) to devote his energies mainly to earning a living, incidentally doing his share towards the national life and responsibilities. Secondly, by his training he finds betrayal of trust and distortion of truth to be distasteful to the point of prohibition, but they are disqualifications to which the professional politician is not immune. We must realize that in party politics we are in an unfamiliar field, and that issues here are not to be settled judicially by a consideration of pros and cons—but by passion and self-interest catalysed and directed by crafty mob-raisers at the behest of juntas.

When writing to the medical profession itself one can, with hope of success, present a case from a factual standpoint, and a good argument is a sound one. Facts or analogies have a chance of being weighed objectively, but this is emphatically not the case when one encounters the politician *in persona propria*, or his general audience. Here assertion, passion, reckless misstatement, humbug, overt promises repudiable at leisure and all directed to the lower instincts, are the successful tactics. One can have sympathy with the prelate who retired from a public controversy with a well-remembered politician with the remark: "I cannot go on. I realize a gentleman has no defence against a blackguard." Each of these tactics has been employed recently, and not without effect, in reference to the health services.

Should the intrusion of political propaganda into medicine be a danger, then a great danger exists. Yet it will be to the moral credit of the profession if so far it has been overlooked. The danger is that the medical practitioner may fail from this standpoint: that he may depend upon a statement of his case in terms of a scientific discussion of fact which will be brushed aside under a barrage of abuse and passion-raising phrases. As a precedent I instance the Ministerial reaction to the report of the Council of B.M.A. to the Representative Body.

In the political field one must use political methods. The whole business is distasteful, but since the B.M.A. already has a public relations officer it might best be solved by hiring a political officer to run the campaign for them—thus keeping our hands and minds clean. But if this can't be done, then the matter must be faced like an enema or a childbirth—a dirty business but justified of its results. A recent article in the *Daily Herald* referred to the monopolistic vested interest of the medical profession, which was accused of insolence and defiance of democracy by presuming to reject control of its members by the House of Commons. It is futile for any mere doctor to attempt to rebut this excellent example of poisonous political tactics. But if this be the voice of a misguided minority, is it expedient to meet it with silence? Silence is but a short remove from ineptitude.

Upon what authority did the *Times* recently state that owing to the favourable reception given to the White Paper the Ministry is now actively engaged in drafting legislation? I remember a Governmental promise that ample time would be

allowed for the professional organizations to discuss, perhaps even influence, proposed legislation. We shall not be able to guess what time will remain between the A.R.M. and the introduction of the Bill into Parliament until His Majesty makes his Speech next month. The B.M.A. will start with a nine-months handicap. At the A.R.M., and as between medical men, expressions of sincere conviction will be weighed objectively. But if there is to be any conflict between professional doctor and professional politician, let us remember that "bare hands and courage cannot counter tanks." Are those who suggest the urgent need for appropriate weapons to be castigated as dissidents, too?—I am, etc.,

Watton-at-Stone.

MAURICE WIGFIELD.

SIR,—Though deeply divided on side issues the Ministry of Health, the executive of the British Medical Association P.E.P., the Socialist Medical Association, Dr. Gordon Malet, and other organizations and individuals are united in a policy of centralized control of doctors and patients. It can be truly said of these that though they march separately they fight together.

Opposed to this uneasy alliance is the Medical Policy Association, uncompromisingly taking its stand on the preservation of the freedom of doctors as individuals and their inalienable right to act in response to the demands of their patients rather than to the directions of bureaucrats—medical or lay.

The relation to this vital issue of the medical profession as a whole and of the general public is still obscure. It is essential that the situation be clarified. This can easily be done, at least so far as the medical profession is concerned, by means of a *sensible* questionnaire. Why, then, is the profession not given the opportunity to declare its will in this matter?—I am, etc.,

Bexley, Kent.

E. U. MACWILLIAM.

The Young Married Doctor

SIR,—I should like to endorse what your correspondent "Y.M.D." has to say regarding accommodation for married men in resident hospital appointments. As it appears probable that the municipal type of hospital employing an increasing number of senior resident medical officers will increase in the post-war period, it is of the greatest importance that accommodation for married men, preferably on the separate house or bungalow system, should be made available for holders of these appointments.

That committees are prejudiced against married men is only too true, and arises from their experience that the work of a married man with a home outside the hospital area frequently suffers from his divided interests. Under the present system many men are faced with the alternative of unduly delaying their marriage and the starting of a family or of giving up resident hospital work. The first alternative is not only a personal tragedy but also a national one; the second may well prove to be a serious handicap to the growth of a national hospital service. A wider outlook, a little thought in planning, and a comparatively small capital outlay are all that are required from voluntary and municipal hospital authorities to put this matter right.—I am, etc.,

E. A. HOARE,
Medical Superintendent.

Demobilization and the E.M.S.

SIR,—I have just read your issue of Oct. 7 sitting beside a "slit trench" in Holland. It is the sole connexion I have with modern advances and specialized medicine, and fulfils its function only too well. I beg, however, to criticize severely the letter on demobilization and the E.M.S. by Robert J. Rutherford (p. 482). I trust that when the war against Germany has ceased all medical officers in both the B.L.A. and the Far East who have served over three years will be replaced in the Forces gradually by E.M.S. practitioners who have had their experience uninterrupted by war and have lived in relative comfort and security.—I am, etc.,

H. HOLDEN.

Obituary

Dr. HAROLD FRANKLYN, who died on Oct. 17, was well known as a radiologist in Yorkshire. Born in Manchester in 1894 son of Arthur Franklyn, he was educated at Malvern College, at Christ's College, Cambridge (where he took his B.A. in 1916), and at St. Bartholomew's Hospital. He qualified M.R.C.S., L.R.C.P. in 1921, and held house appointments at Bart's, at the Middlesex Sanatorium, Harefield, and at the David Lewis Northern Hospital, Liverpool. He then worked for a time in the electrical department of the Prince of Wales's Hospital, Tottenham, living at High Barnet, and took the D.M.R.E. in 1926. Dr. Franklyn's next and final move was to Bradford, where he acquired a large radiological practice, he became honorary physician in charge of the radiological department at the Royal Infirmary, regional radiologist for East and West Yorkshire in the Emergency Medical Service, radiologist to St. Luke's Municipal Hospital and to the Royal Eye and Ear Hospital, Bradford, and was consultant in his specialty to the Halifax Royal Infirmary and the Skipton Hospital.

Dr. HAROLD AXEL HAIG, who died in retirement at Pagham Beach, near Bognor Regis, on Oct. 21, spent almost the whole of his professional life in the laboratory. He was born in London on March 16, 1877, and studied at University College Hospital Medical School, where he won the Bucknill Science Scholarship. He graduated M.B., B.S. Lond. in 1905. After a year or two as R.M.O. at the Essex County Hospital he was appointed lecturer in histology and embryology at University College, Cardiff, in 1910, and three years later research fellow in cancer at the University of Aberdeen. He served during the last war, with the temporary rank of captain, R.A.M.C., as pathologist to the 15th, 17th, and 21st General Hospitals, Alexandria, and before returning to this country to take up the post of lecturer in pathology and bacteriology in the Welsh National Medical School at Cardiff was for a time research pathologist in the Department of Public Health at Cairo. Dr. Haig joined the B.M.A. in 1914 and was a member of the Pathological Society of Great Britain and Ireland and the Cardiff Medical Society. He published a number of papers on cellular pathology, and was the author of *The Plant Cell: Its Modification and Vital Processes* (1910), and of *An Introduction to the Histology of Tumours* (1924).

The untimely passing of Dr. SELWYN JONES of Ruthin, at the age of 36, after a short illness, has deprived North Wales of one of the ablest of its younger practitioners. He was educated at Epworth College and in 1928 entered King's College Hospital, where his athletic prowess secured him a place in the first rugby and tennis teams. After qualifying in 1933, he set out to prepare himself, as fully as possible, for the arduous duties of his chosen life's work—general practice. He was house-surgeon and house-accoucheur at his own hospital, resident medical officer at the Royal Waterloo Hospital, and then served as R.M.O. at the London Clinic for a year. Thus equipped, he began practice at Kensington, but the lure of his native haunts was too strong and in 1939 he settled down in Ruthin in partnership with his father, Dr. T. O. Jones. In an extensive country practice, all his training was utilized to the great advantage of the community, and in a short time he won its affectionate regard to a remarkable degree. In addition to the claims of practice, he gave freely of his time and energy as medical officer to the Home Guard and lecturer to the Red Cross and St. John Organization. The most noteworthy phase in his character was careful attention to the details of treatment. His case-notes accompanying patients to hospital were models of what such notes should be, and provided clear evidence of his mature clinical judgment. Selwyn Jones, however, was much more than a successful doctor—he was a man of wide culture, a lover of books, a generous host, and he took a deep interest in all country pursuits. The sincere sympathy of a host of friends goes out to his wife, also a medical graduate, to his two young children, and to his parents.—E. W. J.

With the death of Dr. JOHN FERGUSON at his home in Stockport Road, Chorlton-on-Medlock, Manchester, aged 88, the British Medical Association loses a member who joined as long ago as 1877. He was educated at Owens College, qualified M.R.C.S., L.R.C.P. in 1876, and had served as house-surgeon and house-physician at the Manchester Royal Infirmary. He took the M.D. of Durham University in 1896 and the B.Sc. of Manchester University in 1904. Dr. Ferguson was a past president of the Manchester Medico-Ethical Society and vice-president of the Manchester Medical Society.

The Services

Capt. V. J. Downie, M.C., R.A.M.C., and Majors G. McC. Bastedo and C. E. Corrigan, R.C.A.M.C., have been awarded the D.S.O., and Capt. (Temp. Major) A. C. S. Hobson, Capt. L. Crome, J. A. Petre, and A. I. Pine, R.A.M.C., Capt. M. K. Ray and Lieut. D. K. Ramadwar, I.A.M.C., have been awarded the Military Cross in recognition of gallant and distinguished services in Italy.

CASUALTIES IN THE MEDICAL SERVICES

Died—Surg. Lieut.-Cmdr. Duncan MacKay Reid, R.N.V.R.
Killed in Normandy—Capt. James Cowie Thom, R.A.M.C.
Previously reported missing, now presumed to have lost his life in action off Brittany—Surg. Lieut.-Cmdr. Hugh De Lancey Noel Davis, R.N.V.R.
Missing in action, now presumed killed—Surg. Lieut. Peter Slade Cuthbertson, R.N.V.R.
Missing, presumed killed—Temp. Surg. Lieut. Charles John Sanders Green, R.N.V.R.
Missing at Arnheim—Capt. S. R. Mawson, R.A.M.C.
Reported missing at Arnheim, believed prisoner of war—Capt. A. W. Lipmann-Kessel, R.A.M.C.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a congregation of the Senate on Oct. 2 Dr. T. Shirley Hele, F.R.C.P., Master of Emmanuel College, resigned the Vice-Chancellorship and gave an address before his readmission to the office for the year 1944-5. In naming with reverence and honour those of the older generation who had died during the year Dr. Hele said that Sir Humphry Rolleston, formerly Regius Professor of Physic, was an outstanding figure in the field of medicine, who would be remembered not only for his literary and scientific work but for his unfailing courtesy and sympathetic understanding towards all who sought his advice. The University had done its utmost to guard the interests of those members of the staff away from Cambridge on national service, and for some long time had refused to make any permanent appointments, as these might be regarded as injurious to the absentees. A new policy had been adopted by the University in the course of the year in allowing a teaching officer, whether resident in Cambridge or absent on national service, to be appointed on a permanent basis when his appointment would not interfere with the interests of others. A committee was in being, representing the University and Addenbrooke's Hospital, to prepare the ground to implement the recommendations of the Report on Medical Schools issued by the Goodenough Committee, if and when the recommendations in the report were accepted and the necessary financial support was available. Preliminary steps had been taken to arrange for instruction in the hospitals of the Eastern Area, at the earliest possible moment after demobilization, for young medical officers whose normal training had been curtailed.

At a Congregation held on Oct. 20 the following medical degrees were conferred, all by proxy:

M.D.—F. H. Coeman
M.B., B.Chir.—A. Comfort, G. I. C. Ingram, R. H. Boardman, P. Venables
M.B.—E. B. Pawson

In the list of titles of degrees conferred by diploma on members of Gorton and Newnham Colleges during the months of July, August, and September, appears the name of M. M. Tunstall-Behrens, as receiving the M.B., B.Chir.

UNIVERSITY OF LONDON

At a meeting of the Senate held on Oct. 25 it was announced that the Faculty of Medicine had elected as its Dean for the period 1944-6 Mr. J. B. Hunter, M.C., M.Ch., F.R.C.S.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly Comitia held on Oct. 26, with the President, Lord Moran, in the chair, Air Vice-Marshal C. P. Symonds, Dr. T. L. Hardy, and Dr. J. A. Charles were elected Councillors.

The following were elected Representatives of the College: Sir Adolphe Abrahams on the Committee of Management of the Conjoint Board, Sir Comyns Berkeley on the Council of the Central Midwives Board, Sir Stanley Woodward on the Central Council for District Nursing, and Dr. J. Hay on the Court of Governors of the University of Liverpool.

Dr. H. E. Magee was appointed Milroy Lecturer for 1946. The Jenks Memorial Scholarship was awarded to Philip Hague Lovell, late of Epsom College. Prof. C. Bruce Perry will deliver the Bradshaw Lecture on "The Aetiology of Erythema Nodosum," on Thursday, Nov. 9, at 2.30 p.m., at the College.

The following, having satisfied the Censors' Board, were elected Members of the College:

*Y. Abd el Ghaffar, M.B.; J. N. Agate, M.B.; A. D. Barlow, M.B.; A. J. V. Cameron, M.B.; *Squad. Ldr. T. A. W. Edwards, R.A.F.; *A. El Mofly, M.D.; *Mahmoud N. el-D. Fahmy, M.D.; E. A. Fairburn, M.B.; *M. A. R. Favez, M.D.; J. L. Fluker, M.B.; Flying Officer J. H. Friend, R.A.F.; M. R. Geake, M.B.; Wing Cmdr. J. G. Howlett, R.C.A.F.; *Capt. J. A. Inglis, R.A.M.C.; Squad. Ldr. R. W. Lass, R.A.F.V.R.; F. K. Lau, M.B.; J. M. Lipscomb, M.B.; *Major F. L. A. Lydon, R.A.M.C.; R. I. McCallum, M.B.; *D. R. Macdonald, M.B.; G. Marcel, M.D.; Major R. J. G. Morrison, R.A.M.C.; *A. H. Mousa, M.D.; P. B. Newcomb, M.B.; *A. Omar, M.B.; J. Overton, M.B.; *Y. Rizkalla, M.D.; Dorothy H. Robertson, M.B.; Lieut. J. R. Trounce, R.A.M.C.; *H. Whittaker, L.R.C.P.; Major J. V. Wilson, R.A.M.C.

*Admitted in absentia.

Licences to practise were conferred upon the following 174 candidates (including 27 women) who had passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board and have complied with the necessary by-laws of the College:

Doreen M. Aaröe, E. W. R. Alderman, P. Allebone, P. M. Anderson, J. D. Andrew, John Andrew, Joseph Armstrong, Roy Astley, F. J. Aumonier, A. D. Bangham, R. H. O. Bannerman, J. C. Barclay, M. A. Barker, F. Batley, Katharine M. O'B. Beadon, M. F. Bethell, D. T. A. Brown, A. Bruce, Alice E. Buck, Joan Bullough, R. D. Calcott, G. R. H. Calleja, M. D. Caplan, H. S. Capore, D. Cappon, J. A. Carr, H. E. Claremont, C. B. Clarke, I. F. Collic, Pamela J. Coope, A. R. Corbett, J. H. Coulson, R. A. Cranna, G. E. Crece, R. Crese, R. H. Cuthforth, Jyoti K. Datta, P. L. H. Davey, Edith M. Wright, V. J. K. Wright, M. Zoob.

Diplomas in Ophthalmic Medicine and Surgery (sixteen) and Medical Radiology (five) were granted, jointly with the Royal College of Surgeons of England, to the candidates whose names appear in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of Aug. 19 (p. 260).

Medical Notes in Parliament

Standardized Hearing Aids

In the House of Lords on Oct. 24 the DUKE OF MONTROSE asked, in view of demobilization, what progress had been made by the Government in their negotiations with the hearing-aid manufacturers to produce national standardized hearing aids.

Lord TEMPLEMORE replied that the Medical Research Council had appointed a committee to investigate the electro-acoustic problems connected with the manufacture of hearing aids. It was hoped that this committee would be able to recommend specifications for standard models which could be sold at a reasonable price. The committee had already held several meetings, and a number of physicists had been invited to collaborate with otologists and physiologists in experimental work on their behalf. Such discussions as had taken place between Government Departments and the hearing-aid manufacturers had been very informal. He understood that the Association of Hearing Aid Manufacturers had prepared a tentative specification for a standard hearing aid, and had submitted some information about it to the committee. It was too early yet to give any indication of the price at which any standard hearing aids would be sold, but they were supplied free of charge to ex-Service men suffering from deafness due to war service.

New National Loaf

Dr. SUMMERSKILL asked on Oct. 25 whether the Minister of Food was satisfied that the vitamin content of the new loaf was as high as in the old. Col. LLEWELLYN said that before he altered the extraction rate of flour he was assured that he could

do so without there being any appreciable loss of vitamin content in the national loaf. Now that the new flour was produced on a large commercial scale he had samples continuously taken so that he could be sure that this was so.

Research under an N.H.S.

Asked by Mr. Salt on Oct. 26 to what extent questions of medical research would be dealt with in the national health scheme, Mr. WILLINK said encouragement and assistance of research would continue to be primarily the function of the Medical Research Council, which was set up by Royal Charter for the purpose. The Government intended that research and opportunities for research should be continually developed with the help of the Council.

Supply of Doctors in Defence Areas.—Mr. JEWSON inquired on Oct. 19 whether steps had been taken to provide an adequate increase in the number of medical men in defence areas from which the ban had been lifted, causing the return of the population. Mr. WILLINK said the Local Medical War Committees were keeping the situation under review. No special difficulty in these areas had so far been brought to notice. If and when the need arose the committees would no doubt make recommendations to the Central Medical War Committee in the normal way.

Rubber Gloves.—On Oct. 24 Mr. HOGG asked the President of the Board of Trade whether, in view of the increased supplies of rubber, he would increase the allotment for the provision of surgical gloves. Mr. GARRO-JONES, who replied, said that surgical gloves had to be made partly of natural rubber, supplies of which had not increased. The Minister of Supply, who was responsible for the production of these gloves, was not aware of any substantial volume of complaint that supplies were insufficient to meet essential civil needs.

Food Shortage in Holland.—On Oct. 24 Mr. FOOT informed Mr. Harvey that he had received information from the Dutch authorities that the shortage of food in Holland was acute. His Majesty's Government and the United States Government, in consultation with the Netherlands Government, were endeavouring to make arrangements for bringing relief to the civilian population.

Pneumoconiosis Compensation Cases.—Mr. HERBERT MORRISON on Oct. 29 told Mr. DAGGAR that the number of applications to the Silicosis Medical Board for certificates under the Pneumoconiosis Compensation Scheme for coal-miners in South Wales and Monmouthshire had for some time past considerably exceeded the capacity of the medical board to deal with them. In recent weeks additional doctors had been appointed to the board in South Wales with a view to expediting the examinations, but some time must elapse before the arrears were overtaken.

Notes in Brief

Penicillin is produced in India only on a laboratory scale. No difficulty is foreseen in meeting from elsewhere all military requirements.

The combined United Kingdom and U.S.A. authorities, in collaboration with the Greek Government, have made plans for introducing medical supplies into the liberated areas of Greece. UNRRA will act as agents.

No scientific attachés have yet been appointed to British missions in foreign countries, but in Washington a British mission exists to exchange scientific information with the United States Government. In Chungking Dr. Joseph Needham, F.R.S., directs an office to promote scientific contacts with China.

Medical News

The Pharmaceutical Society of Great Britain announces a lecture on "Properties and Uses of Penicillin in Relation to Pharmacy," to be given by Mr. A. L. Bacharach at 17, Bloomsbury Square, London, W.C., on Thursday, Nov. 9, at 7 p.m., with lantern-slide illustrations. This is the first of a series of meetings arranged for the winter session, to be held on the second Thursday in the months of November, December, January, February, and March.

The U.S. Office of War Information states that the problems involved in the international control of venereal diseases will be discussed by representatives of England, Norway, Mexico, Canada, and the U.S. at the post-war venereal disease control conference to be held from Nov. 9 to 11 at St. Louis. The conference will consider methods of broadening the application of recent advances in treatment and will bring together experts in all phases of venereal disease control.

Lord Moran and Prof. G. W. Pickering are to address the London Branch of the Science Masters Association on Saturday, Nov. 11, at 2.30 p.m., on "Pre-medical Education." The meeting will be held at Mercers' School, Holborn (opposite Gamage's), and admission is free. Any doctors interested are invited to attend.

The annual general meeting of the British Medical Students Association will be held at B.M.A. House, 1 Tavistock Square, London, W.C., on Nov. 10, 11, and 12. The Minister of Health is attending the session beginning at 4.30 p.m. on Friday, Nov. 10, and the chair will be taken on that occasion by Mr. H. S. South. The programme of that particular session will be: (1) Chairman's opening remarks; (2) Presentation of results of questionnaire on a National Health Service to the Minister by a member of the student body who will make a short speech; (3) Address by the Minister; (4) Questions; (5) Votes of thanks.

A meeting of the Middlesex County Medical Society will be held at Redhill County Hospital, Edgware, on Saturday, Nov. 11, at 2.45 p.m., when a clinical demonstration will be followed by three short papers on the treatment of strychnine, by Dr. M. Rose; the choice of the anaesthetic, Dr. S. W. Collin; and the problem of the treatment of varicose veins, Mr. Frank Forty.

A joint meeting between the Section of Psychiatry, Royal Society of Medicine, and the Association of Industrial Medical Officers will be held on Tuesday, Nov. 14, at 1, Wimpole Street, W.1, at 4 p.m. The subject of the discussion is "Psychiatric Advice in Industry." Speakers: Dr. Aubrey Lewis, clinical director, Maudsley Hospital; Dr. Elizabeth Banbury, investigator, Industrial Health Research Board; Dr. Ernest Capel, medical officer, Joseph Lucas Ltd.; Dr. Russell Fraser, investigator, Industrial Health Research Board.

At a meeting of the Medical Society of London to be held at 11, Chandos Street, W., on Monday, Nov. 13, at 5 p.m., Mr. John Everidge will open a discussion on "Clinical Aspects of Renal Ecstasy and Fusion."

At a general meeting of the Tuberculosis Association at 26, Portland Place, London, W., on Nov. 17 at 3.45 p.m. there will be a discussion on "The Place of Work as a Therapeutic Measure in Tuberculosis—a Re-assessment." The opening speakers will be: Drs. F. R. G. Heaf, P. W. Edwards, W. L. Yell, and J. H. Crawford.

Sir Joseph Barcroft, F.R.S., will lecture to the Food Education Society on "Food and Processing—the Nutritive Value of Processed Food," at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C., on Monday, Nov. 20, at 2.30 p.m.

The Ministry of Health emphasizes that whole-time public health medical officers who are of military age must, before applying for any other post, first obtain the prior permission of the Minister. This requirement was set out in Circulars 2818 and 2881. If the permission is not obtained before making application the Minister will not approve their appointment. A number of candidates have recently found that they have been disappointed because the Minister has felt obliged to insist upon strict adherence to this requirement.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales during the week notifications of infectious diseases rose by the following numbers of cases: measles 596, scarlet fever 220, diphtheria 58, whooping-cough 37, acute pneumonia 27.

In Durham there were 139 more cases of measles, in Lancashire 108, and in Staffordshire 75. The recent rise in the incidence of scarlet fever has been greater in Lancashire, where during the week reviewed 124 more cases than last week, and almost one-quarter of the total for the country, were notified. Diphtheria is particularly prevalent in the north, and the counties of Lancashire, Yorkshire, and Durham together had 42% of the total.

The notifications of dysentery fell by 32 to 358. The only new local outbreak of any size was in Oxfordshire, Bullington R.D. 20. The other large centres of infection were London 54, Lancashire 47, Glamorganshire 42, Suffolk 28, Hertfordshire 26, Essex 13, Norfolk 12.

In Scotland the incidence of diphtheria rose by 35, and of measles by 76; the cases of dysentery fell by 28. Measles notifications in Dundee were 40 more than last week. The number of cases of dysentery in Edinburgh and Glasgow were 17 and 51, compared with 32 and 64 of the preceding week. The 3 recent cases of typhoid in the town of Greenock are thought to be due to shellfish gathered from the Firth of Clyde.

In Eire notifications of scarlet fever rose by 17, and those of whooping-cough fell by 26.

In Northern Ireland scarlet fever rose from 55 to 105, almost half the notifications being recorded in Belfast C.B. The incidence of measles also increased in this city, from 56 to 91.

Week Ending October 21

The returns of infectious diseases during the week in England and Wales included: scarlet fever 2,176, whooping-cough 970, diphtheria 580, measles 3,779, acute pneumonia 640, cerebrospinal fever 36, dysentery 391, paratyphoid 6, typhoid 9, acute poliomyelitis 14.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 14.

Figures of *Excess of Notifiable Diseases* for the week and those for the corresponding week last year for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland.

Figures of *Births and Deaths* for the week and those for the corresponding week last year for: (a) The 126 great towns (b) London (administrative county) (c) The 15 principal towns in Eire (d) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944					1913 (Corresponding Week)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary forms for England and Wales, London (administrative county) and Northern Ireland.

‡ Includes paratyphoid fever for England and Wales and Eire.

§ Due to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Antilogia Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Diagnosing Mild Graves's Disease

Q.—A young lady fainted five minutes after the insertion of a tablet of homatropine and cocaine hydrochloride aa gr. 1/50 into each conjunctival sac. On recovering consciousness she had no perceptible radial pulse for a short time, but in half an hour recovered completely. She has slight exophthalmos, and the thyroid gland is moderately enlarged. Her pulse rate was about 86. She is 5 ft. 5 in. in height, and 5 st. 4 lb. in weight, having gained 4 lb. during one week of holiday. She is not unduly nervous, but becomes breathless on exertion. She has not been treated for Graves's disease, but appears to have presented the symptoms for several years. What further investigations are necessary in order to give a prognosis and indications for treatment? Does hyperthyroidism cause increased susceptibility to either of the drugs mentioned?

A.—The diagnosis of mild Graves's disease is often very difficult to make with certainty, largely because we have no test for thyroid function. The signs and symptoms are those of increased oxygen consumption, which may occur in other disorders, of the associated psychological and autonomic imbalance, which is not necessarily associated with thyroid disease, and of the toxic action of excessive thyroid secretion on the heart, which occurs as a rule only in obvious cases. Exophthalmos, the cause of which is not known with certainty, is a notoriously unreliable sign. The further investigations suggested are the B.M.R., which is normally raised, and the blood cholesterol, which is normally lowered; but in all probability the most useful investigation is a period of rest in bed under the eye of a physician experienced in such cases and capable of weighing all the pros and cons. In the patient in question the pros are the exophthalmos, the thyroid enlargement, the low weight (slightly offset by the recent gain), and the breathlessness on exertion. An important con is the lack of apparent nervousness, but she may be very self-controlled. The single pulse reading does not help one way or the other. Thyrotoxic patients almost to a woman have hot feet and dislike hot weather. Hyperthyroidism does not cause an increased susceptibility to either homatropine or cocaine in doses so small as the ones this patient received. In all probability she had an ordinary "vaso-vagal attack." Patients with hyperthyroidism are often unduly excitable, and therefore liable to faint.

Diuretic for Fluid Retention

Q.—A woman patient aged 48 years has hyperpiesia and fluid retention with excessive weight, probably indicating pituitary dysfunction. Great relief is obtained by the taking of diuretic. Is this drug best taken in small doses regularly, or in larger doses with an interval every few weeks or months? The patient's salt intake is kept at a minimum.

A.—A certain degree of tolerance is acquired if the caffeine tablets are taken regularly, and this probably applies to diuretic, which is theobromine with sodium salicylate. If large doses are given for some time the stomach is likely to be upset. For both these reasons it is preferable to give short courses of treatment with full doses at intervals rather than continuous treatment with small doses.

Use of Proflavine

Q.—I understand that proflavine powder, though an admirable antiseptic, causes tissue damage when applied to a wound. For this reason it is generally diluted with sulphathiazole. In what strength can proflavine be safely used? Under what circumstances is it especially recommended?

A.—Pure proflavine powder, as originally reported by G. A. G. Mitchell and G. A. H. Buttle (*Lancet*, 1942, 2, 429), can safely be applied in an amount not usually exceeding 0.5 g. to chronic suppurating wounds. The tissues in fresh wounds are more easily damaged, and for application to these it should be diluted with a sulphonamide powder: the usual mixture is one part of proflavine and 99 parts of sulphathiazole. Several recent papers have reported

favourably on the use of this powder for the prevention or treatment of sepsis in wounds of various kinds. J. S. Jeffrey and Scott Thomson (*B.M.J.*, July 1, 1944, p. 1) refer to its use as an alternative to penicillin for preparing an infected gunshot wound for suturing. P. B. Ascroft (*Lancet*, 1944, 1, 594) applied it prophylactically to operation wounds. G. Y. Feggetter (*ibid.*, p. 593) used it in war wounds both as a preventive of infection and for the treatment of established sepsis, and J. McIntosh and F. R. Selbie and their colleagues (*ibid.*, p. 591) describe its use for a variety of purposes in civilian practice.

Barotrauma

Q.—I have a medical friend who lost his hearing in a short journey by air. What are the dangers and the remedies therefore?

A.—The information given is very meagre. Before giving a reliable answer it would be necessary to know far more of the clinical features; the time elapsed since the trip; how much of the hearing has been lost; the presence of pain on descent; the drum appearances; and the result of auto-inflation by Valsalva's method. However, the most likely cause is barotrauma, with or without a pre-existing cold in the head, leading to partial obstruction of the Eustachian tubes. Perforation of the drum with otitis media and sequelae is very rare and a theoretical danger. More likely is the production of a middle-ear effusion and deafness from a severe barotrauma. If the tubes have remained closed and the drum tension unrelieved for some time then there is a risk of permanent middle-ear damage and deafness. Careful examination of the drum (or drums) is necessary to determine what has happened. If there is no movement on auto-inflation then gently politizerize; if unsuccessful then Eustachian catheterization must be carried out by an expert. Treat a persistent cold with inhalations, etc. Should deafness persist after the tubes are patent then seek the advice of an E.N.T. surgeon with barotraumatic experience. Early lip-reading is a wonderful help, but this is taking the gloomiest view of the condition, particularly as the trip is described as short, and so the barotrauma may not have been severe.

"Red Vision" after Cataract Operation

Q.—A lady now aged 70 had an operation for cataract some four or five years ago. She has been persistently, almost continuously, troubled by "red vision." Everything is coloured red, more or less. Nothing has done any good. Can any suggestions be made as to cause, cure, or alleviation?

A.—Such disturbance of vision is uncommon, and though there are several explanations for it none is satisfactory. Apart from the unlikely possibility in such a case of an intra-ocular haemorrhage, it seems reasonable to suppose that the lens of the patient offered an unusual obstruction to the red end of the spectrum. When the lens was removed, that part of the spectrum was able to reach the retina in an unaccustomed degree, giving a warmer hue to objects. It is also a fact that, owing to the chromatic aberration of the eye, overcorrection with a convex lens tends to favour the red as against the green end of the spectrum. Alleviation may be obtained by checking the correcting lens, failing which a tint in the lens reducing the brightness of red colours might help. As a rule, however, the red coloration is not seen on all occasions so that a tinted glass should be used with discretion.

Hormone Treatment of Enlarged Prostate

Q.—A man aged 54 suffered from frequency of micturition, especially at night. He was seen by a surgeon who found a slight prostatic enlargement, but not enough to justify operation. He was advised to try stilboestrol, and after taking 1 mg. three times a day for three weeks, he noticed a swelling of the breasts with some scabbiness (? dried discharge) of the nipples. Although it is now nearly two months since he stopped taking the stilboestrol, the breasts are still prominent and tender. Can anything be done to relieve the condition? There has been no improvement in the frequency.

A.—This condition of the breasts sometimes occurs in men who take oestrogens, but it is unusual for the condition to persist two months after the cessation of such therapy. Testosterone should be tried, and may ameliorate the condition. It can be given in the form of injections, 25 mg. three times a week, or methyl testosterone, 5 mg. t.d.s., allowed to dissolve under the tongue. If the condition does not improve within two weeks, this therapy is unlikely to be helpful. As to the original condition of urinary symptoms due to an enlarged prostate, favourable reports on the effect of stilboestrol have been recorded, but on the whole the results are disappointing, in contrast to the favourable results (usually temporary) with stilboestrol in carcinoma of the prostate. A few years ago testosterone or methyl testosterone were strongly advocated for benign enlargement of the prostate, but a controlled series of cases undertaken by the Medical Research Council did not confirm these claims. Nevertheless, in practice several clinicians still prescribe testosterone, and claim objective improvement. If enlargement of the prostate is associated with the male climacteric and gradual decrease of testicular function, testosterone would be logical therapy.

Satisfactory Contraception

Q.—What is considered to be the most satisfactory contraceptive for a woman, married in the early thirties, to have had no children? What are the disadvantages or objections to intercourse during menstruation apart from the aesthetic aspect and risk of infection to the woman?

A.—The choice of contraceptive depends to some extent on the woman concerned, her intelligence and outlook on these matters, the shape of the vagina, direction of the cervix, etc. A Dutch vaginal pessary or a cervical cap would probably be the most satisfactory appliance, but should be used in conjunction with a chemical contraceptive—e.g., phenyl mercuric acetate—incorporated in a jelly or soluble pessary, at a high degree of safety is to be achieved.

Objections to coitus during menstruation are to some extent based on old religious views and superstitions to the effect that at such time a woman is 'unclean' and that the menstrual discharge contains noxious factors. Such ideas are deep-rooted and even to-day probably play an important, even though subconscious part in the increased modesty of women during menstruation. In any case coitus during menstruation would sound a messy procedure and, on that account, repugnant to most people. Yet coitus is probably more frequently practised during menstruation than is generally realized. Indeed, in some individuals—and it applies to either partner—sexual desire appears to be increased at that time. When both husband and wife are healthy, there can be little objection on purely medical grounds. The alleged risks of vaginal tears and menorrhagia are largely theoretical, although tenderness of the vagina which some women experience during menstruation would be a contraindication. If active or latent infection is present in either male or female genital tract then the position is altered. The resistance of the female to infection is lowered during menstruation. Moreover, if a woman has chronic and dormant infection in the cervix or tubes then there would be an increased chance of an exacerbation and extension of the trouble. As the questioner points out, the real objection to coitus during menstruation is the obvious aesthetic one, and it operates particularly when the flow is at its height. When, however, the discharge is scanty or intermittent, and the couple are mutually desirous of intercourse, there does not appear to be any valid reason for advising against it.

Carbon Monoxide Poisoning

Q.—What is the treatment of chronic carbon monoxide poisoning? A patient of mine, a blacksmith, has symptoms corresponding to those described by H. S. Stannus in the *JOURNAL* of July 22, which, he says, are also found in chronic carbon monoxide poisoning. As my patient is a blacksmith, chronic carbon monoxide poisoning is the more probable diagnosis. Blacksmiths are usually good beer drinkers. My patient is not. Has the taking of alcohol anything to do with preventing chronic carbon monoxide poisoning in these people?

A.—Carbon monoxide is not a cumulative poison. There is therefore no such condition as the expression "chronic carbon monoxide" would imply. Regulation of working hours should be such that a man lives in an atmosphere not contaminated with carbon monoxide for at least twice as long, in the 24 hours, as he does in one that is contaminated. In pure air and with a normal volume of breathing, small amounts of carbon monoxide are readily ventilated out of the blood. Repeated exposures, as in the case of the blacksmith, may temporarily, but only temporarily, affect health, more often a compensatory polycythaemia develops to compensate for the lack of oxygen. Symptoms such as loss of appetite, digestive disturbances, headaches, diminished vigour, poor colour, and apathy disappear upon removal of the patient from the exposure. Stannus, in his paper in the *Journal* on July 29 (p. 144), suggests "that riboflavin deficiency interferes with the normal functioning of the capillary with the production of a tissue anoxia," and draws a parallel between such a condition and that which arises if the tissues are fed with CO haemoglobin. He points out that carbon monoxide is believed to inactivate cytochrome oxidase and thereby inhibit oxygen consumption by preventing electron transfer by uniting with the iron in the ferrous form. There is no association between riboflavin deficiency and carbon monoxide poisoning. Alcohol has no effect in preventing "chronic" carbon monoxide poisoning.

Prevention of Mould

Q.—How are the following prepared to prevent mould formation: (a) 1/2% solution ephedrine for nasal spraying and (b) novocain acid boric liq. adrenalin 1/1000 eye drops?

A.—The method of preparing solutions etc. will not alone prevent the formation of moulds in susceptible preparations, but the use of sterile materials and the employment of aseptic conditions when making will help to retard it. It is now quite common for fungicides to be incorporated in addition to the therapeutic ingredients, and a number of proprietary articles, mostly esters of parahydroxybenzoic acid, are on the market. They have the

advantages of being stable, non irritant, and non toxic, and are effective in very low concentrations. Parachlorometacresol (chlorometacresol of the B.P. Third Addendum) and phenylmercuric nitrate also have these virtues and are in frequent use. In the strength required to be bactericidal (0.25%) parachlorometacresol sometimes causes irritation in the eye but it is effective as a fungicide in a concentration as low as 1 in 10,000 and in this concentration is non irritant. A 1 in 100,000 of phenylmercuric nitrate is an effective fungicide and may be used for most preparations, including the two in question, but it is not soluble in oil whereas parachlorometacresol is, and may therefore be used for the oily as well as the aqueous ephedrine spray.

Mortality from Heart Diseases

Q.—What are the figures for the mortality from (a) angina pectoris (b) coronary artery thrombosis (c) heart failure due to high blood pressure for (1) the first year for which figures are available, and (2) the most recent year for which records are available?

A.—In 1940 the deaths of 1,671 males and 706 females were attributed to angina pectoris without mention of coronary disease, in 1939 the corresponding figures were 1,677 and 684. Deaths from coronary artery thrombosis are included with diseases of the coronary arteries, in 1939 and 1940 10,242 and 10,648 males and 5,241 and 5,605 females respectively were said to die from such disease. Before this the deaths from both these conditions were included with diseases of the coronary arteries. It is not possible to reconstruct the two subheadings for earlier years, but for the combined group there has been a progressive increase in mortality in the past twenty years. During 1911-21 the crude death rate was fairly constant around 36 per million for males and 16 for females; the rate then began to rise and was 216 for males and 87 for females in 1931, and, in 1940, 675 for males and 292 for females.

Deaths from heart failure due to high blood pressure were not tabulated separately until 1939, in 1940 1,072 males and 945 females were certified as having died from this cause. The reconstruction of this cause for the preceding ten years was made in the *Statistical Review* of 1940, which showed a steady rise in mortality from 7 per million in 1931 to 59 in 1940 for males, and from 8 to 44 for females. In the years preceding 1939 these deaths had been included in the group of abnormalities of blood pressure, which were tabulated for the first time in 1924, when 21 males and 26 female deaths were classified as due to abnormality of blood pressure.

Piercing the Ears

Q.—It has been the custom for ladies to resort to the piercing of the lobule of the ear prior to wearing earrings. Jewellers in most cases have ceased to carry out this practice and consequently application is made to the doctor. What is the technique which should be followed, and what sort of earring should be inserted in the pierced ear while healing is taking place?

A.—Perforation of the lobule of the ear should be carried out with careful aseptic precautions. There is hardly need for anaesthesia since the lobule is very insensitive to pain. The puncture may be made by a sterilized, large, round bodied needle or perhaps better still by a small trocar. A small piece of sterilized cotton wool may be placed against the opposite side of the lobule to prevent haemorrhage while the puncture is made. Jewellers usually recommend the insertion of a small split metal ring (which should also be sterilized) which can be left in for several days and moved round the ring until the ear-ring itself may be inserted.

B. Newport Enteritis

Q.—Can you suggest any cure for B. *newportensis* of several years' standing? I have tried (a) stovaine and (b) sulphaguanidine with no effect. The condition has been similar for 10 years. The patient is a lady aged 75.

A.—An attack of bacterial food poisoning due to a *Salmonella* organism like the *Newport* bacillus is usually characterized by severe vomiting and diarrhoea of 1 to 2 days' duration. The organism producing the intestinal upset by reason of its 'enterotoxin' may remain in the gut for some days or weeks after the acute attack, but persistent carriers of the food poisoning group of organisms are very rare. Sometimes however the *Salmonella* organism, instead of causing an enteric local irritation in the bowel, gets into the body tissues and produces a continual fever with little intestinal upset. In such a case or even after a typical attack of food poisoning, the organism may gain access to the gall bladder and remain there, particularly if the patient is suffering from gall stones. Something of the kind may have happened with this patient who with a 10-years history must be regarded as a chronic *Salmonella* carrier. Recurrent attacks of diarrhoea and intestinal catarrh are a feature in some chronic typhoid carriers—a kind of auto-intoxication—and this may be the explanation of the enteritis in this patient. If so, the only hope of permanent cure is to remove the focus of infection, most likely the gall bladder, but cholecystectomy in a woman of 75 is not lightly to be recommended or undertaken. Unfortunately the intestinal sulphonamides—sulphaguanidine and succinylsulpha-

thiazole—are not effective against the *Salmonella* family, and recourse must be had to palliative treatment—e.g., a chalk or bismuth mixture. Of course, the enteritis may be due to some other cause than the Newport bacillus, and if the patient's health is deteriorating a thorough overhaul in hospital may be indicated.

Chronic Diarrhoea in Childhood

Q.—What is the treatment of a child of 2 who is suffering from a mild chronic diarrhoea, with much mucus with the stool? The pathological report on the faeces shows an almost pure growth of the haemolytic streptococcus. In other respects the child seems perfectly well. There seems very little in the literature on this subject.

A.—Mild chronic diarrhoea with much mucus in the stool is relatively common in children of from 1 to 3 years, an observation all too familiar to nursery-school nurses. The almost pure growth of a haemolytic streptococcus is probably the result of the diarrhoea and not the cause. The condition may be due to an unsuitable diet or a particular difficulty with the digestion of fat, vegetable matter, or starch; to an infection with one of the dysentery bacilli or the tubercle bacillus; or to infestation with a parasite such as *Giardia intestinalis* (lamblia). Three stools at least should be examined microscopically for ova, parasites, or cysts, and for food residues. Unfortunately, in the majority of cases no cause will be found, and then if the child is well and is gaining weight properly, no treatment is needed. In any case treatment by low-residue diet, oil, rice, in minim doses, or pulv. ipecac. co. is disappointing. A good account of chronic diarrhoea in childhood has yet to be written.

Pregnancy and Phthisis

Q.—We know that pregnancy increases resistance to phthisis, but parturition diminishes that resistance. Would you tell me whether anyone has tried to treat tuberculosis with (among other things) extracts of corpus luteum with calcium and vitamin D intramuscularly? This should be possible in females at least.

A.—The supposed beneficial effect of pregnancy on pulmonary tuberculosis was noted by Hippocrates, but, in spite of a strong clinical impression, there is little if any scientific evidence that pregnancy has any effect on the course of the disease. Many authorities think that improvement during pregnancy and relapse during the puerperium may be explained by the mechanical effect of the abdominal tumour, which raises the diaphragm and thus restricts the movements of the lungs. It has been suggested that a pneumoperitoneum should be induced after delivery in tuberculous women to compensate for the shrinkage of the uterus. Nevertheless, there is some experimental work which suggests that the gonadotropic hormone found in the urine of pregnant women exerts a favourable influence on the progress of experimental tuberculosis in animals (Steinbach, M. M., and Klein, S. J., *J. exp. Med.*, 1937, 65, 205). The questioner is referred to an article by W. D. W. Brooks (*J. roy. Inst. Hyg. publ. Hlth.*, 1940, 3, 67) for a recent summary of the whole position.

Mixing T.A.B. and Tetanus Toxoid

Q.—Is there any contraindication to mixing the annual booster dose of 0.5 c.cm. of T.A.B. vaccine and 1 c.cm. of tetanus toxoid? The preparations we use (R.A.S.C.) are mixed typhoid and paratyphoid vaccine by the Army Medical College and Wellcome tetanus toxoid—i.e., into a 10-cm. syringe take 6 c.cm. of T.T. and 3 c.cm. of T.A.B. and give 1.5 c.cm. of the mixture to each soldier.

A.—Probably no lessening of immunizing power would result from mixing, but this is an assumption; and before to-day assumptions have led to disconcerting results when various antigens containing different antiseptics have been mixed. I should therefore not adopt this practice as a routine or convenience until someone has fully tested the procedure in controlled experiment. I should mix these prophylactics in an emergency if limitations of time, space, or syringes made that advisable. I should then be careful to mix thoroughly by movement of the piston and should rigorously discard any material not made up at one sitting.

INCOME TAX

Re-starting in Private Practice: Purchase of Car

C. B. is at present working full time in the E.M.S., using his car for his honorary posts and receiving no income-tax allowance for travelling expenses. He will shortly start a consulting practice—from scratch, as his pre-war practice has been dispersed. Will it be to his advantage to put off buying a new car until after he recommences private practice?

A.—In the circumstances we are of opinion that C. B. will be unable to resist the contention that the cost of purchasing the new car will be capital outlay and not deductible as an expense of carrying on the new practice. He will, however, be entitled to claim the usual depreciation allowance, calculated on a percentage of the capital value as at the commencement of the new practice.

The only difference, therefore, which an immediate purchase of a new car would create would be that he would lose the depreciation allowance on any reduction in value of the car due to the period from the date of purchase to the date of restarting private work. We gather that this would be negligible.

LETTERS, NOTES, ETC.

Fracture-dislocation of Talus

Col. R. JACKSON, M.B., C.M. (St. Helen's, Lancashire) writes: On Sept. 16 you published an article by Squad. Ldr. Theodore James, describing a fracture-dislocation of the astragalus, with x-ray illustrations. Two prints of an almost identical condition, which were taken by me in 1899, were published, with an account of the case, in the *Quarterly Medical Journal* (Yorkshire) in February, 1900. This was a very interesting case, as the man refused any treatment for over twelve months, and in the end made a perfect recovery and went back to his work down the mine.

Simple Splint for Fracture of the Clavicle

Mr. FRANK COLEMAN (London, W.1) writes: I was interested in Mr. Whitchurch Howell's "splint" (*B.M.J.*, Oct. 7, 1944). Mr. McAdam Eccles, when in charge of an aid post at which I was a medical officer, showed us how to use two rubber rings such as those used in deck tennis, and it appeared to be a highly satisfactory way of dealing with this common form of fracture. Mr. Howell does not state the material he had his rings made of, but as rubber is scarce it might be that "light plastic" could be used in the future.

Rhubarb

Mr. D. C. L. FITZWILLIAMS, F.R.C.S. (London, W.1) writes: Under the heading "Rhubarb and Breast Milk" (Oct. 14, p. 518) the answer stated, "the cathartic principles . . . are present . . . only in the fruit"—by this I suppose the stalk is meant. The answerer then proceeds to say that the "root . . . is used as a source." Let him try next season to put a little of the young yellow leaf at the top of the young stalk in a salad; it is excellent, but be very careful that it is only a little, as he will find that the active principles are not at all confined to what he calls the "fruit."

* During the last war severe poisoning from oxalic acid occurred in persons eating rhubarb leaves.—Ed., *B.M.J.*

Syringe for Self-administration of Insulin

Dr. F. M. HILLIARD, F.R.C.P.I., writes from Blackpool: I enclose a cutting from the *B.M.J.* of Oct. 23, 1925, p. 632, in which you published a modification of the Record syringe which I devised for the automatic control of insulin dosage. It was made by Messrs. Allen and Hanburys, and had an advantage over that described by Dr. C. T. Andrews (Oct. 21, 1944, p. 534) in that the dose could be more accurately adjusted by means of two locking nuts on a threaded piston shaft. Since then I have used it frequently for diabetic patients with failing eyesight. As a result of my original notice, I received many letters of appreciation from patients who found the idea helpful. Nowadays the hospital engineer can thread the shaft and fit two nuts on any standard Record syringe.

Tetanus

Dr. JOHN FODDEN (Huddersfield) writes: It has been my experience in a short postgraduate career to witness four cases of severe clinical tetanus. These cases were supported by bacteriology. May I quote two, as they were all very similar. The first was that of a young cotton-worker in a crowded industrial district, who pierced her thumb with a large clean needle while at work in a factory. After two days slight sepsis developed over the small puncture wound. Six days later she developed all the signs and symptoms of acute tetanus toxæmia. To this she succumbed. The second case was that of an adult male, who was at work in an iron foundry. A large piece of pig-iron fell near his foot. A protruding jagged cone of metal pierced his boot and entered his great toe. The depth of penetration was very slight, though a small hæmatoma was obvious some time later. The man was not away from work. There was no crushing of the toe whatsoever. The wound did not heal well, and the surrounding area of skin was somewhat discoloured. Eleven days later the clinical onset of tetanus made its appearance. After a severe fight for existence this man lived. Isolated bacteriologically in all the cases were pathogenic aerobes, as well as the tetanus bacillus. In none of these cases was there any trauma worth mentioning, and certainly no loss of blood supply. Thus, with reference to your correspondent's reply (Sept. 16, p. 391) regarding tetanus prophylaxis, I feel that sufficient emphasis was not placed upon small wounds of this type—i.e., small puncture wounds. Further, surely more importance must be attached to these wounds occurring in an agricultural area than to those which happened in an area peculiar to industry. I am afraid that I now look upon the much-perpetuated facts of gross muscle damage, trauma, and loss of blood supply as only part of the life-story of tetanus infection and its symptoms.

ACUTE PERFORATED PEPTIC ULCER FREQUENCY AND INCIDENCE IN THE WEST OF SCOTLAND*

BY

C. F. W. ILLINGWORTH, F.R.C.S. L. D. W. SCOTT, M.R.C.P.

AND

R. A. JAMIESON, F.R.C.S.

During the past half-century several hundred reports have been published on the frequency and incidence of perforated peptic ulcer. Nearly all of them, however, have been based upon the experience of individual surgeons or single hospitals, and have thus been limited in scope. It seemed to us, therefore, that there was a need for a survey based upon a wide region and dealing with a large series of cases. We are fortunate in having in the West of Scotland such a region with a population for which the Census provides accurate data as to size and composition; and since perforated ulcer is exceptionally common in this region our series is a large one—far exceeding any previously reported—and eminently suitable for statistical analysis.

The region comprises the city of Glasgow and the counties of Argyll, Dumfries, Lanark, and Renfrew. This area was selected because it forms the natural (and, as regards emergency work, exclusive) catchment area for a comparatively small number of hospitals, mainly situated in Glasgow. It can be stated with confidence that practically all perforations within this area are treated in the hospitals listed, and, moreover, that these hospitals treat practically no perforations from beyond this area.

According to the Registrar-General's estimate for 1938 (the last figures available) the population of this area was 2,169,959. Over 80% of the population lies in the congested city of Glasgow, the towns of lower Clydeside, and the industrial districts of Lanarkshire. The remainder includes the sparsely populated highland county of Argyll. The 1931 Census shows that 92.2% of the population is urban, 7.8% rural. The population is thus predominantly town-dwelling and industrial. The industries are mainly of the heavy type, particularly mining and quarrying, engineering, shipbuilding, and allied trades.

In this region we have obtained records of all perforations treated in hospitals of over 15 beds and in private practice during the year 1943. For earlier years, since the records of the smaller hospitals are not available, we have restricted our survey to the three main Glasgow voluntary hospitals (Royal, Western, and Victoria Infirmarys). These hospitals in 1943 treated 80% of perforations in the region; this proportion is known to be correct also for 1938, and our knowledge of local conditions convinces us that it is reasonably accurate for earlier years; we therefore feel confident that the records of these hospitals may be used as a basis for assessments in regard to the whole population. In these three hospitals we have obtained records of all perforations treated during the 20-year period 1924-43, and this series, which comprises over 7,000 cases, provides the material for the greater part of this report.

Frequency of Perforated Peptic Ulcer in the West of Scotland, 1943

Information regarding perforations treated during 1943 was sought from all hospitals of over 15 beds and from all surgeons in private practice in the area. Full records were obtained

from all the hospitals except three small cottage hospitals and from 25 of the 28 surgeons circularized. Our figures (Table I) may therefore be regarded as substantially complete.

TABLE I—Perforated Peptic Ulcer: West of Scotland, 1943

	No. of Cases
Seven cottage hospitals	376
Private cases	45
	31
	10
	9
Total	471

It will be noted that of the total of 471 cases 376 (79.8%) were treated in the three voluntary teaching hospitals. The records of these hospitals form the basis for the remainder of this report. The number of cases treated in municipal hospitals was small, as was to be expected in view of the fact that these hospitals in Scotland do not commonly admit emergency cases. It will be seen also that only 9 cases are classified as "private cases." This low figure may be due to the fact that in Scotland members of all the social classes seek hospital admission for urgent surgical treatment. The incidence of perforation in different social classes merits investigation.

Annual Incidence during 20-Year Period, 1924-43

To ascertain the incidence of perforated ulcer in the 20-year period 1924-43 we have obtained records from the three main Glasgow voluntary hospitals, the Royal, Western, and Victoria Infirmarys.

Fig. 1 shows that the number of perforations treated annually increased rapidly in the period under review. In the pre-war

* A survey made under the auspices of the Nuffield Provincial Hospitals Trust.

years there was a fairly uniform increase from rather less than 200 in 1924 to rather more than 400 in 1938. During the war the number of perforations was higher in 1940-1 and lower in 1942-3 than would have been expected on the

Estimating the total cases in this way, and using the Registrar-General's estimates of population (which are available only up to 1938), the incidence of perforation per 100,000 from 1924 to 1938 is:

Year:	1924	'25	'26	'27	'28	'29	'30	'31	'32	'33	'34	'35	'36	'37	'38
Incidence per 100,000	11	12	16	17	19	20	19	20	20	19	23	22	22	22	25

The significance of this increase in incidence during the 20-year period is best appreciated in the light of earlier observations. Perforated ulcer is said to have been rare in

basis of the trend in the previous 16 years; both the excess and the deficiency are statistically significant. It should be added that these changes are not due to war-time changes in the population.

The figures given provide a basis for estimating the changing incidence of perforation in a known population. We have already shown that the records of the three main hospitals represent 80% of the total hospital admissions. We believe, further, that the total hospital cases approximate very closely to the total number of cases occurring in the population. Doubtless there has been some improvement in the diagnosis of perforation in the period under review, but since the pain following perforation is so commanding, the clinical features so characteristic, and the urgent need for operation so clear, it seems reasonable to suppose that even 20 years ago very few patients failed to reach hospital.

the 18th and the early part of the 19th century, and it was only in the closing years of the 19th century that a notable increase in incidence appeared. This is illustrated by the experience of the Western Infirmary, Glasgow, where the records go back to 1870. The first perforation was admitted in 1896 (Fig. 2), and from then until 1941 with few exceptions each year has seen an increase. Admittedly no great reliance can be placed on these early figures, for the value of surgical treatment for perforated ulcer gained wide recognition only about the turn of the century, and during the succeeding two decades undoubtedly the admission rate was influenced

by improving diagnosis, increasing population, and better transport facilities; but even when due allowance is made for these factors it would seem that a remarkable increase in frequency has in fact occurred.

Incidence of Perforations during the Present War, with Special Reference to Air Raids

We have drawn attention (Fig 1) to the marked rise in incidence of perforations in Glasgow in 1940-1. A similar rise has been noted by workers in other parts of the country (Stewart and Winsor (1942) in London, Rendle Short (1942) in Bristol, Wilson (1942) in Liverpool and Riley (1942) in Newcastle).

In Fig 3 our records are shown alongside those published by Spicer, Stewart, and Winsor (1944) for comparison. Admittedly these graphs which show average incidences for different parts of the various years are deceptive for they take no account of seasonal fluctuations but at any rate they show that the general trend in the two cities was closely

the high incidence of perforations in March cannot be attributed to them, for of the 36 perforations recorded in March no fewer than 41 occurred before the air raids began.

From these observations it is clear that in Glasgow the local air raids cannot be held responsible for the 1940-1 increase of perforations, and other factors require to be considered. During the period in question the whole country was in a state of nervous strain as a result of the war situation. From the summer of 1940 onwards, also there was a great increase in the amount of overtime work, and there were additional duties in connexion with the Civilian Defence Services and the Home Guard: the resulting weariness, lack of sleep, and irregularity of meal hours might well be tolerated for a few months but might later precipitate perforation. Finally, it is possible that the food shortage

similar. In London the rising incidence was noted shortly after serious air raids began (in Sept., 1940), and a similar correlation was noted in Bristol and Liverpool. So far as Glasgow is concerned, however, a close study of the figures leads us to the conclusion that such a correlation did not exist.

In Fig 4, which shows the incidence by months from 1938 to 1943, it will be seen that in Glasgow the incidence rate began to rise in the autumn of 1940, reached a high peak in March, 1941, and remained abnormally high until the end of June, 1941. But in Glasgow the rise in incidence did not follow air raids, on the contrary, it anticipated them. In Glasgow there was nothing comparable to the prolonged bombardment to which London was subjected. Apart from a few desultory raids, which excited greater interest than apprehension, the first attacks to be sustained were the two heavy raids in March 1941. These raids occurred on March 13-14 and 14-15 but

which was beginning to be evident at that time may have exerted an influence.

The fall of incidence after June, 1941, and in 1942-3 is equally interesting and even more difficult to explain. It could be suggested that ulcer patients who might have perforated in 1942-3 had already done so in 1941, but this explanation will not hold water, for one perforation does not protect against subsequent ones. There is indeed no ready explanation of this fall in incidence.

Sex Distribution (3 Main Glasgow Hospitals; 20-year Period)

The sex distribution is shown in Fig 5. The great preponderance of males is clear, and the overall ratio of males to females is 6796 to 360, or 19 to 1. It will be seen that the incidence rate of perforations increased in both sexes

throughout the 20-year period, and the ratio of 19 to 1 was substantially maintained, though there were wide fluctuations from year to year. The rise in 1940-1 and the fall in 1942-3 are seen to be confined to males. In females the general trend of the pre-war years was maintained. This finding is somewhat surprising in view of the great changes which have taken place, especially since 1939, in the habits and working conditions of women.

Age Distribution (3 Main Hospitals; 20-year Period)

The general characteristics of the age distribution are at once apparent from Fig. 6, which shows the 7,156 cases of our series arranged in 5-year groups. To obtain the true incidence at different ages a correction must be applied, to allow for the diminishing numbers in each age group in the population as age advances. The results are given in Fig. 7, which shows (for both sexes and for males) the incidence rate per 100,000 living in each age group. It will be seen that the incidence reaches its maximum between 35 and 45 years and falls only slowly thereafter.

An interesting feature is the sudden increase in the frequency of perforation at adolescence. Perforation in childhood is rare: in our series (exclusive of the few cases which may have been treated in the Royal Hospital for Sick Children) there was one perforation at 8, one at 11, and one at 12 years. From age 13 to age 19 there is a truly remarkable increase, the numbers observed at successive single years of age being 1, 6, 16, 32, 44, 86, 101 (see Fig. 8).

The age distribution did not remain stable throughout the period. Between 1924 and 1943 the mean age rose by some $3\frac{1}{2}$ years, the rate of increase being fairly uniform. The rise is doubtless due in part to the increasing mean age of the population in the area served: this does not, however, appear to be the whole explanation, and the question is being studied further.

In males and females the age distribution is dissimilar. It will be seen from Fig. 6 that the mean age of males is 3 years less than the mean age of females. Analysis shows that it is extremely improbable that a difference of this magnitude has arisen by chance. Nor is the difference to be explained by a discrepancy in the population served, for the mean ages of adult males and females in the population are almost equal. We believe, in consequence, that there is a small but nevertheless a real difference in age incidence in the two sexes.

(To be concluded in next week's issue)

EPISIOTOMY

BY

J. D. S. FLEW, M.D., M.R.C.O.G.

During the training of the medical student and pupil midwife in the labour ward much stress is laid upon the prevention of perineal tears, and to a great extent their skill at delivery is judged on the results obtained by them in this direction. Whilst agreeing that, in general, an intact perineum is better than a torn one, this statement needs qualification and consideration before it can pass unchallenged. Lubin (1932) has stated: "It is presupposed that a patient without a lacerated perineum fares better than her more unfortunate sister in so far as puerperal morbidity, comfort, future pathology, and disability are concerned." The damage incurred by the patient in order to maintain the integrity of her perineum must be considered.

Disadvantages of a Torn Perineum

What are the possible disadvantages of a torn perineum? The greatest is a complete tear through the sphincter and mucous membrane of the rectum, so that the patient is left with a recto-vaginal cloaca, incontinent of flatus and faeces. This is a disaster, and the repair of a complete tear a major surgical operation, upon which depend that patient's future comfort and happiness, for without complete rectal control she will be forced to segregate herself. Even if the operation is "almost successful," so that she has sphincter control restored but is left with a recto-vaginal fistula, she will be miserable and

remain a social outcast until at a subsequent operation that fistula is repaired.

A patient whom I saw in 1937 illustrated this condition. She had a complete perineal tear at the birth of her first baby, four years previously. This had been sutured, but she was left with a recto-vaginal fistula, which had defied three attempts at repair, after which her advisers had told her that nothing further could be done for her, but that in time the fistula might close spontaneously.

For four years that woman had been afraid to associate with others. She has never been to a neighbour's to tea or asked anyone to her house. If she became constipated, flatus escaped through the fistula; at other times the vagina was always contaminated by faecal matter. No coitus had occurred since her confinement, and as the result of all these facts her mental condition had deteriorated, and at times she had considered suicide.

I admitted her to University College Hospital, and, using silver wire sutures, as first advocated by Marion Sims for vesico-vaginal fistula, successfully closed the fistula and a most miserable period in that patient's life.

There can be no argument against the statement that a perineal tear involving the rectum must be avoided at all costs. Tears which do not reach the rectum are less serious, but they involve the risk of sepsis, they need to be repaired, the sutures are uncomfortable during the 7-10 days in which they are *in situ*, and if good apposition is not obtained (by no means always easy) the patient may be left with a painful scar, which at times results in dyspareunia.

These facts are good evidence in favour of guarding the perineum from injury, but do they justify the enthusiasm of many labour-ward sisters and other teachers of midwifery, as a result of which their pupils come to regard their task as one in which the three essentials are to leave a live baby and a living mother in whom the perineum is intact?

In order to prevent perineal laceration the second stage of labour is often grossly lengthened. The mother is subjected to unnecessary pain and the foetus to prolonged pressure. The perineum is stretched so that it becomes of tissue-paper thickness, but it remains intact. True, the baby may be in white asphyxia or even dead, the mother distressed, the uterus exhausted so that post-partum haemorrhage is more probable since it has been working hard to overcome the resistance of the perineum, augmented by the strong hand of the anxious accoucheur. Nevertheless, we repeat with pride: "The perineum is intact."

Aetiology of Prolapse

What is discovered if cases subjected to such treatment are followed up? In any gynaecological clinic approximately 25% of the multiparous patients attend on account of symptoms referable to prolapse, and of the same group admitted for operation the figure is nearer 50%. Do these cases occur because of perineal tears? No. Many cases of unrepaired complete tear of years' standing have no prolapse at all, whereas by prevention of perineal rupture, especially in primigravidae, many cases of prolapse are unwittingly caused.

Koster (1935) states that the uterus cannot be supported by any structures at the base of the broad ligament, nor by any structures attached to it. He maintains that the muscles closing the pelvic aperture are the true uterine supports, and that once these are damaged the intra-abdominal pressure, especially when raised as in straining, coughing, etc., causes descent of the uterus. This would indicate that the uterus is pushed downwards from above rather than pulled downwards from below.

Mengert (1936), however, states that it is doubtful if the pelvic floor affords any support to the uterus, and bases his opinion on experiments performed on eight cadavers. A weight of 1 kg. was attached to the cervix in each case and various structures were divided. No uterine descent occurred until the lower third of the broad ligaments and upper two-thirds of the paravaginal tissues were divided. Then there was an average uterine descent of 10.5 cm., in spite of the fact that the pelvic floor was intact in all cases.

Here are two diametrically opposite opinions—and does not the truth lie between the two? Surely the uterus is supported from below by the pelvic floor and suspended from above by such structures as the cardinal and utero-sacral ligaments? Of these, the support from below is the more important, and whether the uterus can descend or not depends

primarily upon the integrity of the pelvic floor. Mengert's theory would explain those cases of vault prolapse which may occur in nulliparous patients and which account for only a small proportion of the total number of cases. Koster's theory must be criticized because of the statement that the uterus is pushed downwards by coughing, straining, etc. Certainly this may aggravate the condition, but is it the primary factor?

One has but to see a few cases of prolapse to realize that a cystocele and rectocele occur low down in the vaginal wall within an inch of the introitus, not high up about the vaginal fornices. This sagging of the vaginal wall tends to pull the uterus downwards, since they are attached to the latter about the level of the internal os. Furthermore the distance to the vaginal supports allows the bladder in front and rectum behind to protrude into the lumen of the vagina covered only by the lining of the latter. The protruding viscera then keep apart and further separate the damaged vaginal supports and the condition is a true hernia of bladder and possibly urethra in front, and rectum and anal canal behind.

The symptoms of which patients complain are in the main referable to these herniae rather than to the actual position of the uterus and the term 'prolapse of the uterus' is a misnomer which in most cases should be discarded for the term 'vaginal hernia' or should the term 'prolapse' be retained it should be regarded primarily as prolapse of the vaginal wall rather than of the uterus.

During the puerperium not only does the uterus involute but the vaginal and uterine supports undergo the same process. Sepsis is said to be an important factor in causing subinvolution of all these structures and overstretching and tearing of deep-seated fibres is equally important in preventing the utero vaginal supports from regaining their previous tone and returning to approximately their previous length. Already it has been mentioned that sepsis may gain entrance to the pelvic cavity via the torn perineum, more commonly it does so via the placental site or torn cervix. In the majority of first labours when the presenting part meets the pelvic floor a trickle of fresh blood can be observed, indicating damage to soft parts. If, after delivery, the labia are separated and the vagina inspected in a good light a ragged torn area can often be seen on the commencement of the posterior vaginal wall, even when the perineum is intact. Should the perineum be torn then this area would doubtless be incorporated in the repair, if it is not how often will this wound alone be repaired? Here is another site for the entrance of infection—an important factor in the aetiology of prolapse.

These facts should make us pause to consider whether our management of the second stage of labour needs revision, and if our enthusiasm for maintaining the integrity of the perineum is always justified. Salmond and Dearnley (1935) considering this question, gave it as their opinion that episiotomy may be an important factor in the prevention of prolapse. That this opinion has not received more serious consideration is possibly due to the fact that even in those cases in which episiotomy has been performed, it has been carried out too late in labour for the patient to reap its main advantages.

Management of the Second Stage of Labour

Every primigravida incurs some degree of permanent damage to her pelvic floor during her delivery per vaginam and while gynaecologists have spent much time and thought in perfecting operations to cure the resulting symptoms comparatively little has been done by obstetricians in devising methods by means of which the damage would be reduced to a minimum. There is much truth in the statement that gynaecologists live by obstetricians' errors.

In 1742 Sir Fielding Ould, in his *Treatise on Midwifery*, suggested the possible advantage of perineal incision but the first favourable notice came in 1799 from Michaelis who advised incision in the median line. The name 'episiotomy' came later from Carl Braun, who, however did not consider the operation necessary or desirable. In 1892 Kustner, and in 1896 von Ott, advocated median episiotomy, and Stahl of Chicago in 1895 practised and published the same advice, stating that 'it aids as no instrument can in preserving that life and

body of both foetus and mother. DeLee (1915) advocated a medio lateral perineal incision as a tension release, to hasten termination of the second stage of labour, in the interest of the child and find more than usual emphasis on its advantage to the mother in the conservation of pelvic integrity.

The necessity for some kind of treatment in many cases has therefore been recognized for 200 years, yet in modern textbooks of obstetrics although episiotomy is mentioned, but little practical advice is given concerning the exact way in which it should be carried out and the cases in which it should be performed.

In 1918 Pomeroy went so far as to advocate cutting and reconstructing the perineum for every primigravida. This would seem to be going to the extreme, for its practical result would be that an incision would be necessary in the majority of multiparous patients as well, since the old scar would usually rupture. This might well be the lesser evil.

The indications for episiotomy must now be considered. Broadly speaking in any case in which the perineum seriously delays the birth of the presenting part, or in which there is the need for intravaginal manipulation or forceps delivery in all primigravidae and some multiparae, an episiotomy should be performed. These cases must now be reviewed in detail.

What should be regarded as serious delay in the birth of the presenting part? Actual time is of but little value in assessing this without also taking into consideration the strength and frequency of the pains. In the majority of cases in which the presenting part has been on the perineum for half an hour episiotomy is indicated, and earlier if there is foetal distress or undue maternal distress, or in spite of good frequent pains the presenting part is making but little advance. Should the perineal skin start to split superficially before the head is crowned, then a tear is inevitable unless prevented by a timely incision.

A word concerning foetal distress: forceps are frequently considered necessary on account of this. How often are the delay in preparation for forceps delivery the anaesthetic and trauma to the foetus however slight the final blow in extinguishing the last spark of life? An episiotomy and fundal pressure are quicker and less injurious to the foetus. Often when the head is on the perineum these methods will suffice and should be practised more frequently. Berland (1932) advocates episiotomy strongly in all cases in which the foetus is known to be premature in order to prevent cerebral haemorrhage.

I well remember my pride as an obstetric house surgeon conducting 15 consecutive forceps deliveries in primigravidae without a single perineal tear or episiotomy. Now I shudder to think of the danger to which those babies were subjected and of the damage, then hidden and unseen, which those patients suffered. Delivery of a primigravida by forceps is an absolute indication for episiotomy. A breech delivery in a primigravida is another absolute indication, both for the delivery of the after-coming head and for any intravaginal manipulation such as the bringing down of an extended leg. How difficult this manoeuvre can be! With the lower uterine segment gripping the manipulating hand, the latter soon becomes cramped and the perineum forgotten. How gallant, when at last the foot is successfully produced outside the vulva to find the perineum gaping torn perhaps into the rectum! The spontaneous delivery of a persistent occipito posterior face to pubes, a face presentation, and any case in which there is a narrow pubic arch should be placed in the same category. If a patient who has previously had a colpo-perineorrhaphy performed be delivered per vaginam then episiotomy is essential.

The difficult operation of suturing a torn cervix will sometimes be facilitated by an episiotomy, but the manual removal of the placenta and bimanual compression seldom of themselves call for episiotomy: the already stretched birth canal will easily admit the cone shaped hand.

These cases comprise the commonest in which gross damage is likely to occur to the genital tract, and therefore those in which episiotomy is most indicated—a formidable list, capable of extension.

The actual moment at which the episiotomy is to be performed is often difficult to decide but it must be remembered

that this operation is being done in order to minimize the damage to the unseen utero-vaginal supports, in addition to preventing a visible perineal laceration, and, as stated by Gusman (1932), it is useless to wait until the perineum is of but tissue-paper thickness, for by then the former damage has already been incurred. There is no doubt that the majority of episiotomies are performed too late in labour to benefit the patient to the fullest extent. In a suitable case the episiotomy should be carried out as soon as perineal bulging is marked. Far better perform this too early than too late; for the disadvantages of the former are slight, of the latter gross.

Now that the rules of the Central Midwives Board have been altered so that a pupil midwife has to undergo a year's training and obtain two certificates before she can practise as a midwife, should she not receive instruction in performing episiotomy during the latter six months of her training; and, when qualified, be permitted to perform it, if and when she considers it necessary? Must her patient's genital tract be permanently damaged because "medical aid" cannot be obtained immediately? The suturing of the wound should certainly be left to a medical officer; thus the case would become notified, and any midwife who abused this operation would soon be detected.

Before describing the actual operation, certain points concerning the anatomy of the perineal region must be considered.

Points concerned in the Anatomy of the Perineal Region

A complete description of the anatomy of the perineal region need not be given here, but there are certain anatomical relations which need emphasis because of their practical importance (Fig. 1).

The first concerns the blood supply. The superficial and transverse perineal arteries which supply this area arise from the pudendal artery in the anterior portion of the ischio-rectal fossa and, becoming superficial to the superficial perineal muscle, pass medially to anastomose with the corresponding vessels of the opposite side. Thus, apart from a few twigs from the inferior rectal artery, the perineal blood supply arises at its lateral borders and passes medially. During pregnancy the blood supply to this area is increased, and the amount of erectile tissue around the vagina is augmented; thus any tear or incision in this region may bleed profusely.

FIG. 1.—1a, Internal pudendal artery 1b, Inferior haemorrhoidal artery. 2, Bartholin's gland and duct, the latter looping downwards. 3, Spongy tissue, greatly augmented during pregnancy. 4, Median raphe.

The second concerns the muscles. These are attached to a median raphe, and the fibres run medially and backwards. When these muscles are incised the medial portion will therefore retract backwards, and when repairing such an incision care must be taken to pull the median portion upwards before inserting the sutures, otherwise correct apposition will not be

obtained. In addition, the external anal sphincter extends approximately one inch from the anal margin, and therefore any incision lateral to this will not involve this muscle.

Finally, a word concerning Bartholin's duct. This is about 2 cm. in length, opening into the groove between the labium minorum and the hymen. Its course is U-shaped, with the

FIG. 11.—1, Lateral (incorrect). 2, Medio-lateral (correct). 3, Median. 4, Author's method.

loop downwards, so that an incision of the perineum which does not start strictly in the midline runs the risk of dividing this duct.

The above anatomical points should be remembered when performing an episiotomy.

Technique of Episiotomy (Fig. 11)

Since this is such a slight operation, easily performed, it is generally described in the textbooks in a few lines, augmented by a diagram, often inaccurate. Four types of episiotomy have been used: the median or perineotomy, in which the incision is confined strictly to the midline; the medio-lateral, in which it starts at the fourchette and extends laterally; the lateral, where it starts on the lateral vaginal wall and extends towards the ischial tuberosity; and, lastly, multiple small incisions around the vaginal orifice. To-day only two of these are in general use—the median and the medio-lateral, the latter now being termed "lateral episiotomy." It is here that the diagrams in many textbooks are at fault, for the incision is often shown starting to one or other side of the midline.

The old lateral episiotomy has been abandoned on account of the danger of haemorrhage. Finkelstein (1939) describes such a case, in which episiotomy had been performed prior to forceps delivery, and in which the haemorrhage from the incision was so great that delivery had to be postponed. Doubtless the erectile tissue around the vagina had been opened up in this case. Had the incision begun truly in the midline, perhaps this massive haemorrhage would not have occurred. Incision commencing away from the midline places Bartholin's duct in danger. Should this be cut, a Bartholin's cyst may subsequently develop, thus providing more work for the gynaecologist; and the loss of one of the ejaculatory systems is a serious matter, for an abnormally dry introitus may cause difficulty at subsequent coitus.

In all cases, therefore, it is essential that the incision starts strictly in the midline; and from the anatomical facts already mentioned it would seem advisable to continue in this direction. By so doing the blood is but little disturbed, there is no risk of

damaging Bartholin's duct, and good apposition is most easily obtained. The obvious danger of this method is that, should the opening still be insufficient, the resulting tear will be directed through the sphincter towards the rectum thus bringing about the major disaster that must be avoided and who can always be certain that the central incision will be adequate? Gillis (1930), describing 300 consecutive cases of midline episiotomy performed by him stated that extension into the rectum occurred in 8 cases (1.6%). Thus even in skilled hands there is a definite danger of this happening which danger will increase markedly with a less experienced operator. It is in order to avoid this danger that the lateral episiotomy of today is so widely used. Starting in the midline it extends laterally towards a point midway between the anus and the ischial tuberosity. A large incision can be made and even if extension occurs there is no risk of rectal involvement.

Personally, I attempt to combine the advantages of both median and lateral episiotomy. A blunt pointed curved pair of scissors are used and the incision made in the midline, until it reaches a point 1 in from the anterior margin of the anus. The scissors are then directed towards the ischial tuberosity and the incision completed with the curved portion. In this way the sphincter is avoided and should the incision extend there is no rectal involvement.

In rare cases in which even a large lateral incision seems inadequate Taylor (1937) and others advocated bilateral episiotomy. This should never be done for in this way almost the whole of the blood supply to the perineum is cut since it comes from the lateral borders and personally I have seen two cases of severe perineal sloughing result from this operation. Both these were clean cases performed in hospital and are the only serious complications I have seen resulting from episiotomy itself.

Already it has been stated that episiotomy should be performed more frequently and earlier in the second stage, than it usually is. Whenever it is done it should be performed at the height of a pain for then the tissues are stretched and it is easier to see exactly where the incision is being placed. Furthermore, sensation in the part is then dulled even if no anaesthetic is being used—a rare occurrence—the operation does not seem to be unduly painful and the Junker or "gas and air" apparatus can make the patient oblivious of the fact that the tissues are being incised, or the incision can be made very satisfactorily under local analgesia. Whatever incision is being adopted in manipulative cases, it is advisable to "iron out" the vagina with the well lubricated hand before making the incision, and in all cases essential to divide the whole depth of tissue in the wound and not merely to incise the skin.

Results

In 135 consecutive primigravida private patients delivered per vaginam I find the following results

Normal delivery without episiotomy, 63 cases	46.7%
Episiotomy performed in 72 cases	53.3%
Of the episiotomy cases 52 had a normal delivery and therefore the total normal delivery rate (115 cases in 135) is	81.1%
Among the remainder 11 of whom had episiotomy performed there were 17 forceps deliveries	12.6%
The remainder 3 cases comprised 2 extended breech and 1 performance of a hydrocephalic head	

The relatively low forceps rate for primigravidae in private practice I attribute almost entirely to the episiotomy rate of over 50%.

Apart from the case of hydrocephalus all the babies were alive and well with the exception of one delivered by forceps, which died on the sixth day from pneumonia. Post mortem examination showed no cerebral haemorrhage. Of the 72 episiotomy cases 2 (2.8%) had symptoms referable to vaginal laceria 6 months later, but these were slight, and improved with palliative treatment, whereas of the 63 cases of normal delivery without episiotomy, 5 (8%), one of whom had colporrhaphy performed, had the same symptoms.

Apart from these figures the average "tone" of the vaginal walls was much better in the former group than in the latter.

A patient always thanks her doctor if she has no stitches in the puerperium. Instead, should she not thank him because he has?

Summary

The disadvantages of a torn perineum are discussed and compared with the disadvantages of unseen damage that may occur as a result of keeping the perineum intact.

In order to minimize all these disadvantages early episiotomy is advocated and the cases in which episiotomy should be performed are stated.

The relation of injury sustained during labour to prolapse and vaginal hernia is discussed.

Certain perineal anatomical points of practical importance in performing episiotomy are mentioned.

The methods of performing episiotomy are described.

Figures are given which indicate that patients on whom early episiotomy is carried out are less prone to pelvic damage than those in whom the perineum remains intact.

RAPID REPLACEMENT OF FLUID IN HAEMORRHAGE AND SHOCK

By

JAS. D. P. GRAHAM, M.D.

Capt., R.A.M.C.

Although numerous papers on the effects of transfusion of the human subject with blood and blood substitutes have appeared in the last five years very few refer to the hazards of overloading of the circulation with fluid. Black (1937) states that 20 minutes should be taken in introducing 600 c.cm. of blood otherwise an acute dilatation of the right side of the heart may be encountered while Brennan (1940) suggests that 300 c.cm. of plasma in 20 minutes may be considered rapid. Marriott and Kekwick (1940) state that 368 c.cm. of blood in 30 minutes is usual, and distinguish between this rate of infusion and that desirable in debilitated patients (1 c.cm. per lb. wt. per hour) in whom, according to Murphy, Grill and Correll (1940) injection of relatively small amounts of fluids by vein causes increase in the venous pressure and slowing of the circulation. De Gown and Hardin (1940) gravity-fed from 5 to 40 c.cm. of fluid a minute to their cases with success. Dealing with battle casualties, Whitby (1942) states that failure to restore blood volume is a much greater danger than pulmonary oedema from necessary massive transfusion (experience of 120 cases) while Kilduffe and DeBakey (1942) quoted by Drummond (1943) have given 600 c.cm. in 3 minutes, and the latter says he may have to give 368 c.cm. in 15 minutes without ill effects. Sharpey Schafer and Wallace (1942) deal specially with the question of possible overloading of the circulation from rapid infusion of fluid in man. Of 10 subjects with normal cardiovascular apparatus given up to 2,000 c.cm. of serum at a rate of 34-100 c.cm./min. 5 developed headache or constriction of the chest, 3 had slight changes in the T-wave of the electrocardiogram, their pulse rates increased slightly, and the haemoglobin fell by 3.3 to 23.3%. If the haemoglobin fell markedly there was a rise of venous pressure with an increase in the diastolic size of the right heart, but no pulmonary oedema. In 9 cases which had a venesection of 740-1,100 c.cm. (approximating to battle casualties) followed by infusion of 1,500-1,800 c.cm. of 0.9% saline at a rate of 88-138 c.cm./min. or an infusion of 700-2,000 c.cm. of serum at a rate of 6-140 c.cm./min., the most striking effect was vasodilatation with reddening of the face and engorgement of superficial veins. Unless enough time had elapsed for the haemoglobin to fall considerably, no rise in venous pressure followed infusion until at least 1,000 c.cm. of fluid had been given.

Brewer, Maizels, Oliver, and Vaughan (1940) state that there is no apparent association between either the amount of blood given and the risk of reactions or the rate of administration and the risk of reactions: Edwards, Kay, and Davie (1942) state that it is rare for a patient to lose more than 3 pints of blood, as the fall of blood pressure in such cases is so great that the haemorrhage ceases; while Keith (1919) declares that a systolic pressure of 70–80 mm. Hg indicates a loss of 30% of the blood volume, and a pressure below 60 mm. Hg a loss of over 35%—i.e., 2,100 c.cm.

It was decided to increase the quantity and the rate of fluid infused into a series of battle casualties dealt with in a mobile A.D.S. in the Mediterranean theatre of war, and to observe the cases closely for ill effects on the heart and circulation in the lungs. Cases were received at very variable periods after wounding 1/2–22 hours in the selection reported; all had been fit men, young, highly trained, and well fed; all were suffering from physical fatigue, a degree of anxiety neurosis, dehydration, and the effects of severe trauma and blood loss; all received 3,000 units A.T.S. intramuscularly and 2.5 g. sulphanilamide by mouth in addition to other treatment. Resuscitation measures consisted chiefly of control of haemorrhage, dressing and immobilization of wounds with the minimum of disturbance, morphine, sweet tea, and warm venous infusions, supplemented by the application of hot-water bottles and blankets. Infusion fluids were administered under pressure created by attaching a Higginson syringe to the air inlet of the standard giving set. The cases were German and Italian P.O.W. and British troops.

Case Histories

Case 1.—Aged 22. Shell splinter, amputation of R. foot just above ankle, with severe blood loss, about 15.30 hours. Given morphine 1/2 gr. s.c. at 17.10 hours; received 18.40 hours; T. 97.2° F., P. 110, R. 14, B.P. 80/?; Hb 90%. Mentally confused; hands clammy; no urine passed. Heated with bottles; limb dressed and fixed in wire box-splint. By this time he was semicomatose. Transfused with four 600-c.cm. bottles of reconstituted plasma in 20 mins., when the blood pressure rose—85/45, 100/50, 105/55, 105/50—and the pulse rate was 130, 130, 120, 124, thready at first, then stronger. Heart sounds became drumming and lungs remained clear. Five minutes after the last bottle his state was: T. 98.4° F., P. 124, R. 10, B.P. 110/50, Hb 58%. Had a good night; lungs and heart normal. At 08.30 hours, B.P. 95/50, T. 102° F., P. 180, R. 32. Blood volume, 4,350 c.cm.; estimated loss, 1,650 c.cm.; infused 50% of volume on reception.

Case 2.—Aged 27. Bomb wound, compound fracture L. femur, with severe flesh and blood loss, at 10.15 hours. Given morphine 1/4 gr. sublingual 10.20 hours, 1/4 gr. s.c. 10.45 hours. When received T. 97.4° F., P. 92, R. 14 (sighing), B.P. 90/10, Hb 104%; mentally clear and apprehensive; hands cold and dry; no urine passed. Given tea and morphine; local dressing of wound with Tobruk plaster (Thomas splint), by which time he was collapsed. Transfused with four 600-c.cm. bottles of reconstituted plasma in 18½ mins., when the B.P. rose from 100/45, 110/60, 120/65, to 140/60, and the pulse rate was 90, 110, 116, 120. During infusion of the first 600 c.cm. the patient complained of tingling of face and hands, and towards the end of the fourth bottle he developed a pain in the wound and across the chest at the nipple level. The heart sounds remained normal throughout. After 5 mins. his state was: T. 99.2° F., P. 98, R. 20, B.P. 140/60, Hb 68%. The patient arrived M.D.S. at 13.05 hours: condition good; T. 100° F., P. 110, R. 20, B.P. 120/68; no pulmonary oedema. Blood volume on reception, 4,533 c.cm.; loss, 1,467 c.cm.; infused 50% of volume after wound.

Case 3.—Aged 20. L.M.G. bullet wound penetrating arch of L. foot, with fracture and haematoma, considerable blood loss, at 13.00 hours. Picked up 14.20 hours; received 14.30 hours and given morphine 1/2 gr. s.c. T. 97.2° F., P. 110, R. 16, B.P. 70/?; Hb 96%; comatose; hands cold and clammy; no urine passed. Given morphine, heat, tourniquet (10 mins.), and tight dressing to control ooze. Transfused with five 500-c.cm. bottles of reconstituted plasma in 32½ mins., when the B.P. rose from 90/40, 105/50, 128/40, 140/60, to 140/75, and the pulse rate was 132, 128, 110, 116, 120. At first thready, the pulse became strong and the patient was restless during the infusion of bottle 3. During the infusion of bottle 5 the neck veins became engorged, the face flushed, and the heart sounds drumming. Final state (5 mins.): T. 99° F., P. 120, B.P. 132/75, Hb 64%; congestion less; lungs clear; heart sounds normal. Arrived M.D.S. 18.25 hours: T. 99.6° F., P. 100, R. 18, B.P. 128/70; no congestion. Blood volume on reception, 5 l.; estimated loss, 1 l.; infused 50% of volume after wound.

Case 4.—Aged 33. Shell wounds both legs, no fractures, but severe blood loss, at 12.15 hours: given morphine 1/4 gr. i.v., 1/4 gr.

i.m., at 17.00 hours. Received 18.30 hours; T. 97.4° F., pulseless, R. 12, B.P. 85/40, Hb 90%; comatose; hands cold; passed 120 c.cm. urine at 02.00 hours. Dressing not changed; given heat; no improvement. Transfused with four 600-c.cm. bottles of serum in 21 mins., during which the B.P. rose from 90/50, 110/50, 150/95, to 155/110, and the pulse rate was 120, 104, 120. Towards the end of the last bottle the neck veins were engorged and slight irregularity of the heart sounds like coupling appeared, which died away after 10 mins. Final state: T. 98.4° F., P. 112, R. 12, B.P. 160/110, Hb 62%. Kept overnight; next day, at 06.30 hours, T. 99.8° F., P. 100, R. 14, B.P. 110/50; lungs clear. Arrived M.D.S. 08.00 hours: T. 100° F., P. 110, R. 12, B.P. 115/70; no congestion. Blood volume on reception, 5,311 c.cm.; estimated loss, 689 c.cm.; infused 47% of volume on reception.

Case 5.—Aged 27. Shell wounds legs, extensive loss of flesh and blood from thighs, at 07.30 hours; given morphine 1/2 gr. by mouth at 07.35 hours, and 1/4 gr. s.c. at 12.00 hours. When received, T. 100.4° F., P. 80, R. 14 (sighing), B.P. 105/60, Hb 95%; mentally apprehensive; cold and clammy. Given tea, when he had nausea; felt the worse for treatment. Transfusion of three 600-c.cm. bottles of serum in 19 mins., when B.P. rose from 105/70, 110/80, to 140/60, and pulse rate from 80, 104, to 108. During infusion of the first bottle there was a short rigor for 30 seconds, repeated during bottle 3, when a tight pain across the chest developed towards the end. Final state (5 mins.): T. 99.6° F., P. 96, R. 24, B.P. 140/65, Hb 67%; lungs clear. Arrived M.D.S. 14.30 hours: T. 102.6° F., P. 120, R. 24, B.P. 140/65; lungs clear. Blood volume on reception, 4,307 c.cm.; estimated loss, 1,693 c.cm.; infused 39% of volume.

Case 6.—Aged 25. L.M.G. bullet compound fracture tibia and fibula, moderately severe blood loss, at 16.30 hours; given morphine 1/2 gr. at 17.00 hours on admission. T. 97.4° F., P. 90, R. 14, B.P. 145/85, Hb 110%; hands cold and damp; mentally clear. Tight dressing and box splint applied; kept overnight at A.D.S. At 01.00 hours, oozing having occurred, T. 96.5° F., P. 130, R. 12 (sighing), B.P. 75/?; Hb 94%. Transfusion four 500-c.cm. bottles of reconstituted plasma, when B.P. rose from 95/40, 105/55, 110/60, to 125/65, and pulse from 130, 128, 124, to 124. Final state (5 mins.): T. 99.8° F., P. 120, R. 18, B.P. 120/65, Hb 70%. No pulmonary oedema; heart sounds normal. Evacuated in good shape; arrived M.D.S. 08.30 hours: T. 100° F., P. 124, R. 16, B.P. 110/60. Blood volume before transfusion, 4,859 c.cm.; loss, 1,141 c.cm.; infused 37% of volume.

Case 7.—Aged 25. Shell wound L. buttock, penetrating abdomen, with moderate blood loss, at 11.30 hours. Given 3/8 gr. morphine 12.05 hours; admitted 14.30 hours. T. 96.8° F., P. 120, R. 18, B.P. 95/50, Hb 98%; hands cold, dry; anxious mentally. Simple dressing with abdominal binder. Transfused two 500-c.cm. bottles of serum in 12 mins., when B.P. rose from 110/55 to 115/55 and pulse steadied from 125 to 110, with relief of abdominal pain. Final state (5 mins.): T. 97.8° F., P. 110, R. 16, B.P. 115/58, Hb 80%. Arrived M.D.S. 17.20 hours: T. 98.4° F., P. 110, R. 16, B.P. 96/60; pale but no air hunger. At operation about 2 pints of blood in abdomen. Blood volume on reception, 4,444 c.cm.; loss, 1,556 c.cm.; infused 22.7% of volume.

Case 8.—Aged 27. Mine splinter penetrating L. iliac fossa, with internal haemorrhage, about 16.30 hours. Picked up next day at 11.30 hours; given 3/8 gr. morphine s.c. at 14.00 hours. On reception, T. 97.8° F., P. 130, R. 26, B.P. 45/?, Hb 90%; hands warm; urine nil; delirious. Given heat, morphine, simple dressing, when restlessness subsided and flexed L. leg relaxed. Transfused six 400-c.cm. bottles of reconstituted plasma in 23 mins., when B.P. reacted as follows: 105/62, 105/70, 95/65, 108/70, 95/70, and 90/70, and pulse fell from 160, 158, 146, 140, 140, to 128. No cyanosis, engorgement, or pulmonary oedema occurred, but pulse and heart sounds were of better quality after bottle 2 than after bottle 6. Received at M.D.S. 17.00 hours: T. 102° F., P. 160, R. 40, B.P. 95/40; cyanosis of lips; rales at both bases. Blood volume on reception, 4,800 c.cm.; loss, 1,200 c.cm.; infused 50% of volume.

Case 9.—Aged 37. Crush wound of abdomen (? rupture spleen) at 07.30 hours. Admitted 07.55 hours; given morphine 1/4 gr. s.c.: T. 98.2° F., P. 120, R. 20, B.P. 90/40, Hb 110%; drowsy; hands warm. Given heat, tea, elastoplast to lower L. ribs; became paler, respiration sighing. Transfused after 1/2 hour with three 600-c.cm. bottles of reconstituted plasma in 15 mins. B.P. rose from 98/50, 100/60, to 100/60, and pulse from 106, 104, to 110; lungs clear; heart sounds normal. Final state (5 mins.): T. 98.6° F., P. 112, R. 22, B.P. 70/?; Hb 72%. Arrived M.D.S. 11.35 hours: T. 97.4° F., P. 140, R. 14, B.P. 70/?. Given drip transfusion whole blood and sent on; died before arrival. Blood volume on reception, 3,410 c.cm.; loss, 2,590 c.cm.; infusion of 55% of volume.

Case 10.—Aged 21. Shell wound of chest with haemopneumothorax and compound fracture of humerus, ? penetrating wound of abdomen, at 07.30 hours. Received 09.00 hours: given 3/16 gr. morphine; T. 96.2° F., P. 128, R. 22, B.P. 75/10, Hb 80%; hands clammy; drowsy. Transfused two 600-c.cm. bottles of serum in

20 mins. During bottle 1 the pulse became stronger, BP 90/20, R 40, P 132, but during bottle 2 he developed a severe pain in the chest and abdomen and felt bubbling and splashing in the chest. Final state (5 mins.) T 97° F, P 120, R 40, BP 95/20, Hb 60%. Received MDS 14 30 hours T 101.6° F, P 130, R 40, BP 80/40, condition poor. Sent on with whole blood drip. Died that night. Blood volume on reception, 3,600 c.c.m., estimated loss 2,400 c.c.m., infused 33% of volume.

Discussion

The 10 cases reported in detail are considered typical of a larger number treated. The majority of battle casualties suffering from shock are not so exsanguinated, and do well with 1,000 c.c.m. of blood substitute transfused in 20 to 30 minutes, preferably being evacuated with a continuous drip running, but where the blood loss is estimated to be severe (about 2 litres) replacement cannot be too speedy. Analysis of the cases on the basis of the formula of Bushby *et al.* (1940) indicates that they lost 1.54 litres of blood on an average and this was replaced as quickly as possible with some excess to allow for oozing and loss of serum from damaged surfaces, to the extent of 33% of the intact volume or 43.4% of the blood volume after wounding. The incidence of reactions with rapid transfusion seemed less than that found when small quantities of fluid were given slowly (1/2 hour to 1 pint). Where sufficient time had elapsed for the haemoglobin to fall considerably there appeared to be no more signs of overloading of the circulation than in fresh cases, but what was most marked, and is clearly brought out in the case histories reviewed, was that cases of embarrassment of the cardiovascular system from toxæmia (Case 8), damage to the thoracic contents (Case 10), or continuing internal haemorrhage (Case 9) do badly with rapid transfusion. The ideal case for this technique is one of trauma to the limbs with gross haemorrhage. Perhaps cases of internal haemorrhage not involving gross toxæmia would do equally well if haemostasis were secured by operative means shortly after wounding.

It is widely held (Moon, 1938) that even in profound shock the heart is capable of functioning strongly, and if supplied with enough fluid can produce a normal or higher than normal blood pressure. Shock is defined as a state of circulatory deficiency, neither cardiac nor vasomotor in origin, characterized by decreased blood volume, decreased cardiac output, and increased concentration of the blood. Shock may be produced by trauma, etc. (when haemoconcentration takes place), or by haemorrhage (which is followed by haemodilution, fall in Hb and in r.b.c. count), or by a combination of these factors.

According to Moon *et al.* (1941) the effects of haemorrhage and of shock should be clearly distinguished. The initial similarity between shock and the effects of haemorrhage results in part from the fact that each evokes the same mechanism of compensation and in part from the deficiency of circulation which each produces. Points of contrast between shock and the effects of haemorrhage are so numerous that the assumed identity of these conditions is no longer tenable. In traumatized dogs Cullen *et al.* (1941) found that haemoconcentration was not a significant factor and that the earliest sign of shock was a marked reduction in the peripheral blood flow, there being an approximate correlation between the product of the change in blood pressure and the haemoglobin percentage with the circulation time (Olson *et al.*, 1941). Werle *et al.* (1942) indicate that a continuing state of post-haemorrhagic hypotension is not necessarily equivalent to shock, because (in dogs suffering from the effects of bleeding only) arterial pressures and pulse rates were restored to normal for many hours by reinfusion of the withdrawn blood even when such animals were on the verge of cardiac or respiratory failure and the viscera showed no pathological changes at necropsy, whereas the converse was found in dogs suffering from traumatic shock without blood loss. If, however, the intensity and duration of post-haemorrhagic hypotension were great enough then haemorrhagic shock "developed, marked by failure of transfusion to restore the circulation, and oedema, etc., of gut and lung."

Consideration of the above case histories shows that these casualties suffered mainly from post-haemorrhagic hypotension combined with a certain degree of shock, except Cases 8 and 10, in which the latter predominated. Case 9 illustrates the effect of continued hypotension leading to "haemorrhagic

shock." They show that, if shock is not too profound, (a) the heart is capable of dealing adequately with large volumes of infused fluid, and (b) the vascular bed is capable of retaining this added fluid for utilization by the circulation. It is evident that if the standard blood volume of the intact subject be taken as 6 l the hypotension develops after the loss of 25% of the blood volume (average blood loss after wounding calculated from the formula given by Bushby *et al.* (1940), and can be speedily and successfully combated by the rapid infusion of 33% of the initial blood volume. The subjects considered cannot have suffered from any great degree of traumatic shock affecting vascular "tone" or of anoxic depression of the myocardium since the heart could successfully deal with 43% addition to the available fluid volume.

Summary and Conclusions

Details are given of 10 battle casualties suffering from shock due to trauma and blood loss, and the effect of rapid replacement of the estimated loss of fluid on the temperature, pulse, respirations, blood pressure, haemoglobin, and general condition.

Rates of infusion in the nature of 143 c.c.m. a minute in no way embarrassed the cardiac mechanism.

Cases of toxæmia (peritonitis) and lung wounds developed pulmonary oedema after massive transfusion, cases of peripheral trauma and haemorrhage without sepsis did not.

The statement of Edwards *et al.* (1940) is not considered exact, while that of Keith (1919), though frequently correct, is misleading. Blood pressure readings alone are not sufficient to estimate blood loss or to differentiate serious states of shock from temporary hypotension.

Reactions other than transient rise of temperature were few.

It is strongly recommended, therefore, that an estimate of blood volume lost be made in all battle casualties thought to need transfusion, from the history and the findings modified by experience, and that this be checked subsequently from haemoglobin readings taken before and after infusion of plasma, which must remain the mainstay of the infusion technique in the field unless refrigeration facilities increase greatly. The estimated fluid loss should be replaced at speed with the aid of pressure, thus ensuring adequate volume replacement and preventing simple post-haemorrhagic hypotension from developing into true shock.

In a Chadwick Lecture entitled "Some Observations on the Management of Hospitals in Peace and War" given on Oct. 31, Mr. Somerville Hastings, F.R.C.S., said that no single hospital could provide economically and efficiently for every type of case. Hospitals must therefore be grouped under the direction of a central co-ordinating body. Nevertheless, local interest must be maintained by a committee of management for each individual hospital. The staff of a hospital must be able to make suggestions for the improvement of its administration, and medical, nursing, and lay staff committees were desirable. Each department of a hospital, general or special, should be organized on the clinical unit system, with a doctor of consultant status in charge. The superintendent of a general hospital should not be a skilled clinician, but a doctor with administrative experience. The medical staff of a hospital should be full-time officers who should live in or near by. They should have complete professional, intellectual, and political freedom and there should be abundant clerical assistance at their disposal. Change of hospital was desirable, at any rate till middle age. Short-listing for promotion should be undertaken mainly by doctors engaged in the same branch of practice. The presence of students added to the prestige of a hospital and improved both the status and the efficiency of the staff.

UNDERWATER BLAST INJURIES OF THE ABDOMEN*

BY

THOMAS MOORE, M.D., M.S., F.R.C.S.

Major, R.A.M.C.

In modern sea warfare abdominal injuries caused by underwater blast are common, and increasing numbers of cases are now being reported. As the mechanism underlying the injuries is still uncertain, and the mortality in cases with intestinal perforations coming to operation in the series reported by Pinnock and Wood (1943), Goligher, King, and Simmons (1943), Gill and Hay (1943), and Cameron, Short, and Wakeley (1943) has varied from 100% to 50%, it is important to study all cases available. I should like, therefore, to give my experiences of the condition, and the opinions which I have formed about it, based on the personal treatment of 18 patients, nine of whom were subjected to operation, and the interrogation and examination of 22 others who were under my care after operation elsewhere, two of whom required late operations for intraperitoneal abscesses—one subphrenic and one in the right iliac fossa.

The wave of positive pressure may be caused by depth charges, already primed, which go off when a sinking vessel submerges to the required depth; or by bomb, mine, or torpedo blast directed at other ships in the vicinity; or by depth charges dropped by neighbouring ships at an offending submarine. The blast in water differs from that in air, physically in that there is no after-wave of negative pressure, and clinically in that the abdomen is more affected than the thoracic cavity. Probably the fact that the chest is usually partly out of the water and protected by a life-jacket of the "Mae West" type accounts for the latter difference. It is interesting to hear described the actual sensations experienced by the victims. All feel the shock of the explosion on the abdomen. Many describe it as "like a severe kick," others as "a vice-like tightening around the abdomen," others as "if the abdominal contents were being forced up through the body into the head," and others as "if a giant hand were squeezing me from the waist downwards." Many have the sensation of their legs being shot away, and several have actual temporary paraplegia. None of my patients has described pain in the testes noted by other writers. The abdominal pain usually abates, and most patients manage to swim. Frequently no abdominal pain is noticed until they are picked up by another vessel, when they find that they cannot straighten themselves or walk because of it. One of my patients actually had a shower and a meal before he felt any abdominal pain. It is not uncommon after rescue for an urgent desire to defaecate to occur and a blood-containing stool to be passed. Only one of my patients complained of any difficulty in micturition. Vomiting is a very common symptom, and is often erroneously attributed to the swallowing of oil-contaminated sea-water. Three of my patients complained of chest pain, but none had haemoptysis. In no case was there any injury to the parietes.

Clinical Condition

These cases have been subjected to a generalized severe disruptive abdominal blow, which affects all the abdominal contents, including blood vessels and nerves. Many die at once, or in a very short time, from shock and haemorrhage. The clinical picture in those that survive to be picked up varies according to the time interval after the injury at which they are seen and the extent of the internal injuries. Although they can be very ill without perforations having occurred, in general the more severe the injuries, particularly if intestinal perforations are present, the more severe the abdominal pain and vomiting and the more severe the shock. When seen in the later stages the shock has disappeared and the condition is one of spreading peritonitis. The first essential of diagnosis, no matter at what stage the patient is seen, is to decide if intestinal per-

foration has occurred or not. Many have written on the excellence of the general condition in some of these cases although perforations have been present, and they have been misled into postponing operation so late that death has followed.

While all aspects of the case, both general and local, must be taken into account in coming to a decision, I believe that it is the local signs to which the greatest attention must be paid. Abdominal tenderness, rigidity, and the absence of peristaltic sounds, and diminution in liver dullness, must all be taken into account. The most important are tenderness and rigidity. In the early cases the latter is of the typical board-like variety. In the later cases—and the cases are usually late owing to the distances they have to be transported to hospital—the rigidity is more-muscle resistance associated with some abdominal distension. Skill in abdominal diagnosis is bred of long experience, and each must learn to assess the relative value of clinical findings and come to a definite decision. In these cases it is essential for the safety of the patient to decide early whether an intestinal perforation is present or not. It may be simulated by intraperitoneal haemorrhage and by injury to the lungs. One sign can no more make a diagnosis than one swallow can make a summer. There is one sign, however, on which I personally place the greatest reliance. Abdominal examination is carried out extremely gently with the flat hand. The abdomen is generally examined for rigidity both in inspiration and in expiration. If the rigidity is caused by peritonitis due to perforation it does not relax during expiration. I have never known this sign to fail. Some of these cases have blast injury to the lungs, which may have accentuated the abdominal pain and rigidity. The actual local signs of this injury are extremely slight, and consist of an increased respiratory rate, diminution of the percussion note, diminished air entry, and rales in the affected part of the lungs. When no perforation has occurred the abdominal pain disappears in a day or two without any further symptoms. However, sometimes intestinal haemorrhages arise, and are manifested by haematemesis or melaena. Cases have also been reported in which perforations of the intestine have occurred after seven days—no doubt due to infection of an intestinal haematoma, with late perforation.

Pathological Lesions

Haemorrhages.—A common finding in these cases is subperitoneal haemorrhages. In my experience these are of three types—viz.: (1) Scattered pin-point haemorrhages beneath the peritoneum covering the bowel, usually parts of the terminal ileum, and pelvic colon. (2) Peculiar linear subperitoneal haemorrhages arranged in transverse rings around parts of the terminal ileum. (3) More massive subperitoneal haemorrhages of irregular shape on various parts of the bowel, but particularly over the ascending colon and in the subperitoneal tissues lateral to it. I have also seen small petechial haemorrhages in the mesentery of the terminal ileum.

Perforations.—Perforations have been found in my cases in a loop of the terminal ileum 6 in. to 12 in. long, and about 2 ft. to 3 ft. from the ileo-caecal valve—in the apex of the loop of the pelvic colon—and in the ascending colon just below the hepatic flexure. In size the perforations have varied from a pin-point to 3 cm. in diameter. They may occur on the antemesenteric border of the bowel or on one of the lateral walls. Some have been situated just at the attachment of the mesentery to the bowel. In some cases the perforation has been an oblique slit in the bowel wall near the mesenteric attachment, and has been found only on careful examination. Frequently only one perforation is present, but one of my patients had three perforations in the ileum and two in the pelvic colon.

Personal Cases: Post-mortem Findings.—In addition to findings noted at operation, at necropsy submucous haemorrhages have also been found, particularly in the lower ileum. In one case there were two curious herniations of the mucosa of the colon through the circular muscle just below the splenic flexure and in the pelvic colon. In both sites there was marked haemorrhage in the wall of the bowel. Some interstitial haemorrhage into the free anterior margin of the liver was found in one case. In one fatal case almost the whole of the right lung was the site of massive interstitial haemorrhage, and to the naked eye looked very much like liver. Micro-

* A paper read before the Inter-Allied Medical Congress, Algiers, Feb 1944

scopical examination of the intestine has shown submucous haemorrhages with rupture of the muscular coat in parts. Examination of the affected part of the lung has shown the typical appearances of blast-lung.

Additional Pathological Findings Reported by Others.—Perforations of the duodenum, caecum, and transverse colon have occurred. Sometimes tears of the mucosa of parts of the bowel have been observed. Some writers have noted haemorrhages below the tunica albuginea of the testes in fatal cases. Similar lesions have also been produced experimentally in animals.

Mechanism of the Lesion

It is interesting to note that it is only gas-containing abdominal viscera which are markedly affected, and it has been suggested that it is the liberation of kinetic energy by the pressure wave at surfaces where two different media join which is the cause of the injury. There is some experimental evidence to suggest that the wearing of an absorbent protective over the abdomen will lessen the injury. From my cases the effective distance from the explosion appears to be anything up to 200 yards. Patients facing the explosion are usually more severely injured than those with their backs to it. Although the best safeguard against injury is distance, the safest position appears to be floating on the back. I have never seen a person who was floating on his back at the time of explosion who has sustained any severe intra-abdominal injury. Two patients whom I have treated were in the water together; one was floating on his back, but the other was unable to do so because of some difficulty with his life-jacket. The former was uninjured, and the latter sustained a perforation of the ileum.

Treatment

Treatment is carried out on orthodox lines. Rest, warmth, and morphine are essential. If much shock is present intravenous infusions may be used, but they are better avoided because of the possibility of associated lung damage. If they are essential, blood or plasma is the safest. Where marked chest lesions are present oxygen should be administered by the B.L.B. mask. When perforation is not thought to be present the case is carefully observed until recovery is complete. It is most important, because of the danger of late perforation, to keep the patient under observation for at least ten days. If a perforation is diagnosed operation must be undertaken as soon as the patient is fit for surgery. In late cases, although the shock has been recovered from, I always use a continuous intravenous drip of saline and glucose given at a slow rate, so that fluid by mouth can be very limited after operation, and a solution of sulphapyridine can be conveniently given by it. The anaesthetic is of importance. Owing to associated chest lesions ether is contraindicated. Spinal analgesia, skillfully used, is suitable for these cases if shock has been overcome. I have also found intravenous pentothal, combined with local block to give relaxation, very useful in these cases. The abdomen is opened by a right paramedian or midline incision. The intestine is carefully examined for perforations, and those found are carefully sutured and oversewn. All blood and intestinal contents, and inflammatory exudates, are sucked out of the peritoneal cavity. In the absence of sulphadiazine, or other more suitable sulphonamide preparation, I have usually gently swabbed the peritoneal cavity with a weak solution—about 1%—of sodium sulphapyridine. The wound is closed, with drainage of the peritoneal cavity. When the colon is involved I have performed suture in the ordinary way with success. On one occasion when there was a large irregular sloughy perforation in the ascending colon I performed exteriorization. Though it was successful I have the feeling that it was unnecessary and that it would probably have been safe to perform simple suture. In late cases such as I have treated it is essential, after operation, to have continued gastric aspiration through an inlying Ryle's tube and fluid intravenously by drip. This method, the greatest advance in surgical treatment in the last thirty years, is a great life-saver. It is amazing how long patients can go with this artificial existence, with large quantities of fluid being withdrawn from the bowel daily, and make an excellent recovery. Combined with the intravenous glucose-saline, I always give 4 to 5 g. of soluble sulphapyridine daily for 4 to 5 days.

Personal Cases

Eighteen cases have been treated, of which 5 were admitted to hospital 20 hours after the injury and the remainder 16 hours after. Two estimated that they were respectively 500 to 700 yards away from the explosion, and one that he was 200 yards away; two were 100 yards distant, and the remainder from 5 to 50 yards. Neither of the first two had any symptoms, and one who was 100 yards away but floating on his back escaped injury entirely. The other 15 all had symptoms of varying degrees of severity. The one who was 200 yards away had melaena only for a few days. Five patients had some abdominal pain and vomiting on admission, but recovered with conservative treatment. One of these collapsed suddenly on the night of admission, and was thought to have had an internal haemorrhage. He recovered with conservative treatment, and passed a melaenic stool two days later and had melaena for a few days. No later complications occurred among these cases, and all made a complete recovery. Nine cases were submitted to operation. Eight of these were thought pre-operatively to have perforations. The other was believed to have a perforation with local peritonitis, or a large sub-peritoneal haematoma. It was thought safer to operate. At operation perforations were found in all eight cases. Four had solitary ileal perforations only, one had three ileal perforations, one had two ileal perforations and a perforation of the pelvic colon, one had two ileal perforations and two in the pelvic colon, and one had a perforation of the ascending colon just below the hepatic flexure. Suture was performed, in all cases with drainage of the peritoneal cavity, except in those with a single ileal perforation, when the wound alone was drained. In the case of rupture of the ascending colon the bowel was exteriorized; as the transverse colon was full of hard faeces it was thought that there might be abnormal tension on the sutured bowel. In the ninth case a large sub-peritoneal ecchymosis was found covering most of the ascending colon and the peritoneum lateral to it. Appendicectomy was performed and the wound closed.

Anaesthetic.—Spinal analgesia with heavy percaine was used on three occasions and light percaine on one occasion. Pentothal, local nerve-block, nitrous oxide and oxygen, in combination, were used on each of the other five cases.

Results.—Two deaths occurred. One of these cases had two perforations of the ileum and a large 2-cm. perforation of the pelvic colon with diffuse peritonitis. At necropsy a severe degree of blast-lung was found. The other death occurred, just as operation was about to be started, in a short-necked emphysematous patient. A spinal analgesic had unfortunately been administered by the Etherington-Wilson technique. It was undoubtedly the cause of death. At necropsy he was found to have a large perforation in the ileum and a minor degree of blast-lung. In my series there is thus a mortality of 22% among operative cases.

Post-operative Complications.—Apart from peritonitis, from which all the patients were suffering, three were much troubled by a widespread purulent bronchitis, but made satisfactory recoveries. The patients with the perforation of the ascending colon developed acute small-bowel intestinal obstruction two months after operation. At the second operation a fibrous band beneath which a loop of the jejunum was tightly constricted was divided. To make subsequent closure of the colostomy safer a transverse ileo-colostomy was performed at the same time. No other complications have occurred in my cases. Two cases previously treated elsewhere for perforations of the bowel were operated upon successfully by me: one two months later for an intraperitoneal abscess in the right iliac fossa, and the other three months later for a right posterior subphrenic abscess.

I wish to thank Col. T. Menzies, O.B.E., officer commanding the hospital at which these cases were treated, for permission to publish these results.

TOXIC REACTIONS AFTER ADMINISTRATION
OF PARALDEHYDE

BY

R. E. HEMPHILL, M.D., D.P.M.

Medical Superintendent, Bristol Mental Hospital

AND

H. HELLER, M.B., B.Ch., Ph.D.

Reader in Charge, Department of Pharmacology, University of Bristol

The sedative drug most widely used in mental hospitals is paraldehyde. Scanty references in the literature to ill effects attest to its high safety margin and its wide range of permissible dosage. However, the danger of decomposition on storage of *B.P.* paraldehyde has been emphasized by pharmacists (Toal, 1937). The present report furnishes clinical evidence of such an occurrence.

Clinical Observations

Six out of nine patients were concerned. To each of them 120 min. of *B.P.* paraldehyde was given during the night as a hypnotic draught. These patients later showed a variety of symptoms, ranging from drowsiness and headache to a comatose condition, which persisted for more than 24 hours. All were chronic mental patients, well accustomed to the drug; neither before this nor since has any one of them shown a similar reaction. Dispensing on this occasion was according to the normal practice at the Bristol Mental Hospital. This is as follows. Paraldehyde, for night use, is dispensed each day in separate bottles containing 120 min. of the drug with mucilage and water to 1 fl. oz. A supply of these draughts is given to the night sister, to be administered according to indications. There are usually a number of spares in excess of estimated requirements. These draughts supplement diurnal sedatives, which may or may not contain paraldehyde. On Saturday a double supply of night draughts is issued for the week-end.

All the toxic reactions were reported on Monday morning and were confined to a group of female patients, every one of whom had received paraldehyde on the previous night. The week-end draughts were therefore suspect. The issue of paraldehyde was stopped pending investigation, but this step was taken too late to allow examination of the draughts as issued on Saturday. Arriving on duty on Monday morning, the dispenser drew the residue of one carboy, about 6 fl. oz., into a glass measure and filled up to 20 oz. from one newly opened; hence the dilution of the residue was 1 part in 3 or 4. (Paraldehyde is supplied in 40-lb. carboys, which cover the requirements of the hospital for about 7 days.) From this new mixture he prepared draughts for use that night. These freshly prepared draughts he packed, as was customary, in dispensing boxes for male and female wards. Together with these latter draughts he included those that were unused from Saturday. It was impossible, thereafter, to separate suspect (Saturday's) from non-suspect (Monday's) draughts. The remainder of the mixture of old stock and fresh paraldehyde, in the 20-oz. measure, was reserved for subsequent analysis.

The following combination of circumstances explains why all the toxic effects occurred only in a small group of female patients and on one night. The week-end draughts were dispensed late on Saturday afternoon, when the carboy of stock paraldehyde was nearly empty. Paraldehyde, believed to be pure, was drawn from the bottom of the container on this, as on previous occasions. The draughts for the male wards were dispensed first. Subsequently the double supply for the female side was made up from the last paraldehyde used that week, drawn from the almost empty carboy; about 6 oz. remained. Paraldehyde is widely employed as a sedative at this hospital, either alone or combined with other drugs. For use during the day it is dispensed in bottles containing $1\frac{1}{2}$ to 3 fl. oz., which, according to indications, will last each patient 3 to 6 days. In the dispensing of these mixtures a large quantity of paraldehyde is used. If these mixtures had not all been dispensed before the carboy was nearly or entirely empty a new

carboy would have been tapped and there would have been no residue to be dispensed in single-dose (night) draughts. It was therefore a rare coincidence that the suspect toxic residue was administered to so many different individuals. That all the reactions occurred after Sunday may be explained by the manner of packing the bottles in the night sister's box. It is reasonable to suppose that bottles made up first from higher levels of paraldehyde, above the "concentrated residue," were placed in one end of the box in rotation and were administered on Saturday and Sunday night in the same order. There is therefore sufficient evidence to attribute all the toxic reactions to administration of paraldehyde from the residue of the carboy.

Emergency draughts on Sunday night were administered to 9 female patients. Seven showed toxic reactions; two senile patients were unaffected. These patients belong to five different wards and, although some had received sedative medicine during the day, the only source of supply common to all was the stock of night draughts. Factors such as diet can be excluded. All patients were in reasonably good health. The symptoms may be briefly summarized as follows:

Case 1.—Aged 52, chronic schizophrenia. Slept after paraldehyde at about 10 p.m. Could not be roused next morning, but about 10 a.m. was drowsy, ataxic, with drunken speech; looked ill and was unable to stand; tendon reflexes almost absent; pupils small, practically inactive; cloud of albumin in urine; pulse weak and thin; blood pressure 100/80 mm. Hg. Remained drowsy all day; could stand next day but did not recover for another 24 hours.

Case 2., aged 57, chronic schizophrenia, and *Case 3.*, aged 39, also chronic schizophrenia. Almost identical to Case 1, but no albuminuria. Normal in 48 hours.

Case 4.—Aged 53, chronic mania. Awakened, got up, collapsed before breakfast; returned to bed and was drowsy for about 10 hours; normal thereafter.

Case 5.—Aged 75, senile dementia. Draught at about 1 a.m.; very confused, drowsy, looked ill; coated tongue, tendon reflexes almost absent, pupils fixed, no reaction to light; could scarcely be roused all-day; mumbled in incoherent fashion; slept off and on for the next 24 hours. Recovered slowly in the course of the next 48 hours.

Case 6.—Aged 55, mild depression. Draught at midnight; at 10 a.m. still asleep; roused an hour later; conversed with difficulty in a drunken voice; complained of severe headache and nausea. She slept most of the time for the next 24 hours, and was not free from subjective symptoms for a further 24 hours.

Case 7.—Aged 54, chronic neurosis. Had been in the habit of demanding and receiving two draughts each night almost continuously for years, in addition to any sedative medicine prescribed by day. Her regular nightly requirements were therefore not less than 240 min. of paraldehyde. She was an exceptionally well built woman, with a highly developed tolerance for sedatives of all sorts. She received one draught at 10 p.m., woke up at midnight, was restless, and asked for another. It was administered at 1 a.m. She slept and could not be roused for about 10 hours. She then spoke in a slurred, drunken voice, and complained of violent headache, giddiness, and nausea. For the next 24 hours she remained very much the same, and was not free from symptoms for a further 24 hours.

All these patients were treated similarly with copious fluids, glucose, vitamin B complex, strong coffee, and nikethamide (coramine) 4-hourly for the first 24 hours. Although there was no fatality, great anxiety was felt about Case 1 and to a less extent Cases 2, 3, and 5. The clinical picture was that of intoxication with a drug which exercised a severe depressant effect on higher cortical function and which evidently was slowly eliminated from the body. Patient No. 7, who was well acquainted with the effects of alcohol, described the after-effects as resembling an extreme "hangover," but more prolonged and much worse than anything she had ever experienced. There were no residual mental reactions and no signs of permanent damage to any part of the central nervous system.

Toxicity Tests

These were conducted as follows: The minimal lethal doses of (a) the suspect paraldehyde and (b) a fresh sample of paraldehyde, which complied with the requirements of the *British Pharmacopoeia*, were determined. Suitable doses of 5% solutions (in physiological saline) of the two preparations were injected subcutaneously into mice. The results are recorded in the accompanying Table.

Table showing Results of Toxicity Tests

Dose in ml. of a 5% Solution per 100 g. Mice (Subcutaneous injections)	Proportion of Mice Killed	
	Suspect Paraldehyde	Control Paraldehyde
1.00	3 out of 5	0 out of 5
0.15	2 " " 5	0 " " 5
0.20	2 " " 5	0 " " 5
0.45	2 " " 5	1 " " 5
0.60	4 " " 5	1 " " 5
0.75	4 " " 5	1 " " 5
0.90	3 " " 5	3 " " 5
0.05	3 " " 5	4 " " 5
0.35	5 " " 5	5 " " 5

Mice injected with equal amounts of the suspect and of the control solution were tested on the same day. The test animals were all of the same batch of mice, and had been fed on a standard diet for several weeks before use. LD50 was determined by Karber's method (Burn, 1937). The following figures were obtained: LD50 for the suspect material = 3.69 ml/100 g mouse, LD50 for the control paraldehyde = 3.99 ml/100 g mouse (both figures in terms of a 5% solution). In other words, a somewhat smaller average dose of the suspect material was needed to kill 50% of the mice tested. It will be remembered that the suspect sample was a 1 to 3 or perhaps 1 to 4 dilution of the clinically toxic material with fresh innocuous paraldehyde. Therefore only a small difference between the LD50 of the suspect and the control was to be expected. It would be reasonable to assume that had the suspect material not been diluted the difference would have been more pronounced, the abnormal clinical symptoms and signs can therefore be fairly attributed to a contaminating toxic substance in the suspect paraldehyde and not, for example, to errors of dispensing. This conclusion was supported by the results of tests for chemical purity prescribed by the B.P. 1932. These tests, which Mr E. Lloyd, of the Bristol Royal Infirmary, was kind enough to perform gave the following results:

Boiling point, acetaldehyde, peroxidized compounds, acidity were all within limits. Melting point, 10.5°C (B.P. melting point is not less than 11°C). Distillate from boiling point determination discoloured.

Mr Lloyd added the following remarks:

"Impurities which may be removed by washing are within limits. The slightly low melting point indicates the presence of some other impurity."

Discussion

It is clear from the circumstances under which the present cases of "paraldehyde poisoning" occurred that the toxic effects were due to decomposition products (or contaminating constituents) of the paraldehyde preparation. In a series of 7 hospitalized patients no physical disability obscured the clinical picture. The multiplicity of cases and the system of dispensing rendered a dispensing error unlikely. The same dose of paraldehyde drawn from less- or non-deteriorated samples had previously been administered to these patients on many occasions. The response to the standard dose of paraldehyde was therefore known, and the abnormal symptoms described cannot be attributed to idiosyncrasy. The patients have since received the same dose of a paraldehyde preparation which complied with pharmacopoeial requirements without exhibiting any abnormal reaction. Toxicity tests on mice, when compared with the effect of a "normal" preparation of paraldehyde, showed a smaller mean lethal dose (LD50) of the suspect sample.

Toal who investigated 7 commercial samples of paraldehyde in 1937, found that only one satisfied pharmacopoeial requirements. Formation of peroxidized compounds and an increase of acidity were the main changes which had taken place. One case of "paraldehyde poisoning" traced to excessive formation of acid compounds in the deteriorated sample has been recorded (Hutchison, 1930). An additional change noted by Toal was the increase in the specific gravity of the deteriorated samples. This was not associated with the development of acid or peroxidized compounds, but, in his opinion, was due to decomposition and polymerization combined. Our sample did not contain excessive amounts of acid or peroxidized compounds. Its toxicity, as manifested clinically and in a toxicity test on

mice, will therefore have to be ascribed to chemically undefined products of deterioration, possibly to polymerization products of acetaldehyde other than paraldehyde. It is remarkable that toxic effects of paraldehyde in therapeutic doses have not been noted more often, if decomposition of paraldehyde occurs as frequently as Toal's findings suggest, and, to our knowledge, no series comparable to ours appears in the literature. However, several reasons for this may be advanced: (1) in isolated cases it may have been difficult to exclude the possibility that an overdose had been administered by accident, (2) when used as a basal anaesthetic a toxic effect of paraldehyde may have been masked by the subsequent use of a volatile anaesthetic or may have been attributed to the latter, (3) if the deteriorated sample appeared to furnish the pharmacological picture of an enhanced action of pure paraldehyde the toxic effect may have passed unnoticed, especially if the drug had been given to a single case for the first time. A more intense and prolonged effect of paraldehyde may have been attributed to idiosyncrasy (Brown, 1935, Kotz, Roth, and Ryon, 1938).

The clinical picture presented no specific features. Severe cases showed ataxic drunken speech and corresponding gait. There were no significant reflex or ocular abnormalities, but all patients complained of intense headache, a feeling of nausea, and prolonged drowsiness. They compared the subjective symptoms to those of the after-effects of a severe intoxication with alcohol. (It is of interest that the U.S.P. XI requires that paraldehyde should comply with purity tests for impurities derived from fusel oil and amyl alcohol.) The effect, though largely due to a cortical disturbance, was evidently unlike the response to overdose of pure paraldehyde. The long duration of the "hangover" and the slow recovery were remarkable, especially in one of the patients (No. 7), who, as a drug addict, showed herself, both before and since the event, to be highly resistant to hypnotic drugs.

The present report cannot detract from the value of paraldehyde as a clinically satisfactory and, normally, very safe hypnotic. It may, however, be regarded as a toxicological supplement to the observation (Toal, 1937, and others) that the drug, though stable when stored according to the prescriptions of the B.P. 1932, will deteriorate "under the practical conditions of every day use." It reinforces the plea for an official sanction for the addition of a suitable preservative to the pharmacopoeial preparation of paraldehyde. Its storage in use should be carefully supervised and the residue of any that has been in hand some time should be regarded with suspicion. In mental hospitals only enough emergency draughts for one session should be kept and, for purposes of check up, the date of issue should be stamped on the label. In general hospitals, where paraldehyde is used as a basal anaesthetic, a large quantity should not be stored and only fresh supplies should be administered.

Summary

Severe and alarming toxic reactions after the administration by mouth of 120 min doses of paraldehyde were observed in a series of 7 out of 9 mental patients.

A toxicity test on mice showed that the suspect sample had a higher toxicity than that of a standard preparation.

The suspect sample did not conform entirely to B.P. requirements.

The toxic reaction was due not to acid or peroxidized substances but to some unknown product(s) of decomposition.

The clinical picture was similar to a severe intoxication with ethyl alcohol, but the "hangover" was more prolonged.

S. Zelman (*Amer J med Sci*, 1944, 207, 461) determined the blood diastase in a series of 59 cases of mumps on admission to hospital and on discharge. 73% were above normal on admission and 9% on discharge, 3% were subnormal on admission and 20% on discharge. Of this series 15% showed evidence of pancreatitis some time during the course of the illness. In the pancreatitis cases there was an especially high percentage of increased diastase values on admission.

Medical Memoranda

Cranial Nerve Paralysis following Cerebrospinal Fever

The chief interest in the case described lies in the picking out of two different cranial nerves on opposite sides and the escape of closely adjacent nerves

CASE RECORD

A coolie aged 20 was admitted to hospital at 5.30 p.m. on Dec. 19, 1943. He was semiconscious, extremely restless, and resistant to examination. A history of headache and fever of one day's duration was obtained from his companions. On examination the temperature was 102.6 F., there was marked nuchal rigidity, but Kernig's sign was absent. The pupils were equal and circular and reacted sluggishly to light; there was no strabismus. Heart and lungs and abdomen, *nil* abnormal. Urine, *nil* abnormal. Lumbar puncture was performed and very turbid CSF under low pressure obtained. Microscopically many pus cells and Gram-negative intracellular diplococci were seen. On culture a pure growth of *N. meningitidis* was obtained.

The patient was treated with sulphapyridine, 2 g. of "daganan soluble" being given intravenously at once, and 1 g. sulphapyridine orally every 4 hours thereafter. A total of 31 g. was administered. On Dec. 20 ptosis of the right eyelid was noticed, and on closer examination a complete third-nerve paralysis on the right was discovered. The right eye was deviated laterally and the patient could not move it upwards or nasally. Slight downward movement accompanied by a clockwise rotation of the globe was possible, showing that the fourth nerve was unaffected. The pupil was dilated and fixed and there was slight oedema of the bulbar conjunctiva.

The general condition steadily improved but the third-nerve paralysis remained. It was not until Jan. 2, 1944, that it was noticed the patient was unable to close the left eye completely and that he had difficulty in keeping saliva in his mouth. On examination a bilateral facial paralysis was found. By Jan. 8 the seventh-nerve paralysis on the right side had cleared up, but it remained on the left. There was now inability to open the right eye fully or to close the left eye. The right side of the brow could be wrinkled and the right corner of the mouth elevated. An attempt was made to determine if there was any loss of taste sensation on the left, but owing to language difficulties and lack of co-operation by the patient no definite conclusion was arrived at. Similarly it was not found possible to determine if the eighth nerve on the left side was affected. There appeared to be no sensory loss in the distribution of the fifth nerve. The third, fourth, and sixth nerves on the left were unaffected. The Kahn test was negative.

After 3 months—on March 7—the condition had almost completely cleared up, there was slight external strabismus of the right eye when at rest, but full external ocular movements were possible. There was still slight weakness of the left side of the face.

Diphtheria in an Infant

It is appreciated that nasal diphtheria may occur even in the newborn, and the following report of such a case includes a record of the state of the mother in relation to diphtheria.

CASE HISTORY

A male child was born on March 24, 1944, the first child of its parents. At birth it weighed 7 lb. On March 31 it developed a purulent nasal discharge, and on April 9 was admitted to hospital, a nasal swab being positive. It was a normally nourished child but had a profuse watery nasal discharge. There was no clinical sign of faucial diphtheria. Routine swabs from nose and throat on admission gave growths of the intermedius type of Klebs-Loeffler bacillus. It was given 4,000 units of diphtheria antitoxin intramuscularly. The mother denied any symptoms to suggest diphtheria, and was found to be swab-negative and strongly Schick-positive. The nasal discharge continued and swabs were persistently positive until July 12. During the interval a virulence test was twice performed. On each occasion the result was positive. Throat swabs became negative after May 15. The child's Schick test at July 10 was negative. The only other item of interest during its stay in hospital was an intimate exposure to a case of measles developing in the next cot. Protection against this infection was apparently given by the intramuscular injection of 10 c.c.m. of fresh convalescent measles serum.

The patient's general condition throughout was satisfactory, and on discharge from hospital on July 24, after three successive negative swabs from nose and throat, his weight was 11 lb. 8 oz.

Reviews

ALLERGY AND ANAPHYLAXIS

Allergy, Anaphylaxis and Immuno-therapy. Basic Principles and Practice. By Bret Ratner, M.D. (Pp. 834; illustrated 58.50 or 47s.). Baltimore: The Williams and Wilkins Company, London: Baillière, Tindall and Co.

Allergy is a medical topic much less talked and written about in Britain than in America, where, indeed, it seems to be more prevalent phenomenon than it is here. It is not a popular subject with the medical student, and most practitioners have rather hazy notions about what it is or is not. This volume of over 750 closely written pages (and 56 pages of references) will lighten his darkness, for all aspects of allergy, anaphylaxis, from the experimental and theoretical to the clinical and practical, are fully described and often graphically explained. It tells about the nature of the proteins, antitoxins and the like, which are mostly responsible for allergic reactions, the clinical manifestations and laboratory findings in serious sickness, and the methods for recognizing the hypersensitive individual and for preventing serum accidents. Transfusion risks are discussed, and the chapter on sulphonamide sensitivity is particularly valuable and topical; numerous examples are given of the accelerated type of allergic reaction to the drug, especially in patients who had shown sulphonamide sensitivity during an earlier course. The practitioner will find the section on immuno- and chemo-therapy of bacterial infections, listed alphabetically, very useful, though the expert may question some of the views and recommendations expressed there. Unfortunately there are no chapters devoted specifically to serious allergic diseases as asthma, hay-fever, eczema, and food allergy. For the immunologist there are good descriptions of the mechanism and rationale of allergic and anaphylactic phenomena, including physiological pathology, blood chemistry and cytology.

The book, which is well produced and freely illustrated, should prove useful alike to the fever expert, the general practitioner, and the laboratory worker.

GYNAECOLOGICAL DISORDERS

The Symptomatic Diagnosis and Treatment of Gynaecological Disorders. By Margaret Moore White, M.D., F.R.C.S., M.R.C.O.G. With foreword by F. J. Browne, M.D., F.R.C.S., F.R.C.O.G. The General Practitioner Series (Pp. 229; illustrated 16s.). London: H. K. Lewis and Co. 1944.

This little book of just over 200 pages has been written for general practitioners. As the title indicates, the subject is discussed from the point of view of symptoms and symptomatic treatment. Each of the first 17 chapters opens with a tabulated summary of the contents which recalls memories of a "synopsis" type of textbook. A brief description of each condition with notes on appropriate treatment follows. The last two chapters, on contraception and radiation therapy, are by Dr. Mary Redding and Mr. I. G. Williams respectively.

In spite of the excellent detail it contains there is something unsatisfactory about this book. Criticism may be epitomized by a consideration of Chapter 17, which is devoted to pre- and post-operative treatment and complications. This is surely the province of the specialist and not the practitioner. If the latter is sharing the control of a case with the former he should be given his instructions according to the specific needs of the case and the practice of the surgeon. In other words, there must be a close relation between the practitioner and the specialist. There are things the general practitioner should take responsibility for and things he should not, but there is little in this book to guide him through the difficult no-man's-land of borderline cases. Accurate diagnosis must obviously precede intelligent treatment. The practitioner may well expect to investigate and treat pruritus vulvae or vaginal discharge but if the tragedies of gynaecological practice are to be avoided he must know the dangers and be able to realize when the time has come to seek help. He must be warned of the dangers of leucoplakia and kraurosis, and not wait until carcinoma has developed before he refers his patient elsewhere. As accurate diagnosis, he cannot find much help in an academic summary of possible causes. For example, in dealing with

ulcers of the vulva the author refers to conditions such as tuberculosis, which the busiest of consultants will see on the rarest occasions and the busiest general practitioner may never see, but she omits carcinoma, which is all too common. True, it is included under tumours of the vulva, but if summaries are to be used for instruction these summaries must be complete at least so far as the common lesions are concerned. An adequate chapter on "danger signs" in gynaecological practice would add much to the value of this book, which in its present form may even mislead those practitioners it seeks to help.

A BOOK ON TUBERCULOSIS

A Manual of Pulmonary Tuberculosis, Part I and an Atlas of Thoracic Roentgenology, Part II. By David O. N. Lindberg, M.D. F.A.C.P. (pp. 232; illustrations 55 or 368) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox. 1943.

The jacket of this volume tells us that "every page is practical. Practical diagnosis, practical treatment, and practical prevention of pulmonary tuberculosis are covered adequately and briefly. Theory, experimental, and controversial subjects are not included. Well-planned charts and graphs relieve the busy practitioners from excessive reading and searching." Referring to Part II of the book—which constitutes two-thirds of it—we read: "The quality of these plates suggests that this Atlas Section will be of greater diagnostic value than any published series of chest roentgenograms." The contents of the book unfortunately provide a marked contrast to this advertisement. The tuberculosis specialist will learn little from either the text or the atlas, and the student or busy practitioner will be left with a feeling of confusion and inadequacy. "Reinfection" pulmonary tuberculosis is divided strictly into "exudative" and "productive" forms, apparently distinguished without difficulty by means of a radiograph. Collapse therapy is referred to as compression therapy. And lastly, under "General Treatment Considerations," the reference to syphilis reads: "The problem of tuberculosis and syphilis is still under extensive study. The treatment, in general, should be actively directed to whichever disease is the more fulminating."

The illustrations consist of 44 figures, charts, and tables in the text, and 145 reproductions of radiographs in the atlas. These are negative prints, reproduced postero-anteriorly.

Notes on Books

There is a recognizable tendency in modern medical literature towards the production of small books which are little more than pamphlets, dealing with a very limited aspect of a subject or with a point in technique. This is well exemplified in *Local Anaesthesia: Brachial Plexus*, by Prof. R. R. Macintosh and Dr. William W. Mushy, a book of some 50 pages consisting for the most part of a series of very excellent drawings (by Miss McLarty) and photographs of the anatomical basis of brachial anaesthesia, with the necessary explanatory text. The method described is that of Patrick, and he would indeed be a poor technician who failed to produce adequate anaesthesia after studying these illustrations, for every point is made perfectly clear and the correct visualization of the anatomical relationships involved is rendered easy. The publishers (Blackwell Scientific Publications; 10s. 6d.) are to be congratulated on the general production of a book which is up to a good peace-time standard.

Mr. Kurt Colsen's small book on *Fractures and Fracture Treatment in Practice* for the use of medical students and practitioners was favourably noticed in our issue of Oct. 7, 1943. The author is tutor in the department of surgery and registrar to the surgical unit of the University of the Witwatersrand. A second edition has now been received from the Witwatersrand University Press, Milner Park, Johannesburg, South Africa. The price is 12s. 6d.

The International Bureau for the Suppression of Traffic in Women and Children (12, Old Pye Street, Westminster, London, S.W.1) has published under the title *The Abolition of Tolerated Prostitution* a series of lectures given at an international meeting held in October, 1943, at the London School of Hygiene and Tropical Medicine. Two of the lectures dealt with the medical argument; they were given by Prof. Cyril Burt, who referred particularly to psychological factors, and by Dr. Edward Glover, who spoke on pathological factors.

Preparations and Appliances

APPARATUS FOR SYSTEMIC ADMINISTRATION OF PENICILLIN TO YOUNG CHILDREN

Dr. C. A. ST. HILL writes from the Department of Pathology, University of Liverpool:

Systemic administration of penicillin to infants and young children by the subcutaneous or intramuscular route presents problems not encountered in the treatment of adults. The small size of the patients prohibits the use of an ordinary continuous drip or of the Ministry of Health's "Eudrip" No. 1, as the amounts delivered per day by these methods are too large. Thus, the "Eudrip" No. 1 delivers 100 c.cm. per day. This in an infant weighing 7 lb. is equivalent to 2,000 c.cm. in a 10-stone adult, and would certainly produce waterlogging in a short time.

For this reason an apparatus has been devised and used which delivers 12 to 24 c.cm. of penicillin a day by an intermittent drip method, and which can be rapidly constructed from apparatus in everyday use in a routine pathological laboratory.

The apparatus consists of the following parts:

The main reservoir (A in diagram) is a 50 c.cm. capacity separating funnel. The stem of this, shortened to a length of about 3 in., forms the inlet for the secondary reservoir (B). This latter consists of a two-holed 1-in. rubber bung with an ordinary surgical rubber glove-finger drawn over it, the contained volume being adjusted to 2 c.cm. The outlet tube curves downwards and passes, via a short length of rubber tubing fitted with an adjustable screw spring clip, to a dripper with as fine a jet as possible. Both the inlet and outlet tubes of the secondary reservoir end flush with the lower surface of the rubber bung to facilitate expulsion of bubbles. The dripper is connected to the delivery needle by a length of 3/16 in. rubber tubing.

After filling the apparatus and expelling air bubbles, the main reservoir is sealed off from the second reservoir by means of the stopcock. The solution is allowed to drip into the patient as slowly as possible. As this proceeds, the rubber glove-finger gradually becomes emptied and consequently collapses. When emptying is complete the flow of solution automatically ceases and there can be no emptying of the dripper and lower lengths of tubing with consequent production of air locks when the secondary reservoir is refilled. Two hours after the first injection has been started and at 2-hourly intervals subsequently, the nurse in charge of the case refills the secondary reservoir by opening the stopcock for a few seconds. Immediately the secondary reservoir is refilled the drip will restart and continue until the 2 c.cm. contained in it has drained away.

The advantages of the apparatus, therefore, are: (1) Small amounts of fluid are given. (2) A minimum of supervision is necessary. (3) The 2 c.cm. of penicillin solution contained in the secondary reservoir are delivered to the patient once every 2 hours without the danger of the apparatus being emptied. (4) The apparatus is easily made from material readily available.

At the last quarterly court of the Directors of the Society for Relief of Widows and Orphans of Medical Men, with Dr. R. A. Young, president, in the chair, the death of one of the vice-presidents, Mr. Ernest Ware, was reported and also the death of one of the widows in receipt of grants: she came on the funds of the Society in 1929 and received in grants on behalf of herself and son £1,925; her late husband paid in subscriptions £52 10s. It was decided that a Christmas present be made to each widow next December. Membership is open to any registered medical man who at the time of his election is resident within a twenty-mile radius of Charing Cross; relief is granted only to the necessitous widows and orphans of deceased members. A new list of members is shortly to be printed, and the secretary would be very grateful if members would send any recent change of address to him at 11, Chandos Street, Cavendish Square, London, W.1.

POST-WAR REHABILITATION AND RESETTLEMENT

BY

G. D. KERSLEY, M.D., F.R.C.P.

Major, R.A.M.C.; Specialist in Physical Medicine

Rehabilitation, the complete range of treatment continued till the fullest working capacity is restored, has exercised many minds for many months. Numerous aspects have been dealt with by various authorities: the Army at the convalescent depots and selection centres, the R.A.F. at rehabilitation centres, the Ministry of Health at their rehabilitation departments at the main hospitals, the Ministry of Labour at their centre at Egham—where “pre-vocational guidance” is also involved—the Ministry of Pensions at Roehampton, the miners, the dock workers, and now even private enterprise backed by various industrial firms, are all engaged in tackling this problem in their own particular way. The field is vast, and includes not only the treatment of injuries and the scourge of rheumatism, but also planned convalescence, the prevention of breakdown in health, pre-vocational guidance so as to ensure correct placing of labour according to physique and mental fitness, vocational training, and provision of sheltered workshops. Yet, so far, co-ordination of these essentials of complete rehabilitation on a national basis is lacking. Below an attempt is made to outline the services necessary to carry out such a scheme.

The natural sequence of rehabilitation may be shown diagrammatically thus:

An *Out-patient Rehabilitation Centre*—the medical equivalent of a fracture A unit, with which it could be combined—would provide out-patient treatment and advice. It would be supervised, probably as a part-time appointment, by a medical officer who had had some special training in rehabilitation methods, and it would be visited regularly by one or more consultants. Rheumatic and orthopaedic cases requiring specialized and institutional treatment could be sent from here to a rehabilitation hospital.

General Hospitals would refer cases requiring long-term orthopaedic or rheumatic treatment to rehabilitation hospitals or hospital groups, while those patients requiring planned convalescence would be sent to a post-hospital rehabilitation centre. Each hospital of any size, however, will require its own physiotherapy and diversional occupation departments, and to co-ordinate these and to ensure that active treatment is started at the earliest possible moment a rehabilitation officer will also be necessary. The latter appointment would usually be held by a physician or surgeon already on the hospital staff.

The *Rehabilitation Hospital* or hospital group would receive patients from out-patient rehabilitation centres, fracture B and C centres, and general hospitals. It would consist of one or more hospitals—rheumatic, orthopaedic, and any with fracture A departments—and would have communal amenities in the form of a physiotherapy department, a gymnasium, a heated indoor swimming-pool, occupational therapy workshops, an x-ray department, and a laboratory. It should be situated within easy reach of an industrial area, but in open country, and it should maintain a very close link with the nearest medical teaching school and university in order to facilitate and co-ordinate teaching and research. Four of our largest spas—Bath, Buxton, Droitwich, and Harrogate—could, with a little expansion, easily fulfil these conditions for their surrounding areas, but they would no longer be watermongers. A widespread movement in this, the right direction, was exemplified when recently the chairman of a spa committee announced that his spa's policy was to do all in its power to make it a useful cog in the wheel of the rehabilitation machine, and only to use the waters—applied according to the laws of orthodox physics—as one part of the facilities available to the medical team. The spa rheumatic hospitals would then act as the rehabilitation nuclei for their localities—Bath for Bristol and South Wales, Buxton for Manchester and Sheffield, Droitwich for Birmingham, and Harrogate for Leeds and Bradford. A senior medical or surgical qualification would have to be a *sine qua non* for their senior staff appointments—a regulation already introduced at one of these hospitals—and a closer liaison with the

dean and professors of medicine and surgery of their associated universities would be required. A fourfold plan of co-operation between each spa hospital and its neighbouring university should be considered: (a) the use of the spa hospital for both postgraduate and antegrade clinical teaching; (b) the reference of cases requiring specialized institutional treatment and investigation to the spa hospital from the hospitals to which the university medical schools are attached; (c) co-operation over special research; and (d) a closer staff liaison, including the possibility of the professor of medicine becoming an honorary member of the Hospitals Medical Board and of certain beds being made available to the medical unit of the university. It is hoped that research, in addition to being linked with the university, will also be co-ordinated with that undertaken elsewhere, through a central body such as the Empire Rheumatism Council or an appropriate committee of the British Orthopaedic Association.

As regards the internal administration of such a rehabilitation hospital, co-ordination by a rehabilitation officer would be necessary. Individual treatment such as physiotherapy and specific occupational therapy would be prescribed by the medical officer in charge of the case, who would also place the patient in a grade. Each grade would then have its organized programme of general exercise and diversional occupation or employment, and the technicians would refer to the doctor in charge of the case, by a system of slips via the rehabilitation officer, any remarks on the reaction to treatment and suggestions about alterations or regrading of the patient. Additional privileges in the way of late passes, etc., for the higher grades would act as an incentive to progress.

The *Post-hospital Rehabilitation Centre* would take the place of the convalescent depot in the Army, with the difference that it would have to deal with women as well as men, would take all age groups, and, instead of a hardening programme, diversional instruction and occupation and pre-vocational selection would be substituted. This centre would take patients from the rehabilitation and general hospitals and also direct from work when it was felt that a period of rest, build-up, and possibly change in occupation would avoid a breakdown. It should primarily be a medical unit, but every effort should be made to get away from the hospital atmosphere. An important entity would be a welfare department, which would follow up the progress of the individual in the occupational workshops with a view to replacement, or retraining where it eventually proved necessary. While at this centre many might be able to continue study or training in their own jobs or do some useful work, for which they should receive remuneration. The running of short courses for industrial medical officers, almoners, factory managers, and social workers would be another function of such a centre. On discharge men would return direct to work, to a Ministry of Labour training establishment, or to sheltered workshops.

The Tomlinson report made three main recommendations with regard to resettlement: that employers must accept a fixed quota of the partially disabled, that these disabled persons should be registered, and that certain occupations should be scheduled especially for employment of such “handicapped persons.” This has been criticized (*Lancet*, 1943, 2, 771) in so far as it is felt that a large proportion of the disabled could fend for themselves on the open market if employers were educated as to their use and value, and if both the worker and the employer were protected from financial risk should it be found later that the handicapped person could not “cope,” or if there should be some increase in the old disability or the onset of a new one. The cessation of all sick benefit as soon as any light work is undertaken and the liability of a firm employing a handicapped man, perhaps more prone to accident than normal, both militate against any voluntary solution to the problem of employment of the disabled. Yet a circular from the United States Office of Education showed that 98% of firms employing partially disabled persons found that, when suitably placed, such employees were actually more reliable than their fit co-workers.

Moreover, from another angle the financial security of the individual cannot be disregarded in considering the problem of rehabilitation. Undecided compensation is the greatest single cause of delay in return to work, owing to its psychological effect. If, however, financial security is safeguarded, it is felt that comparatively few could not find a suitable post when aided by suitable pre-vocational guidance and, if necessary, by vocational training. For the few failures, sheltered workshops or communities are, however, necessary. These will require extension in number and scope, and should include facilities for employing the chronic rheumatic in addition to those for the tuberculous, the injured, and the blind.

H. D. Pasachoff, M. J. Madonick, and C. Drayer (*Amer. J. Dis. Child.*, 1944, 67, 201) record cases of four siblings showing the characteristic features of Marfan's disease or arachnodactyly. Two showed mental retardation. Air encephalography revealed definite internal hydrocephalus in one and some dilatation of the ventricular system in the other. The father and paternal grandfather showed elements of the disease.

PARENTERAL TREATMENT OF ANAEMIA

with

NEO-HEPATEX

Rapid remission of anaemia.

Each batch is clinically tested before issue.*

Non-toxic.

Suitable for intravenous use.

Painless on injection.

* A copy of the clinical report is enclosed with each package.

Issued in

Boxes of	{	6 x 1 c.c. 50 x 2 c.c.

'Proctooids' for Haemorrhoids

THE composition and consistency of a haemorrhoidal suppository are its most important assets.

A further important matter for consideration is that of shape, as discomfort can follow the insertion of a badly shaped suppository.

The torpedo shape of 'Proctooids' brand haemorrhoidal suppositories allows the insertion of the large end first, so that once the widest diameter is past the sphincter, the suppository is spontaneously pressed inward, where it is retained, melted, and the therapeutic ingredients liberated.

The increasingly favourable reception of 'Proctooids' attests to their effectiveness in promptly relieving pain and reducing inflammation.

MERSALYL B.D.H.

The Standard Mercurial Diuretic

Undue prominence has perhaps been given to reactions to mercurial diuretics generally, with the result that these valuable therapeutic substances may not be used as frequently as the benefits of their use to the patient justifies.

In common with most therapeutically potent substances, mersalyl may produce toxic effects in high dosage; at the same time it is a matter of clinical observation that the question of its toxicity is of little significance compared with the benefits associated with its controlled use.

Indeed, mersalyl has proved to be the most generally and consistently satisfactory of the mercurial diuretics; it is available as Mersalyl B.D.H. (Injection of Mersalyl B.P.), and, for auxiliary treatment, as tablets of Mersalyl B.D.H., each tablet containing mersalyl 0.08 gm. and theophylline 0.04 gm., and as suppositories, each containing mersalyl 0.4 gm. and theophylline 0.2 gm.

what MILTON is . . .

4. NOT EUSOL*

Milton is not Eusol. Milton is prepared by the electrolysis of sodium chloride in solution, stabilised by a special process and standardised at 1% of sodium hypochlorite. It is non-irritant.

"Eusol B.P.C.," says an independent investigator, "is often incorrectly regarded as a sodium hypochlorite whereas it is really a solution of chlorinated lime buffered with boric acid. It is therefore no substitute for sodium hypochlorite and it is well known to possess irritant properties towards the human skin."

These facts have become widely recognised and accordingly Milton has replaced Eusol in many hospitals.

"Chemically prepared varieties such as Eusol or Dakin's Solution have more irritant end-products. Milton was thus used as it filled requirements."¹

"Eusol for treatment in the wards has been replaced by Milton Solution in the strength of 1 in 20 . . ."²

"It" (slight pain after washing with Milton) "was not comparable to the pain of Eusol dressings on a raw surface . . ."³

For unvarying strength and low alkalinity the choice is Milton—not Eusol.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 11 1944

A NATIONAL THORACIC SURGICAL SERVICE

Thoracic surgery in this country virtually started during the last war and arose primarily from the demands of treatment of battle casualties. Between the two wars the advances in this field of surgery have been so great that the Society of Thoracic Surgeons of Great Britain and Ireland, which was founded nearly 10 years ago, has recently issued a printed memorandum in which it outlines a scheme for the provision of a national thoracic surgical service*. Though it would have been easier to design the pattern of this service if the planning for the future of the medical services for the whole country had reached a more mature stage, it is still important that such a memorandum has been drawn up, and the suggestions made in it deserve attention.

The success of surgical methods in the treatment of thoracic diseases has led to such an increased demand for their use that there is a danger that development will proceed along unsatisfactory or unsafe lines. Thoracic surgery is a difficult branch of medicine and one which requires much special skill and experience if disasters are to be avoided. The time has passed, or should have passed, when the physician calls upon or directs his surgical colleague to perform some particular operation upon the chest. If good work is to be done and advances are to be achieved the thoracic surgeon not only must be highly trained himself but must be able to call upon the help and co-operation of many associated workers. The understanding of thoracic diseases alone requires considerable training and experience, the full investigation of a case before operation is decided upon may be complex and calls for much judgment, the operative procedures necessitate a high degree of surgical skill and must be supported by an equally skilled anaesthetic technique. Proper pre-operative and post-operative management may be time-consuming, and it needs the assistance of a specially trained nursing staff and physiotherapists. Many local authorities and smaller hospitals throughout the country recognize the scope of thoracic surgery and are trying to secure the services of a surgeon for it. For good results the thoracic surgeon must be backed up by a proper organization or team. It should be clearly understood that even a trained thoracic surgeon cannot obtain good results if he is expected to make casual visits for operations and leaves the pre- and post-operative care to unskilled personnel, however enthusiastic they may be. The surgeon untrained in thoracic surgery who undertakes casual work under such conditions is certain to bring disappointment both to himself and to his patients.

The problem arises particularly in the treatment of pulmonary tuberculosis. Many centres exist throughout the

country in which there is as yet no provision for even the simplest methods of treatment by collapse therapy, many such institutions do not possess an x-ray apparatus or provision for artificial pneumothorax treatment. The mortality and morbidity from this disease remain so high that the demand for increased facilities is very great, and thousands of patients yearly are still denied the benefits which surgical treatment alone can bring. Many patients, after much time and public money have been spent on their treatment, reach a stage in which thoracic surgery is needed to complete their cure, and are unable to obtain admission for this owing to the shortage of beds, their condition so deteriorates while they are waiting that the chance of a good result is either greatly diminished or lost altogether. Nearly the same applies to sufferers from non-tuberculous conditions of the chest. To give some idea of possible future requirements it is worth recording that in the two chief chest hospitals in London there is normally provision for some 150 surgical patients. During the war the London E.M.S. chest centres have provided an additional 450 beds, and yet there are still long waiting-lists. It is anticipated that after the war the demand for yet more accommodation will be even greater, and in this regard one must remember that, although some of the present E.M.S. centres may fit into a future national organization, others will have to return to their peacetime use. If, therefore, the public is to have the thoracic surgical treatment of a standard to which it is entitled its needs can be met only by the establishment of a properly organized service with centres adequately staffed and equipped.

Provision for the teaching of thoracic surgery receives special consideration in the memorandum. The student does not require a highly specialized knowledge of any particular branch of surgery, and only enough of his time need be spent in a department of thoracic surgery to allow him to become familiar with the various methods of investigation of cases and the type of surgical help that can be offered to his patients. For this reason the undergraduate teaching hospital needs a department of no more than some 25 beds and an out-patient clinic. Graduates should concentrate on the work of a large chest unit or special chest hospital, where more intensive study is possible. The training of thoracic surgeons is even more important. In the present generation thoracic surgeons have graduated from the field of general surgery, and not a few still practise in that field. The thoracic surgeon of the future should have had a thorough training in general surgery and so should have served for a period of at least two years as a surgical first assistant or registrar. In addition he should have devoted at least two years to the special study of surgical chest diseases. Some of this time could well be spent abroad, but the remainder would be passed at a special chest hospital or one of the special chest centres.

Chest surgery is essentially a branch of medicine which requires area organization, and any scheme will have to be worked in conjunction with the tuberculosis services in co-operation with local authorities. It is proposed that each area should have at any rate one primary thoracic surgical centre, and it is emphasized that each centre ought to handle all types of thoracic surgical disease. Any attempt to separate the surgical treatment of pulmonary tubercu-

* The hon. secretary of the society is Mr A. Graham Bryce, 3, Lorne Street, Manchester, 13.

losis from that of other chest diseases is strongly deprecated. As the thoracic surgeon should be able to obtain the advice of his colleagues in various other departments of medicine and surgery, and will need full facilities for good radiological work, access to pathological laboratories and laboratories for research, the centres in university towns should be part of or very closely affiliated with the teaching hospitals. The work of a centre cannot be carried out efficiently by surgeons and nurses who engage in it as a temporary occupation. The regional medical staff which would be needed should be composed of a director, or assistant director, a number of surgical officers of the standard of registrar, and house-surgeons, physicians, and radiologists.

The department of thoracic surgery at the area teaching hospital might well be the primary regional unit, having 50 to 100 beds; or it might be a much smaller unit owing its existence mainly to the requirements of undergraduate instruction. If the primary unit for the area was situated elsewhere it would still have a close association with the university. In most regions there would have to be one or two secondary or branch units, one or both of which would naturally find their place in the larger sanatoria in which the necessary staff and equipment had been installed. This would satisfy the wish of those who feel that better results will accrue if tuberculous patients are operated upon in a sanatorium than if they are transferred to a city hospital for this purpose. While there is a shortage of trained thoracic surgeons it would be a disservice to patients suddenly to abolish facilities which already exist for the efficient performance of operations of a minor nature in scattered smaller institutions. Such smaller centres will, however, disappear when the surgical work they are doing can be done at the chief centre or one of the larger branch units. An organization of this kind would provide ample facilities for the training of a large and adequate number of thoracic surgeons who not only would work under the supervision of the director during their training but would also be encouraged to consult with him about the management and treatment of cases at subsidiary centres. The director himself would work at the primary regional unit, but would maintain this supervision over and contact with his juniors and assistants at the smaller centres.

The scheme drawn up by the Society of Thoracic Surgeons may at present seem rather Utopian, but it is sound and has been well thought out. If successful it should certainly enable the public to obtain efficient thoracic surgical treatment in almost any part of the country, whereas at present this is limited to a very few places.

THE PROBLEM OF AGEING

We publish to-day a letter from Dr. A. S. Parkes, the chairman of the Nuffield Foundation's medical subcommittee on the causes and results of ageing, asking for information about research at present in progress on problems of interest to the subcommittee. The formation of the Foundation's Survey Committee and Medical Subcommittee is a clear indication of the increasing interest in the social, economic, and medical problems of ageing and

of aged people. On the medical side the problem has received sporadic attention since earliest times, for the most part from the unhappy point of view of rejuvenation. The modern approach, in contrast, is by way of the characterization of the process of ageing and the study of the special disabilities of the aged, and only thence to a consideration of what can usefully be done towards the therapeutic retardation of the process of ageing. The characterization of the ageing process presents peculiar difficulties. It is easy to say that ageing starts at birth (more strictly, at fertilization of the ovum); but the idea is not a helpful one, and in practice it is more useful to regard the onset of ageing as the first impairment of bodily function, for reasons not obviously pathological. The physiological or biochemical factors involved in such impairment, the sequence of events in different organs, the forces initiating the process, and the pathological conditions essentially associated are all problems which arise in the characterization of old age, and only when these have been elucidated can any rational approach to the problem of retarding the process be made.

The decrease in the birth rate and the increase in longevity in the last three or four decades have led to ominous changes in the age distribution of the population and will accentuate all medical, social, and economic problems relating to old people. According to the Beveridge report, men of 65 and over and women of 60 and over who in 1941 comprised 12% of the population, will in 1971 comprise 20.8%, with a corresponding decrease in the proportion of those at productive ages. If there is any substantial increase in the birth rate the increase in the actual proportion of the aged may be less than this estimate, but, short of some most unexpected decrease in longevity, the increase in gross numbers from 5.6 millions to 9.6 millions is inevitable. In so far as the aged are directly or indirectly dependent for support on younger members of the community, the burden on the latter is bound to increase greatly in the next few decades. This point is well shown by the statement in the White Paper on Social Insurance that between 1965 and 1975 there will be an increase of about 800,000 in the pensioner population and a decrease of more than 1,000,000 in the contributing population. In 1945 there will be 16 and, in 1975, 31 pensioners for every 100 contributors; only a small part of this increase will be due to the gradual inclusion of new classes after a qualifying period. Here, then, we have the crux of the economic problem of the aged—the retention of productive capacity as long as possible and the allocation of productive occupations especially suited to old people. Ancillary to this question is the estimation of full working capacity. Physiologically and psychologically it is a truism to say that one person of 40 may be as old physically and mentally as another one of 60; yet the present tendency, especially among the professional classes, is to have a rigid retiring age of 60 or 65. Clearly this policy may have to be revised. It would be of great interest to know whether the increase in longevity over the last century has been associated with an increased duration of working capacity or whether the shorter life of earlier days was more usually fully active until the end. Whatever the answer to this question, it

s quite evident that at the present time further increase in longevity, whether due to prophylactic or to therapeutic measures, will have serious consequences for the nation unless there is a comparable increase in the duration of working capacity

PHYSIOLOGY OF THE VAGINA

The Fallopian tubes, uterus, and vagina are all developed from the Mullerian ducts. It is therefore not surprising that the tubes and vagina resemble the uterus in that they react to ovarian hormones and take part in the menstrual rhythm. The tubes respond not only by changes in the mucosa but also in the activity of their muscle coats. Indeed they have been credited with a menstrual function at times, and have been shown to be capable of a decidual reaction in pregnancy. Cyclical changes in the vagina are less obvious but are nevertheless demonstrable. A relation between the ovary and vagina was first suggested some fifty years ago, but only recently have the specific vaginal responses been determined. In this country Cruickshank and Sharman¹ in 1934 made a valuable contribution to our knowledge of this subject, and now Rakoff and others² present a review of the physiology of the vagina, together with an account of their own studies carried out on 500 women. Oestrogens induce hyperplasia of the vaginal epithelium and bring about a deposition of glycogen in its intermediate and superficial layers. The amount of the glycogen in the vaginal cells at different stages of life is thus directly proportional to the oestrogenic activity of the ovary—a phenomenon to which we recently drew attention³. During the active reproductive life of woman it is said that the amount of glycogen present in the vaginal epithelium is proportionately greater than that in any other tissue of the body with the exception of the liver. The effect of progesterone on the vagina is less clearly defined. Under experimental conditions it appears that very large doses may produce epithelial proliferation and cornification. However, in physiological amounts and when administered in combination with oestrogens its effect is more often opposed to that of oestrogens. It does not influence the amount of glycogen present in the cells. Androgens inhibit both epithelial proliferation and glycogen deposition. The transformation into glycogen of glucose received from the blood is believed to be a special function of vaginal epithelial cells, and it is assumed that the glycogen is the source of the lactic acid which is the characteristic component of the vaginal fluid. A prevalent opinion is that this change is brought about by the action of Doderlein's bacillus, although the reported finding of lactic acid in the sterile vagina at birth does not support it. A second view supposes that the formation of lactic acid is the result of an enzyme, while other theories involving both enzymic and bacterial action have also been put forward. The flora of the vagina certainly varies with its pH, and Doderlein's bacilli predominate when the vagina is most acid. But it has still to be shown which is the cause and which the effect.

The vaginal cycle consists of a proliferative phase corresponding to the follicular phase of the ovary and the proliferative phase in the endometrium. This is followed by further hyperplasia and cornification during the early part of the luteal phase, and later by desquamation during the days preceding menstruation. The vaginal pH also shows variations, the lowest figures being obtained at the mid-interval phase—that is, about the time of ovulation.

This is followed by a gradual rise up to the time of menstruation, after which there is a return to the more acid side. Rakoff and others² point out that not all workers have obtained the same results in regard to the rise and fall of the vaginal pH. The discrepancies may be explained by the fact that the pH differs at different levels in the vagina, and, moreover, unless special care is taken false readings may be obtained owing to contamination with the alkaline secretion from the cervix. In any case, the normal range of variation is small.

All the evidence goes to show that the acidity of the vagina is important in protecting it from infection, and among the few micro organisms which thrive when the pH is within the normal range of 4 to 5 are Doderlein's bacillus and the yeast and yeast-like group. The latter indeed flourish when the vagina is most acid, as in pregnancy, when the pH may fall as low as 3.8, and when it is unusually rich in fermentable carbohydrates. This explains why infection with monilia (vaginal thrush) is most common in pregnancy and in the presence of glycosuria.

NUTRITION IN JAPANESE INTERNMENT CAMPS

The nutrition of Allied nationals in Japanese internment camps is the subject of a recent report¹ based on the evidence of repatriated doctors and nurses. About a dozen camps were set up by the Japanese authorities to house just over 15,000 internees. The Japanese policed the camps and supplied the food, while the internal administration, preparation and cooking of food, and sanitation were in the hands of the interned. In general the rations supplied were low in calories, protein, calcium, iron, and vitamins. Canteen purchases were severely restricted because of lack not only of money but also of food. Black markets flourished in many of the camps, those with enough money being able to buy from their captors sugar, jam, fruit, eggs, and sometimes meat. Black-market extras and comforts provided by the Red Cross enabled some of the internees to survive without serious evidence of deficiency disease. After three or four weeks' internment most of them experienced hunger for the first time. Nearly all adults lost weight, in some camps losses of 40 lb to 60 lb were not uncommon. The basic diet consisted mainly of polished rice, soya beans, potatoes, pot herbs, and a little pork, with water-buffalo meat, duck eggs, and white flour when available. Fresh cows' milk and watered buffalo milk, when obtainable, were given to infants and small children. The average daily calorie intake on this diet was 1,500 to 2,000, the daily protein intake 40 to 80 grammes. The intake of calcium was low (0.12 to 0.25 gramme daily), as was also that of iron. No reliable data are available for the vitamin content of the diet, but it was generally agreed that the intake of vitamin B and riboflavin was low. And the food was unpalatable. This is not surprising, as there were practically no facilities for cooking. This meant that stew containing all the food for the day except bread was the only item on the menu. The Japanese made little or no provision for medical care. The only medical and surgical supplies were those taken to the camp by the interned people themselves and those provided by the Swiss authorities.

Secondary anaemia from lack of iron, and hypotension, muscular weakness, and oedema, due probably to lack of protein, were reported in many camps. Deficiency of vitamins of the B complex manifested itself by loss of energy, restlessness, numbness, paraesthesiae, loss of reflexes, decreased appetite, tachycardia, and pains in the extremities. These symptoms responded to treatment with

¹ *J Obstet Gynaec Brit Emp*, 1934, 41, 208.

² *Amer J Obstet Gynec*, 1944, 47, 67.

³ *Brit Sh Medical Journal*, 1943, 2, 753.

¹ Adolph, W. H., et al., *War Med.*, 1944, 5, 3-9.

vitamin B, and yeast. The clinical symptoms of beriberi and pellagra and some of the manifestations of ariboflavinosis (cheilosis, angular stomatitis, pigmentation of the alae nasi, glossitis, and seborrhoeic lesions) were observed in some of the interned. Diarrhoea was reported from most camps. This was not always infective in origin, as in one camp it yielded to treatment with nicotinic acid. Spastic colitis, due to the unaccustomed amount of roughage in the diet (coarse rice, bread, and vegetables), was common. A nutritional disease affecting the eyes, apparently of neuritic origin, was reported. The symptoms were blurred vision and quick fatigue on reading, or even inability to read at all. This may have been due to a deficiency of the vitamin B complex, though no cure was found for it in the camps.

All this makes disturbing reading. Unless there is quick improvement of the diet of those who are still interned, nutritional disease, with a high morbidity and mortality, will become widespread, and with it an increased susceptibility to such infections as malaria and dysentery.

NEW HOUSES

If post-war England does not come up to the expectations of post-war Englishmen, it will at least not be for lack of Government Departments and Committees. Housing, for example, is engaging more or less of the attention of the Ministry of Health, the Ministry of Works, the Ministry of Town and Country Planning, and the newly appointed Minister of Reconstruction. The Ministry of Health appointed a Central Housing Advisory Committee to make recommendations on the design, lay-out, construction, and equipment of dwellings, and it has been assisted by the reports of 22 expert committees set up by the Ministry of Works. One result is an admirable report entitled *Design of Dwellings*,¹ to which is added the report of a study group on site planning and lay-out in relation to housing.

The dimensions of the housing problem are formidable, and almost every flying bomb that gets through increases them. It is contemplated that during the 10 or 12 years after the war between three and four million houses will be built, more than half of them by local authorities. Such a programme will determine the domestic standards and habits of England for generations; therefore no detail of design can be regarded as unimportant. The houses built during the inter-war period were certainly an improvement on their Victorian and Edwardian predecessors, but some faults were outstanding, such as the marked separation between private and municipal housing, the building of houses without regard to communal facilities, and the location of residential estates too far away from places of employment. In the houses themselves the chief complaint was the smallness of the scullery or kitchen and the lack of a room for the expression of family life apart from the one where, in many families, meals—or their remains—are almost constantly on the table. On the controversy of house versus flat the subcommittee states that flats are largely unpopular. But in such a place as Welwyn Garden City, where the demand for flats might be expected to be low, it was found that roughly 10% of the households preferred that kind of accommodation.

The report makes, and illustrates, some interesting suggestions for dividing up the ground floor of the small house. The one we like best is the provision of a recess in the large living-room—the term “parlour” is banned—for the family meals, so that the rest of the room is available for other activities; also the provision of a small utility room where laundry and dirty household work

can be done. The report calls in general for more space in houses. Attention is drawn to the nervous strain of living in too cramped quarters. Reduction of space below a certain limit actually increases the work of running a house. It is, of course, a saving of labour if family meals are partaken in the kitchen where they are cooked; but how many kitchens would stand the strain?

One problem in the new housing will be to provide accommodation for old people. Old people, if in that term we include those aged 65 and over, number probably 5 millions, as against 1½ millions at the turn of the century. There is a clear case for the provision by local authorities of smaller dwellings for old people, not segregated from the others but embodying certain arrangements with a view to the physical infirmities of the occupants. Accommodation for single people living alone has also been largely overlooked in housing, both private and municipal. The report makes no proposal for the central heating of small houses. The solid-fuel furnace—open fire or some form of stove—seems likely to outlive its detractors. It is disappointing to hear that the subcommittee does not consider it practicable to provide refrigerators in municipal dwellings. It is hoped mass production may in time bring them within the reach of the bulk of the population. On the all-important matter of rent it is considered that the average rent of a three-bedroom post-war house, assuming a 3½% rate of interest, and excluding local rates, should be 13s. 7d., or, if interest is at 3%, it may be as low as 12s. 6d. The subcommittee which produced this report included seven women members, and its recommendations are no doubt of a more practical character in consequence.

THE ALMONER'S WIDENING FUNCTIONS

The term “almoner” still conjures up in the minds of many people a hospital officer whose chief function it is to assess and collect patients' payments. The annual report of the Institute of Hospital Almoners (Tavistock House North, W.C.1) warmly welcomes the extended definition of the almoner's functions given in the report of the Social and Preventive Medicine Committee of the Royal College of Physicians, especially the statement that the almoner's chief function is an assessment of the patient's needs, rather than of his means. The Institute has prepared a memorandum on the almoner's place in the scheme put forward by the Tomlinson Committee for the training and resettlement of disabled persons. Here the almoner's task will be two-fold: to maintain contact with the patient through the successive stages of his treatment, training, and resettlement, and to be the channel through which the health services and the industrial organization may meet and confer. The Institute is now in close touch with the Ministry of Health concerning the supply of almoners to rehabilitation centres. The past year has seen a gratifying increase in the number of local authorities which include an almoner on the staff of their clinics for venereal disease and also of their tuberculosis clinics. In Scotland there has been progress in the employment of almoners by public health authorities: three almoners are now working in public health departments, two in Edinburgh and one at Stirling. The inflow of almoner students is being maintained, thanks to the recognition by the Ministry of Labour that a supply of adequately trained almoners must be continued. During the present training year 125 students are being prepared for almoners' duties—the largest number on record.

The next session of the General Medical Council will open on Tuesday, Nov. 28, at 10 o'clock, when the President, Sir Herbert Lightfoot Eason, will take the chair and deliver an address.

Survey Committee on Problems of Ageing and the Care of Old People

SIR,—In March of this year the Nuffield Foundation announced the formation of a survey committee to consider problems of ageing and the care and comfort of the aged, and of a medical subcommittee to deal with medical problems, especially medical research problems, of the causes and results of ageing. The Medical Subcommittee is now considering its programme of work, and, in order to avoid overlapping and to promote general integration of relevant research, is anxious to make contact with investigators already working on this subject. The questions immediately before the subcommittee relate to the morphological, physiological, pathological, and psychological changes which characterize the syndrome of ageing, and to the factors which expedite and retard the process.

The secretary of the Medical Subcommittee, the Nuffield Foundation (Survey Committee), 12, Mecklenburgh Square, London, W.C.1, will be glad to hear from investigators, medical men, or biologists who have research along these lines in hand or projected, and who are not yet in touch with the committee—I am, etc.

A. S. PARKES

Chairman of the Medical Subcommittee

Neurological Signs in Riboflavin and Allied Deficiencies

SIR,—I have to day received the *Journal* of July 29 containing an account of the Lumleian Lecture by Dr Hugh Stannus and your editorial comment thereon. I am particularly interested in the mention of cerebellar signs in the syndrome of Hawes, Pallister, and Landor, and am able to confirm the clinical neurological aspect of his statements, having made a special study of the neurology in 1940 and 1941 with Dr. E. S. Monteiro. Eighteen cases of the pellagroid syndrome were admitted to the neurological clinic, Singapore, and studied in detail, and from an examination of these cases it became apparent that many of these exhibited spinocerebellar signs of a gross type, and were frequently demonstrated as such. Hawes, Pallister, and Landor were unfamiliar with the cerebellar component of these cases until the demonstration of the spinocerebellar element served to explain the gross ataxias met with, in the absence of adequate posterior column defect and of pyramidal signs. (When I say posterior column loss I am referring to loss of a type of sensation known to be conducted along these tracts. I do not infer that the primary lesion is in the tract. I believe that the tract lesions are secondary to death or disease of cells in the posterior root ganglion.) Pallister and Landor had regarded these cases as somewhat in the nature of subacute combined degeneration, but neither Hawes nor Pallister nor Monteiro and myself, using special neurological technique, had ever been able to demonstrate evidence of pyramidal release. While Monteiro and I were engaged in a neurological study of these cases Pallister's paper appeared in which he described 15 cases of ataxia occurring in the Chinese. Although the findings in this paper were somewhat scantily recorded from the neurological point of view, when these signs are tabulated they give evidence of the cerebellar component. This was done by Monteiro and myself, and in a discussion of this syndrome before the Medical Society of Tanjong Pagar Hospital was demonstrated in connexion with our own cases, which they closely resembled. Dr Hawes was informed by letter of the progress of our neurological investigation, which clarified a subject that he had been studying for years.

The majority of these cases, in which arborescences was marked and in which the cerebellar component was conspicuous, occurred in tonkin coolies. These coolies would frequently go for long voyages in these ships, being fed by a contractor. On their return the chances had often become irreversible, and so far as the eye was concerned an actual corneal ulceration had taken place, usually unilateral though circumferential injection was present on the contralateral side. The eye changes and perleche responded quickly to riboflavin. Photographs of these eyes were taken, the eye condition

being studied simultaneously by Williamson. It was remarkable that the ataxias could come on very rapidly within the course of a few days. These ataxias were sometimes associated with bands of subjective numbness on the trunk of root type. On the other hand, as Dr Stannus says, provided the case was treated early a complete or almost complete recovery would ensue. We had cinematograph and flash bulb photographic tracings of limb movement, using Dr Gordon Holmes's technique, to demonstrate this. In the case of the small girl described by Stannus, nystagmus and vertigo were present, which made recognition easy. Neither nystagmus, vertigo, nor intention tremor was demonstrated in any of our cases, although dissection of movement and dysmetria were readily shown both by direct observation and by means of the flashing bulb with a C38 tuning fork. This accounts partly for the failure of the earlier observers to recognize the cerebellar component in the Malayan cases.

That these cases were apparently spinal in origin led me to believe that the lesion lay essentially in the sensory ganglion cells of the spinocerebellar system—that is, Clarke's column. The signs were essentially sensory cerebellar and not motor. Further, the fact that we were able to demonstrate root involvement in some cases, together with the fact that these changes were labile and reversible, led us to believe that we were dealing with a cell disorder and not a tract one. This, naturally, is a forerunner of Dr Stannus's remark on systematization, in which he says it is based on neuropil. This was put forward as a hypothesis. Dr Stannus's observations on the capillary bed take the matter a step further.

Regarding the morbid anatomy of these cases, only one came to necropsy, the nervous system of which was being studied by Mrs Helen Burke, who held a research scholarship in the Medical College and who was working in the unit as a neuropathologist. This case was not absolutely typical of the Hawes-Pallister-Landor syndrome, exhibiting, as it did, frank pellagra, but nevertheless spinocerebellar signs were demonstrated. The tissue was fixed immediately after death by intrathecal formalin, and the most striking feature in the Nissl preparations was the degeneration of nerve cells in Clarke's column. These showed various stages from a change in shape to complete destruction. A somewhat similar change, though not so gross, existed in the cells of the posterior root ganglion. Tract degeneration was confined to the column of Goll, in which individual nerve fibres had undergone degeneration suggesting that this was secondary to cell degeneration. This patient also exhibited a somewhat similar degeneration of the optic nerve. He had complained of a dimness of vision, but, like most of these cases, did not show recognizable disk changes. The cerebellum itself had not been studied at the time of the fall of Singapore, as Mrs Burke was, together with all American women, evacuated to the United States early on.

Finally, in writing this letter I do not wish to appear pedantic, but I feel that in fairness to Monteiro, who is now a prisoner in enemy hands, and to the Singapore School of Medicine, where the clinical neurology had been worked out, this should be put on record. Monteiro and I had intended to communicate to Dr Stannus our findings before publication for his comment, as we regard him as the world authority on this subject. The original case notes will, I think, be available after the war—I am, etc.

Late Associate Professor of Medicine and
Lecturer in Neurology King Edward VII
Medical College Singapore.

Infantile Diarrhoea and Vomiting

SIR,—The paper by Drs Alexander and Eiser (*Journal* Sept 30) on infantile diarrhoea and vomiting has given me great pleasure. I offer my congratulations to the authors on the success of their diligent medical treatment. I am in complete agreement with all their statements except one. In the summary it is stated that "the aetiology of this killing disease is obscure." With this I venture to disagree, for I believe the aetiology is perfectly clear, and that if generally accepted and acted on much would be done with regard to prevention and cure.

The figures given by Drs Alexander and Eiser give convincing evidence in favour of my contention. In 60 out of 140 cases of diarrhoea and vomiting without evidence of gastro enteritis purulent otitis media was present. This condition cannot exist without adjacent cells being involved—in infants the relatively large mastoid antrum. We may therefore conclude that in these 60 cases mastoiditis was present. But as is shown at operation and in the post mortem room, mastoiditis is common in the absence of otitis media or aural discharge. It follows therefore, that in addition to mastoiditis in the 60 cases it was

present in many of the others undiagnosed. We may reasonably assume that the great majority of infants with diarrhoea and vomiting are in fact suffering from mastoiditis in its catarrhal or purulent stage.

The questions now arise: How is infantile mastoiditis acquired? and, Is diarrhoea and vomiting the cause of mastoiditis or mastoiditis the cause of diarrhoea and vomiting? All are agreed that diarrhoea and vomiting is far commoner in bottle-fed than in breast-fed infants, and that the former are frequently fed 'lying down in a position which invites milk or vomit to enter the Eustachian tubes while swallowing. In this way foreign material enters the tympanum and mastoid antrum and causes mastoiditis, followed by diarrhoea and vomiting. Breast-fed babies are not subjected to this peril and are therefore relatively immune to mastoiditis acquired by feeding in an unnatural position.

A further question now arises: How does mastoiditis cause diarrhoea and vomiting? The tympanic cavity and mastoid cells receive parasympathetic innervation from VII and IX. A reflex from the inflamed cells passes via VII and IX to the parasympathetic portion of X, which supplies motor and secretory fibres to the intestinal canal. This abnormal reflex disturbs the normal harmony between sympathetic and parasympathetic impulses in favour of the parasympathetic, resulting in diarrhoea and vomiting. It will be generally conceded that the younger the infant the more easily is this harmony disturbed, thus explaining the greater severity of diarrhoea and vomiting in younger infants. We are forced to the conclusion that in the great majority of cases diarrhoea and vomiting is a physical sign denoting mastoiditis. There are always additional physical signs which render the diagnosis certain, such as restlessness, crying out, putting the hand to the head, a bald patch caused by rubbing the head on the pillow, and, most significant of all, enlarged glands in the posterior triangle of the neck.

It is not always realized that mastoid sinusitis, like sinus infection in other cells—e.g., ethmoids—occurs in three distinct stages: (1) mucoid, (2) mucopurulent, (3) purulent. In the first two stages spontaneous recovery is often observed, helped by medical treatment on the lines laid down by Drs. Alexander and Eiser. Purulent mastoiditis, however, is usually a fatal condition unless surgical treatment is obtained. If, therefore, a child with diarrhoea and vomiting ceases to improve in spite of medical treatment, and if on examination is found to have some or all of the physical signs enumerated above, purulent mastoiditis should be diagnosed and operation advised. In this way many infants' lives could be saved.

Prevention: (1) Breast-feeding when possible. (2) Never bottle-feed lying down. (3) When a child is too young or too ill to sit up or turn over, never nurse or feed him on his back. Prop him up in his cot on his side and change sides every half-hour. Take him out of his cot for feeding and hold him in the natural position. Strict observation of these three rules would prevent the onset of mastoiditis to a large extent both in healthy infants and in those suffering from air-borne or food-borne infections.

It is my confident opinion that, when cure and prevention are carried out on the lines indicated above, the appalling infant mortality will be materially lowered, perhaps even by half.—I am, etc.,

Birkenhead.

P. W. LEATHART.

Drugs and the Doctor

SIR,—Your leading article of Oct. 21 on drugs and the doctor is both welcome and timely. This criticism of the White Paper is justified, and fortunately it is easy here to see that the interest of the public and the interests of medicine are identical. Therefore there need be no delay in actively tackling the problems so lucidly expounded in your article.

Sane pharmacotherapeutics is not only necessary but is now available over a rapidly extending field. It would appear that the initiative of the American Medical Association in organizing the Council of Pharmacy and Chemistry has produced an effective weapon. May I therefore suggest that the British Medical Association should immediately organize a similar procedure

for this country. An initial conference between the B.M.A. and representatives of the Royal Colleges, the Pharmacological Society, and the Pharmaceutical Society could determine the best form for such a council. We might well improve on the method of the Americans. Such a body will give prestige to the B.M.A. and progressively gain in influence, and its published recommendation could hardly be ignored by the Government.

Some of the problems mentioned in your article, such as the teaching of pharmacology, cannot be dealt with in this manner, but it is unnecessary to wait for the reform of such teaching (and pharmacologists are keenly aware of the urgency of this) before taking such action as suggested above.—I am, etc.,

London, W.1.

HUGH GAINSBOROUGH.

The Metric System and Medicine

SIR,—Among my recently qualified contemporaries there is widespread criticism of the metric system which has so far not been recognized in your columns. Everyone will agree that we are at present unintelligible to foreigners, but very few that I have met will admit that the apothecaries' system is in practice inferior to the metric. In argument my colleagues object to decimal points and "large numbers of noughts," complaining that they are difficult to remember and clumsy to use. Perhaps these and other objections are more emotional than rational and arise from a too recent acquaintance with the task of learning some 150 doses in "the other system." I am surprised, none the less, that the five other letters so far published in favour of the metric system have called forth no murmur of dissent, and I should like to anticipate and answer some common objections. These are: (1) difficulty in remembering doses; (2) danger of misinterpreting the decimal point; (3) inaccuracies in the metric system itself.

Whether the chief difficulty lies in getting the number of noughts right or whether it arises from an Anglo-Saxon distaste for decimals, the fact remains that fractions expressed decimally are distinctly harder to remember. This is therefore a method open to errors in prescribing. Dr. A. H. Douthwaite (*Journal*, Oct. 7, p. 478) has acknowledged this and pointed out part of the remedy, but, with apologies to him, I am keen to argue it further. Secondly, the decimal point can be a source of error even when correctly remembered, for prescriptions are (a) sometimes written hastily, and (b) always read by someone else before being dispensed. Surely, then, the distinction between 1 g. and .1 g., important to the patient, should depend on something more than a single ink-spot. To miss it is rather easier and slightly more serious than to confuse the 3 and 5 signs. Most metric prescribers take the obvious precaution of expressing the tenth as 0.1, but more than one proprietary preparation could be mentioned in which the precautionary nought is omitted from the label on the bottle. I have now been informed of two cases of error arising from this, in both cases the patient fortunately receiving one-tenth of the intended dose. In both, a label printed .5 mg. was read as 5 mg.

It is fundamental to see that (1) and (2) are objections not to the metric system but to the use of decimal fractions. Why should decimals necessarily be used? When we divide the ounce we use whole numbers of drachms or grains. In the metric system, as originally laid down, we divide the gramme into decigrammes, centigrammes, and milligrammes. Those accustomed to using the metric system in medicine find it convenient to think in terms simply of grammes and milligrammes. As Dr. Douthwaite says, it remains for textbooks and examiners to do the same. The B.P., in confining itself to grammes and decimal fractions of a gramme, has used the metric system in the most awkward way possible. The superior usefulness of the milligramme is perhaps not sufficiently well known. With the introduction of whole milligrammes we have practically abolished all fractions, for, in descending the scale, we have to split the grain long before we split the milligramme. Almost all the doses involving fractions lie between 3/4 and 1/64 grain, and can therefore be expressed by whole numbers of milligrammes. Thus the dose of morphine becomes 8–20 mg. Decimals may be harder to learn than vulgar fractions, but

whole numbers are surely easier than any traction at all. But still there are some decimals, it is objected. Why should there be? If we can speak of $1/2$ grain, why not $1/2$ milligramme?

Doses of the order of a few milligrammes are likely to increase with the introduction of greater numbers of potent synthetic preparations, and there is no doubt that the milligramme (and for some vitamins the microgramme) is the unit of the future. When a conservative opponent has been impressed with the useful size of the milligramme, he is apt to object that its relation to the gramme ($\times 1000$) is unwieldy. I feel it would be a mistake to try to please him with decigrammes and centigrammes, for simplicity is our principal aim. The B.P. took a step in the direction of simplicity when it confined itself to the grain and the ounce and, in the metric system, the gramme, and I feel it is desirable that we should be content to add only the milligramme (later, perhaps, the microgramme for vitamins). The size of the gramme is by no means astronomical in relation to that of the milligramme. The number of small units in the big unit is only about twice the number of grains in an ounce, and since alterations of dose, to be effective, frequently necessitate doubling or halving, the mental adjustment to this change should be easy. The effective way in which milligrammes still replace the majority of fractional doses by whole numbers is due to the fact that the gramme is only $1/30$ ounce. This again is desirable, for the drugs which are dispensed in whole numbers of ounces are few indeed. The gramme, of which four go to make a drachm, is a considerably more useful weight.

When we consider liquid measure we may seem to be in a weaker position. The minim is practically never split, except in such terms as $7\frac{1}{2}$ min, whereas the millilitre, being about 17 times larger, is split in 92 of the 197 fluid doses in one hospital's pharmacopoeia. One device would be to use vulgar fractions, another would be to adopt the microlitre, volumetric equivalent of the milligramme. Thus one of the most awkward metric doses—that of tincture of strophanthus (2–5 minims or 0.12–0.3 ml)—would become approximately $1/8$ – $1/3$ ml or 120–300 microlitres. The microlitre, for which some suitable abbreviation would no doubt be forthcoming, is, of course, the cubic millimetre, familiar volumetric unit of clinical pathology. A third alternative would be to make the decimillilitre ($1/10$ ml, or about 1.7 minims) the standard dispensing unit, and slightly alter the strengths of a few tinctures and other preparations which are, after all, expressly laid down at present to give a correct dose in whole numbers of minims. If the metric system were universally adopted it would be simple to make a tincture of strophanthus with a dose of 2–5 decimils.

It is unfortunate for the sake of simplicity, that the litre, standard of measure, should (in water) weigh 1,000 times the gramme, standard of weight, so that a millilitre does not weigh a milligramme, but it is better to have a milligramme occupying a microlitre than a grain occupying 109.7142 minims. Perhaps, in quoting this figure, it is unwise to press the matter to so many decimal places, for the more erudite opponents of the metric system can point out a difference, at about the fifth decimal place, between the mil and the ccm, and between the ccm, and the volume of a gramme of water; this arises only from the improvement in laboratory technique since the original standards, all derived from the metre, were set up. Your correspondent Dr S A W Rushbrooke (*Journal* Oct 7, p. 478) acknowledged this when he stated "Approximately 1 ccm of water weighs 1 gramme." The error, however, is so small that it can be entirely ignored except in the most precise physical and chemical research. I have no doubt that the care with which the original standards were made would satisfy the most fastidious dispenser.

It has been interesting to sound the opinions of some junior medical students on this subject. I have found those fresh from the university unanimously in favour of the metric system. Innocent as yet of the apothecaries' system, they can visualize what quantity of a powder would weigh roughly a gramme, and can estimate with commendable accuracy the metric capacity of a vessel such as a measuring cylinder or a bottle. They have long appreciated that any calculation intrinsic to the system can be performed in the head or on the shirt-cuff,

and their reaction to the arbitrary divisions of the apothecaries' table is frank dislike, while the information that the imperial ounce contains 437 and a half grains is met with incredulous laughter. Yet they seem to change their views. The pale-faced final-year student has adopted the grain and the minim apparently without a struggle. However, there is no doubt that for the new drugs the metric system has come to stay; and with the apothecaries' and imperial systems in full use its presence only adds to the existing chaos. The time has surely come, then, to adopt metric measure for all drugs.

The point I wish to emphasize is that in dropping the old measures we need lose nothing. The milligramme, the gramme, and the mil (or decimil) are units just as suitable for precise and brief representation on paper, and can be just as friendly and amenable to the memory as any other units of weight or measure—I am, etc.

St Albans Herts

T C BEARD

SIR—Few can doubt the advantages of the metric system in medicine. The arguments for it, so well set forth by Prof W C W Nixon (Sept. 2, p. 320) and by Dr. Howard Jones and Mr S T March (Sept. 23, pp. 413, 414), are irrefutable. Why, then, has it not been introduced or why are no active steps being taken at the moment to secure these advantages for the future? The reason is probably the inertia of established custom combined with an unexpressed fear of confusion which might result and perhaps give rise to accidents. Neither of these reasons, however, is really valid, and if doubt remains there is an excellent precedent by which we might be guided. Some few years ago British ships were steered by orders which were derived from the primitive use of the hand tiller. When the ship's head was to be turned to starboard the order given was to port so many points or degrees, because when the tiller was put over to port the vessel's head turned to starboard. For many years it had been obvious that in conformity with custom in some other countries it would be more logical to order starboard when the ship's head was to be turned to starboard. It was argued, however, that to make such a sweeping alteration in helm orders might be disastrous, confusion result, and collisions occur. Nevertheless, both the Admiralty and the Board of Trade, with an admirable strength of purpose and despite opposition from the inevitable "die-hards," determined to make the change, and in one night helm orders were altered by completely reversing them—i.e., port became starboard and vice versa. The result was as surprising as it was satisfactory, for so far as I am able to ascertain not a single collision occurred in consequence. I suggest that if we should make up our minds to change to the metric system it could be done overnight, and that there is every reason to think the outcome would be just as happy as with helm orders—I am, etc.

LAMBERT ROGERS,
Surgeon Captain, R.N.V.R.

"Dissident Doctors"

SIR—Your footnote to Dr. Stark Murray's letter (Oct. 21, p. 340) denounces the actual or prospective existence of Socialist, Conservative, etc., medical associations, and asserts that "there are political organizations in plenty to give medical men what political information they need, and to offer them scope for political activity." You go on to say that "Dr. Murray obscures the issue by confusing medical politics with politics in the familiar use of that term."

To-day political action by politicians gravely threatens our whole mode of life. Politics is being forced upon the medical profession, which, if it is to maintain its integrity and honour, must think politically. State control of the profession is imminent. Here surely, if ever, is an occasion where "politics in the familiar use of the term" has impinged so completely on "medical politics" that there is no distinction between the two. Dr. Murray favours the Government scheme—i.e., the N.H.S.—and in general I find myself in the heartiest disagreement with his views, but I must commend one statement in his letter. He says, "Surely it is the duty of all of us . . . to take part in all political activities that concern our way of life."

But while Dr. Murray sees his political duty to be fostering State control of the profession and building up the "Socialist Medical Association," my own conception of the most urgent need, both in the profession and nationally, is a strong movement to defend our shrinking and seriously menaced liberty.

If I dislike the S.M.A., I should equally dislike a Conservative or Liberal M.A. Nor should I find comfort in Common Wealth or the I.L.P. All our existing political parties appear at present to be united both in their hatred of liberty and in their approval of State control of medicine. The Liberal Party used to claim to be the champions of individual liberty and the opponents of State control. But what was the label of the great prophet of the servile State when he was recently returned as M.P. for Berwick?

Doctors are to give up their own premises and work in welfare centres. They are liable to be sent wherever the State decrees, whether they like it or not. Men who prefer the city will go to the country, and vice versa. The State will own the wretches, lock, stock, and barrel. The Prime Minister, who is so busy winning the war, has nevertheless time to introduce measures for enslaving the medical profession. He should remember that his Government owes its existence *solely* to the need for prosecuting the war, and but for that need he would not be Prime Minister at all. He and his Government have no right to meddle with controversial domestic legislation. He did, in fact, give a pledge to introduce no controversial measures. But it appears that one must be polite and not annoy him with reminders about his promise. Certainly no one bothers to do this.

We are to be under the thumb of frequently changing Ministers of Health, whose interest in "health" is likely to be fleeting and temporary, since during their sojourn in that Ministry their minds will be preoccupied with hopes of "higher" office. In France four years ago a crisis proved that both the political system and most of the parties were rotten. That country has found new life in a movement called "Fighting France." Couldn't we have a "Fighting Medical Movement," or something of the kind?—I am, etc.,

London, S.E.14.

ALLAN A. MACDOUGALL.

SIR,—Your editorial reply to Dr. Stark Murray's letter (*Journal*, Oct. 21) takes up an impossible attitude on the question of medical affairs and politics. If politics mean anything to a man they must influence his actions in all his spheres of activity—professional or otherwise. All the doctors who take part in discussions on the White Paper do so from a political point of view—from that of their party, if they belong to one; if not, from that of the party for which they would vote at an election. The White Paper is a political subject and cannot be divorced from politics. A doctor, no more than any other man, cannot be expected not to apply his general political philosophy to matters concerning his own profession. If he did so he would rightly be, accused of insincerity. Perhaps there is no "Conservative Medical Association" because the British Medical Association already fills the need. To judge from discussions on the White Paper in which I have taken part, or which I have read, there is a preponderance of Conservative opinion among my professional brethren. It is common knowledge that an idea is held to be non-political by Conservatives when it is in accordance with the general policy and outlook of the party. Surely we need not be ashamed of "political" discussion even if it runs on, broadly, party lines, because "politics" are the expression in external affairs of the fundamentals of our philosophy of life.—I am, etc.,

Kingswood, Bristol.

N. S. B. VINTER.

SIR,—Having read your article on the S.M.A. and Dr. S. Smith, and your subsequent reply to Dr. Murray, I feel I still need some clarification on the question of medical men and political organizations.

Members of the S.M.A., so far as I understand, believe that doctors would work best, and the public would have the best medical service, under Socialism. In so far as they have this point of view they are entitled, as any ordinary group of citizens, to form an association and try to bring other medical men to their point of view. Now, the White Paper is by no

means Socialism or even an appreciable advance towards it, but the S.M.A., together with the majority of the profession, unfortunately not so vocal, accept the principles of the White Paper because it is the basis for discussion for an advance upon the present medical services. In advocating this point of view the S.M.A. is not grinding any political axe; it feels, as an association of progressive doctors, it should support any policy which would improve the British health services. I cannot see how this can have anything but a good effect on the B.M.A., for it would strengthen the public's confidence in doctors. * I have yet to hear of members of the S.M.A., either as a group or as individuals, disrupting the B.M.A. or lowering the status of doctors in the eyes of the public. The members of the S.M.A. who have been able to devote a considerable amount of time in the organizations of the B.M.A. have proved themselves loyal and true members of the B.M.A. How, in these circumstances, the S.M.A. can be charged with being even remotely responsible for the M.P.A. it is difficult to conceive. It was precisely this official attitude in Europe before the war, of putting the blame for developing reaction on the mere existence of progressive bodies, that fostered reaction which eventually destroyed the official bodies.—I am, etc.,

Princes Risborough, Bucks.

S. LEFF.

SIR,—It is reasonable to suppose that doctors, who see so much that is grim and distressing in the daily life of the community, could make a sympathetic contribution to the nation's plans for the betterment of social conditions. There must be many medical men and women who would be keenly interested in the consideration of social problems, but who shy away from politics in the familiar use of the term. It implies no derogation from loyalty to the main professional society that some, who would otherwise take little or no share in public affairs, should find an opportunity to apply their special knowledge and experience in company with their medical colleagues who share the same ideas.

It seems harsh that doctors should be criticized in their official journal for participating in an organization whose aim it is to promote a legitimate social and political policy so long as that policy is in accordance with democratic principles. It is surprising that the *Journal* should adopt so didactic an attitude on this matter, especially in view of the almost unanimous vote concerning the safeguarding of the full political rights of doctors under the proposed National Health Service.—I am, etc.,

St. Annes-on-Sea.

JOSEPH PARNES.

SIR,—Dr. Frederick Dillon (Oct. 28, p. 576) appears to have joined the ranks of the eulogists of the scientific method as a panacea for our ills, and he appears to consider this much-vaunted nostrum as "the only possible basis for an ordered life, individual or national." But most of us desire an orderly, not an ordered, life; in fact, we thought that this war was being fought to preserve us from an ordered one.

That reason is good we should, I suppose, all admit; and that scientific method is good is a statement that would also be widely accepted. "But the science of reason is not necessarily the best guide in the conduct of human affairs. It was logical for the French to request an armistice in 1940, and illogical for the British to continue the fight against Germany."

It is very odd that we doctors, whose training has been "a smattering of several sciences, followed by a prolonged study of the human animal in health and disease," should be so easily gulled by the propaganda of authoritarianism. Perhaps we are ashamed to proclaim our freedom, because it is part of an unpopular creed. Latham knew well how mankind, including doctors, could be misled by fashion: "Depend upon it, what all men indiscriminately are told they ought to know, all men indiscriminately will soon pretend to know, be it never so extravagant."—I am, etc.,

Bacteriophage Treatment of Bacillary Dysentery at Alexandria

SIR.—Commenting on my article under the above title (*B.M.J.*, 1942, 1, 719) Col. J. S. K. Boyd and Major B. Portnoy (*Trans. roy. Soc. trop. Med. Hyg.*, 1944, 37, 243), in a reprint sent to me by courtesy of Col. Boyd, ask me what seems a pertinent question. If "the early use of bacteriophage prevents the development of acute bacillary dysentery, why has the established rule to treat acute bacillary dysentery become the established rule to treat acute bacillary dysentery and its frequent precursor enteritis, why has the total annual number of cases of dysentery . . . averaged about 650 during the period [1928-40] and has not gone down to any appreciable extent?" The answer is simple, but I would first point out that the number "650" is an abridgment figure in my article which I am in no way responsible for. It did not figure in my original text. It simply appeared justified to the abridger, for which I am greatly indebted. I would further remark in passing that for none of the numbers of the supposedly impartial official that they were all culled from the supposedly impartial official vital statistics of Egypt. In effect, 650 annual cases of global dysentery (amoebic, bacillary, lambliar etc.) per year for Alexandria, on a population of three quarters of a million, appears to me ridiculously low and must be very wide of the mark. Although this is so I felt justified in using the official statistics because I used them throughout on a comparative basis, to compare Alexandria data with corresponding Cairo and rest of Egypt data in the belief that common errors would thus automatically cancel out. In my original text, which was too long to publish, I criticized some of the flaws in the Egyptian statistics of dysentery about which and vital statistics in general, the authorities are very concerned and are continually talking about reformatting them. Imperfect as Egyptian statistics undoubtedly are it is well to remember that owing to the nature of the problem no country in the world can probably boast at the present hour of perfect dysentery returns and statistics.

Now, to answer Boyd and Portnoy's query. Since nothing has changed in the aetiology of the dysenteries over the years 1928-40 (flies, filth, sanitation in general, grapes inadequately washed, raw figs, etc.) the risk of attack has obviously been the same year by year. The administration of a few ampoules of phage to a few privileged and enlightened individuals here and there in the community suffering from enteritis and acute bacillary dysentery can hardly be expected to eradicate or influence very greatly the foregoing foundations of the various dysenteries. Why, then, should Boyd and Portnoy shy at the statement that the "total annual number of cases of dysentery has averaged about 650 during the period [1928-40] and has not gone down to any great extent"? Phage has never been given prophylactically by me to healthy individuals, although Cmdr Wilson (*B.M.J.* 1942, 2, 81) whom Boyd and Portnoy quote, rather seems to think so. It has only been given by me to sick people. Actually, the former is an experiment that I have often wished could be done, but hitherto supplies have not permitted its being undertaken by me. Hence, Boyd and Portnoy are thinking wide of the mark if that is what they have in mind when they state that my argument is "based on figures which do not substantiate claims made elsewhere . . . to wit, that the early use of bacteriophage prevents the development of dysentery." If that is their view, then such a dish-up is to distort my teaching. What the early administration of phage does prevent, for which I coined the expression "preventive development" (*B.M.J.* 1942, 2, 676) is the development of diarrhoeas and "Guppy tummies" into full-blown attacks of bacillary dysentery. That is what I have insisted on and taught—not the something else which I have insisted on and taught—rightly or wrongly from their writings, Wilson and Portnoy (loc cit.), would have their readers think I have taught. Let it not be forgotten that the article which Boyd and Portnoy incriminate constitutes no more than an attempt to ascertain from impersonal data the equivalent of the U.K. Registrar General's statistics—what might be the general repercussion on a community of its impact with phage. There is no evidence that any of those

whose deaths are recorded ever had phage treatment, or even any specific treatment. Though the enlightened public of Alexandria are phage-minded, there are many backwaters and subsoil pockets among the native non-hospital population of this by Boyd and Portnoy may help to explain what troubles them concerning the vital statistics "figures which do not substantiate claims made elsewhere by this author." Also, therein I have not the slightest doubt will be found the explanation of that proportion of the deaths, due to bacillary dysentery, of the 5% case mortalities from global dysentery, recorded of recent years for Alexandria—I am, etc.,

Undescended or Retractable Testis: Differentiation

SIR.—During conduct of a children's surgical outpatient department I have been surprised how often cases labelled "undescended testis" prove on examination to be examples of "retractile testis," an active cremaster having pulled the organ well up into the region of the inguinal canal. A simple method of examination will easily differentiate the normal from the abnormal. The child should be stripped from the waist and be lying down. The examining hands should be warm. First inspect the median raphe of the scrotum. If the amount of rugose scrotal skin on one side is less than on the other, the probability is that the undeveloped side never contained the testis. If the amount is equal on both sides, then either the scrotum is normal or else neither testis has descended. In the latter case the whole scrotum is symmetrically undeveloped.

Now proceed to palpation, which should be carried out gently and without hurry or fuss, the object being to attempt manipulation of the testis from the region of the inguinal canal into the scrotum. The canal is situated a little (1/2 in) above and parallel to the inner half of the inguinal ligaments. Stand on the affected side and employ the left hand for the right side, and vice versa. Coax the child to give a preliminary cough. This often dislocates the organ from its resting place. Using the pulps of index and middle fingers exert moderate pressure just lateral to the commencement of the whole length of the canal. If a normal testis has been drawn up, it will be pushed by the fingers towards the scrotum, grasped as soon as possible by the fingers and thumb of the other hand, and thereafter pulled down as far as possible. If the testis is truly imperfectly descended then it cannot be pushed or pulled the whole distance to the lower pole of the scrotum, or if ectopic it will reach some site other than the scrotum.

The same manoeuvre can be carried out with the patient standing, but I have found it more satisfactory when he is lying down—I am, etc.,

K. I. MACROSSON

Glasgow

Artificial Insemination

SIR.—I cordially support Dr Harper's appeal (Oct. 14) for an authoritative pronouncement on the ethics of artificial insemination. The letters which you have published from time to time, the references here and there to "semen bureaux or banks" or to "panels of semen donors," and Dr Harper's account, from a country town, of the remarkable invitation to a woman patient of his at a birth control clinic to get her husband to act as a donor to an insemination panel, all give the impression that this new procedure is attaining some magnitude without sufficient recognition of the fact by the profession at large.

The Medical Defence Union has recently published an advisory leaflet to steer the practitioner through the shoals of possible involvement in charges of conspiracy or of adultery levelled against the couple or the donor. The leaflet covers even the extreme case of artificial insemination of the single woman or the widow. The particular claims of the unmarried woman and of the professional woman, to which this might well be a reference, were touched on respectively by Dr. Anne McCandless and Dr. Pearse Williams in your columns a year ago (Oct. 2 and 16, 1943).

Even apart from any pronouncement from such a body as the General Medical Council, surely the profession is already able to form sound conclusions in the light of the fundamental significance of the marriage bond. In marriage, the man and woman in effect take a most solemn pledge, among other things, to have their children by that partner and by no other person. The pledge is not invalidated by childlessness, for the marriage ceremony included no exemption clause for infertility. For the woman to have a child by a donor not her husband is to break that pledge, and to argue that absence of physical conjunction means that the child is not by that donor is merely to play with words. For the medical practitioner to enable the woman to attain this end in this way is to aid and abet her in evading her pledge, even though this be with the husband's collusion. Call it adultery or what you will, I assert that no medical practitioner careful of his personal and professional honour can be a party to such an offence against marriage, however hard the individual case.

To pass from the married to the single woman, and to turn the latter into an unmarried mother by artificial insemination, is again to degrade marriage by assuming that morally it is not always necessary as a preliminary to begetting a family. Can any practitioner, recognizing the social implications of such an assumption, regard himself as acting with honour in aiding such a course?

Artificial insemination of the wife by the husband's semen falls in a different category. Where it is carried out, as described by Dr. Mary Barton (Sept. 4, 1943), by "insemination of the cervix from the vaginal pool following normal intercourse," after elimination of all other hindrances to effective union, the practitioner is only assisting an act entirely right in itself and directed to a right end. The essential objection here, and a sufficiently serious one, is aesthetic rather than moral, in the intrusion of the doctor into so intimate a relation. If the couple are prepared to pay that price, they are, I suggest, entitled to invite the practitioner's help. If, on the other hand, the husband's semen has to be obtained by a process involving masturbation, I would submit—perhaps not so acceptably as in the preceding conclusions, by reason of the bias created by the general adoption of methods of artificial contraceptives—that to the couple that fact should feel so besmirching to the act of conception as to make it wrong to them and therefore to the practitioner.—I am, etc.,

Birmingham.

H. P. NEWSHOLME.

SIR,—Dr. Margaret Hadley Jackson, in her letter on this subject, states: "It is noteworthy, however, that demand by the citizen for legal protection in this matter has not yet been voiced, nor has organized religion committed itself." May I make a clear statement of the position of the Catholic Church on a more fundamental matter, which by inference leaves no doubt of her position *vis-à-vis* artificial insemination? It is a commonplace of moral theology that deliberate ejaculation of semen in any situation other than the vagina—i.e., in normal consummated sexual intercourse—is an unjustifiable infringement of the natural law. That being so, there is no question of waiting to see how the Church will commit herself on this secondary subject.—I am, etc.,

Stannmore.

F. HARWOOD STEVENSON.

Débridement

SIR,—If a word suggests, or can be made to suggest, a vivid mental picture, it is pedantic to reject it on the ground that its applied meaning is not its original meaning. "Débridement" is such a word. The surgical process it so admirably describes consists primarily in the removal of dead flesh, and débridement in its medical sense can be simply defined as the removal of debris. For those who prefer a coined word of English origin, "de-sloughing," with its suggestion of removal of sloughs or potential sloughs, is probably the best. But "débridement" is better than "de-sloughing," since it suggests the removal of dirt, clothing, and other forms of introduced debris, as well as that of sloughs. "Epluchage" to most Englishmen means nothing, and the mental picture aroused by the term "revision" was for most of us fixed long before we had completed the arduous path to qualification.—I am, etc.,

London, W.1.

DAVID H. PATEY.

The Surgeon and the Anaesthetic

SIR,—Mr. Herbert H. Brown's stimulating championship of chloroform (Aug. 5, p. 191) raises several interesting points. He maintains that no danger attaches to light chloroform anaesthesia, arguing from its apparent safety when used to produce analgesia only, which is not quite the same thing. It is true that chloroform, when skilfully given, can produce analgesia without much impairment of cerebral control. The same can be said of trichlorethylene, ether, and nitrous oxide. But it is arguable whether such analgesia can really be produced without "any interference with the special senses or the slightest mental confusion." The fact that "the sense of hearing becomes if anything more acute" is itself inconsistent with this statement. If the effect were a real hyperacusis rather than a distorted appreciation of sound, it would follow that we never hear so well as when slightly anaesthetized, and old ladies would hasten to barter their ear trumpets for a Junker inhaler.

The point that anaesthetists tend to avoid chloroform because of its association with the coroner's court is most interesting, and raises issues which should be widely discussed. But the drug that kills the quicker is surely the more lethal, if only because it gives less time for counter-measures.

Mr. Herbert Brown suggests that "the surgeon should choose the anaesthetist who will give the anaesthetic he prefers in the manner required." It is to be hoped that most surgeons would prefer the anaesthetist who is competent to choose and administer the anaesthetic best suited to the patient in the circumstances. We all recognize the patient's need for a comfortable and quiet night before operation, but some would not agree that it should be obtained "by a small injection of morphine and atropine." Atropine is not a sedative, and it can cause a dryness of the mouth which is anything but comfortable to the patient.

In his last paragraph Mr. Brown resurrects the old bogey that pentothal when once injected into the blood cannot be removed until its time is up. All anaesthetic drugs are carried to the brain in the blood, and none can be removed except by katabolism. In condemning the "one-shot" method, by which an arbitrary dose is introduced all at once into the blood stream (in contrast to the method of keeping the syringe in place and injecting minimal quantities at intervals as they are needed) he will have the support of most anaesthetists but when he gives "a whiff of chloroform" for dental extractions surely he is doing something very like it.—I am, etc.,

RONALD F. WOOLMER,
Surg. Cmdr., R.N.V.R.

Service Medicine

SIR,—I have noticed in your columns many letters which have alternately reviled and praised State medicine as it is practised in the Services, adducing from their arguments point against or for the National Health Service as projected in the White Paper. May I as a Service doctor "for the duration" put the matter as I see it from my station over-seas.

These writers have, politely, called each other liars. The truth is, they are all right in their ways. It is true, as some say, that Service doctors have little to do, and, as others say that their day is always full; that, as some say, the equipment is good, and, as others say, very bad; that, as some say the patient gets better attention than in civil life, and, as others say, much worse. I can easily explain this from my own experience. My day is full, but careful calculation tells me that one-quarter of it is doing the work of a doctor—i.e. healing the sick and the prevention of disease—the other three-quarters is with Service matters—form-filling, indenting inspecting, and other routine matters. The equipment is available if demanded on the proper forms in quadruplicate, giving full reasons (and a few more for luck) and usually several times; but this procedure must be gone through, otherwise the equipment will often be bad.

A man may report sick and receive attention for the most trivial ailment and be treated with courtesy; he can be sent to the appropriate specialist for anything more serious with great ease, and have full investigation made. But he may be admitted to hospital for something trivial, stay there overlong,

and develop a handsome neurosis by contagion. His position on sick parade is prejudiced from the start by the fact that one must put one's loyalty to the Service first. One thinks not of a patient to be healed but of a man who may be trying to get away with something (not a malmonger, for they are rare, but an exaggerator), and he has to prove he is ill before you start to think of him. Then in the background of our minds is a wild procession of forms to be filled in about him. Gradually, in spite of oneself, one ceases to be a doctor in the best sense, a healer, but becomes a State servant.

I know that I, who was at least on the beginning of the path to becoming a good doctor before joining up, am now right off the path and will have to struggle to get back. That all this is necessary to the proper prosecution of the war I have no doubt, but that it is necessary to the prosecution of the peace I have every doubt. That the N.H. Scheme is but another "Service scheme" I have no doubt either, the experience I have had reading orders in the Service gives me a clear view of the mailed fist inside the velvet glove. No sanctimonious blessing over the profession by a Minister of Health can make me give way with a pious hope that things will turn out for the better. Hence as what little I have done in uniform has been a part of a fight for freedom so I hope that when I don a "civil" suit again I shall not have to join in another fight for the freedom of the profession. My service has at least taught me the value of that freedom, and for myself I demand in any State scheme (1) freedom to treat my patient in the manner I think best, with the full resources of medicine at my command without the introduction between of any third party whatsoever; (2) freedom to criticize that scheme in any way I like; (3) freedom to practise where I wish and to choose any branch of study I wish; (4) that neither my conduct nor my treatment in the practice of medicine may be officially censured or criticized except by a properly elected council of my peers.

The main attraction of a doctor's life is its individuality and acceptance of personal responsibility. One's conscience is one's guide, the tradition of the profession one's light, and the judgment of colleagues one's best corrective. In a State service one's conscience is replaced by instructions, tradition by the Service discipline, and the judgment of others and one's advancement depend on one's capacity for treading delicately between forms.

Let me, finally, congratulate the B.M.A. on its statesmanlike handling of this terrible problem, never having lost its temper, when I have lost mine so many times. Because I have presumed to criticize, I must ask you to respect my anonymity. Can there be any worse comment on a State service than that those who praise may publish over their names, those who criticize may not?—I am, etc.,

UNDER THIRTY

Chemically Induced Resuscitation

SIR—The recent literature that has passed through the various columns of the *Journal* on the subject of artificial respiration prompts me to write on matters relating to this, which I propose to call as a title "Artificial Respiration versus Chemically Induced Resuscitation."

It has been my experience, and probably the experience of a number of my colleagues, that ceaseless efforts at any type of artificial respiration, whether it be Schafer's, Silvester's, or Eve's, have failed to resuscitate in the various forms of asphyxia, especially those of poisoning. If it has not failed to resuscitate, the time taken to produce the respiratory mechanism to function is considerably long tedious, and anxious. In the group of poisons I should like those of the anaesthetics, inhalation or basal, to come first, as they are usually the most commonly met with, next in order are the orally ingested poisons, or those administered by a syringe—e.g., morphine, etc.—and, lastly, the carbonic acid type of asphyxia.

I have no hesitation in stating that the following method will produce function of the respiratory mechanism within five minutes in an apparently dead patient and save not only anxiety but ceaseless exertion and probably failure of resuscitation by the ordinary methods.

The method I have adopted and found so effective is this: atropine sulph. 1/50 gr. hypodermically immediately on cessa-

tion of respiration, or, if not in an operation theatre, immediately on contacting the patient. Next an intravenous injection of one of the cardio-respiratory stimulants—I prefer anacardone (nikethiridium)—2 ccm is given within half a minute. As a rule this is usually sufficient in a moderately asphyxiated patient. In one who is more deeply asphyxiated another 2 ccm anacardone is given intramuscularly in the left pectoral region or deltoid after an interval of 3 minutes, and a further injection of atropine sulph. 1/100 gr. 5 minutes after the first injection. Friction over the precordial region with the hand should be done by an attendant. If there is any possibility of resuscitation at all this method produces it, and if done within 5 minutes of asphyxia a taking place.

The most dramatic case I can recall was one of morphine poisoning, suicidal, where artificial respiration for 20 minutes failed to produce any effect. Within 5 minutes of the method described a long drawn breath was taken, and breathing was thereafter maintained. The patient from a completely comatose state, became semi-conscious almost immediately, and was able to get up and walk about, assisted, of course, and completely conscious within the hour.

I think it would be quite logical to presume that the asphyxias of drowning, electric shocks, and poisonous bites would also react to this method. It should be worth a trial. In conclusion I should like to state that only the healthy individual has been considered as the subject for such treatment. It is doubtful whether one suffering from a toxæmia would recover—I am, etc.

London S.W. 16

A. H. BARTLEY

A Question of Priority

SIR—In the interests of independent British scientific research and truth, I suggest that the following facts should be neither overlooked nor suppressed. During my researches in bacteriology I have had the good fortune to add to our knowledge in some branches, but more particularly by my discovery of the "vitamin" in 1910, which I named the essential substance, and by my discovery of the "bacteriophage," which I named the "bacteriolytic agent." The source of this first vitamin—now frequently called vitamin K—was described in a paper read before the Royal Society, Nov. 17, 1910, and published in the *Proceedings*, section B, 83. It is given also in extended detail in the *Proceedings*, sect. on B, 1912, 84, and in the *Centralblatt für Bakteriologie*, 1914, 73. This research received no Government support.

My first description of the "bacteriophage," which I named the "bacteriolytic agent," was given in the *Lancet*, Dec. 4, 1915, and later in more detail in the *Annales de l'Institut Pasteur*, Nov., 1931, 47 (on the invitation of Drs. Roux and Calmette), in the *Journal of Hygiene* July, 1936, and in other papers, but again the research received no Government support. I submit that this indicates a bad national policy.

I may add that the financial resources of the Brown Institution are small, and that since 1936 I have received practically no financial support to enable me to complete my extensive research on viruses, and I have had no colleagues in the laboratories to give any assistance—I am, etc.,

Camberley, Surrey

F. W. TWORT

Relief and Reconstruction in Europe

SIR—Your leading article on relief and reconstruction in Europe (Oct. 28, p. 566) clearly shows the grim urgency of the needs of the peoples of Europe. The immensity of the problem calls for a most determined effort by the peoples of the United Nations and in particular by the British and American, to meet this unprecedented disaster.

Although your references to Italy's plight are, in the given space, comprehensive and sympathetic, I do not think your reference to the Government "without power or popular support" is either exact or helpful. The present Italian Government is in fact, a Government of national union, and has the full support of the several political parties of the National Front, from the right to the extreme left. Its vitality has been recognized by Mr. Churchill and President Roosevelt, and increasing powers are being granted to it, even if too slowly, to my mind. As doctors we are not satisfied with recognizing

that somebody is ill: it is important to diagnose also if the patient is getting better or is getting worse. In spite of inevitable crisis and setbacks I think our prognosis about Italian democracy should be a favourable one.—I am, etc.,

Queen Mary's Hospital, Sidcup.

E. MONTUSCHI.

Princess Tsahai Memorial Fund

SIR.—It was the generous ambition of the Princess Tsahai of Ethiopia to build a hospital in the capital city of her country which would include provision for sick children not hitherto available in any Ethiopian hospital, and would be a teaching institution where her young compatriots with a vocation for hospital service could obtain the necessary training. Her father, the Emperor Haile Selassie, had created a trust for her, represented by a holding of £13,704 in British War Loan. In the summer of 1942, returning on what was then a perilous journey to her country, the Princess signified her desire that in the event of her death this trust fund might be used towards founding a hospital in Addis Ababa. The lamented death of the Princess occurring soon after her return to Ethiopia, the above trust reverted to the Emperor. His Imperial Majesty, in accordance with the Princess's known desire, has most generously placed the whole amount at the disposal of the National Provincial Bank Limited, Overseas Branch, 1, Princes Street, London, E.C.2, for the use of the Princess Tsahai Memorial Council, as and when it can be suitably employed in the hospital project.

The Council most gratefully acknowledges, with warm thanks to the Emperor, this generous gift. £3,000 of the benefaction has already been remitted to Addis Ababa to roof the hospital building, and work is proceeding. A further considerable sum is required to equip and endow the hospital, which commemorates the initiative of the young Princess, whose devoted service in British hospitals is gratefully remembered, and which will be a helpful tribute of friendship from this country to a loyal and sorely tried ally. Three wards in the hospital will commemorate the service of gallant British friends. The General Orde Wingate Ward is to be endowed in the name of the soldier who led the Emperor Haile Selassie's army to victory in 1940. The John Melly Ward will commemorate the doctor who raised and led the British Ambulance Service in Ethiopia when the Italian invasion began in 1935. The Davies Ward will bear the name of the late chairman of the Memorial Council.

I shall be glad to acknowledge both donations and annual subscriptions to the Princess Tsahai Memorial Hospital, addressed to me, c/o Messrs. H. Reynold and Co., Honorary Chartered Accountants to the Fund, 1, Bloomsbury Square, High Holborn, London, W.C.1.—I am, etc.,

HORDER,
Hon. Treasurer, Princess Tsahai
Memorial Hospital Fund.

Universities and Colleges

UNIVERSITY OF EDINBURGH

A gift of £70,000 has been made to the University of Edinburgh by Sir Robert McVitie Grant to found a Chair of Dermatology. This is the first professorship of its kind to be established in Britain, and the development is regarded by the University Court as an encouraging and significant one, in view of the increasing attention now paid to the study of diseases of the skin. The donor is chairman and managing director of McVitie and Price, Ltd. His father, the late Sir Alexander Grant, made benefactions to Edinburgh University for general purposes and in connexion with the Chair of Geology.

UNIVERSITY OF LIVERPOOL

Miss Florence Horsbrugh, Parliamentary Secretary to the Ministry of Health, opened on Oct. 27 the new Department of Child Health which has been established by the University in conjunction with the Liverpool City Council and the voluntary hospitals on Merseyside. The aim of the department, under the direction of Prof. N. B. Capon, the first holder of the chair, is to teach child health to medical students and graduates and to undertake research into the problems connected with child welfare and health. The new department embraces special wings at the Alder Hey and the Royal Liverpool Children's Hospitals. Congratulating those concerned on "the

grand alliance" that had been formed between the Corporation, the University, and the voluntary hospitals, Miss Horsbrugh said it was an encouraging feature that in a time of war, destruction, and suffering they were opening a new department which would combine child welfare services in order to give the next generation a better chance and build up healthy children and healthy citizens. She hoped that the scheme was the beginning of a partnership which would lead the country.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

A quarterly meeting of the Council was held on Oct. 28, with the President, Mr. Eardley Holland, in the chair.

The following were admitted: *To the Fellowship*: Leonard Colebrook, L. G. Parsons. *To the Membership*: J. N. I. Emblin, J. P. Erskine, Agnes M. Stewart, Elsie M. Terry, Irene M. Titcomb. *In absentia*, A. H. MacLennan, R.C.A.M.C.

The following have satisfied the examiners and have been awarded the Diploma of the College: S. J. Barr, E. K. Blackburn, D. W. Briggs, Maud Lovett Buchanan, Alison Clarke, Josephine A. Davidson, A. S. Esslemont, P. K. Holding, J. K. Irving, R. J. McC. Jamieson, D. L. H. Jones, M. Lipsitz, P. A. T. Lowden, J. M. Pallot, B. D. Patel, Jean A. Robertson, Margaret O. Thorpe, R. A. K. Wiener, Ruth M. H. Winter.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examinations, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S.Glas.:

J. E. Bossman, End W. Brett, J. Y. Brown, A. L. Buchanan, J. S. G. Clark W. H. Dempster, T. W. Duff, R. J. Frame, James Gemmell, Philip Harris J. D. Hope, B. D. Jacobson, L. Jaffe, I. S. Lechler, J. Mazel, Gordor Paterson, M. R. Pitts, M. M. Salzmann, E. Shenken, H. Shilling, K. S. Stewart, Richard Thomas, J. S. Tugendreich, R. S. Walker, A. L. Walcott.

N. Klein, M.D., a graduate of a recognized foreign University, was also admitted a Licentiate.

Obituary

ERNEST WILLIAM HEY GROVES, M.S., F.R.C.S.

On Oct. 22, 1944, Ernest Hey Groves died at his home in Clifton, Bristol, after a long and distressing illness, and there passed away with him a great English surgeon.

He was born at Coonoor on the Nilgiri Hills in India on June 20, 1872, the son of Edward Kennaway Groves, a civil engineer. When his father retired he settled in Bristol, bringing home with him his 3-year-old son. The boy had a will of his own, for it is related that on the steamer, finding his shoes too tight and pinching his feet, he took them off and flung them overboard. He went to school at Redland Hill House, Bristol. Thence he gained an entrance scholarship at St. Bartholomew's Hospital, London, where he obtained the B.Sc.Lond. in 1890, and qualified M.R.C.S., L.R.C.P. in 1895 taking the M.B. in 1897 and the M.D. in 1900. He held the post of resident accoucheur at Bart's under Sir Francis Champneys before entering upon general practice. He went first as assistant in various parts of the country, and then settled into practice on his own account at Kingswood Bristol. Here he performed many major surgical operations on private patients in his own house, where his wife assisted in the theatre and nursed the patients. Mrs. Hey Grove (née Frederica M. L. Anderson), whom he married in 1896 had been a nurse at Bart's, and his success in establishing a reputation as an operating surgeon while in general practice in the outskirts of Bristol was in no small measure due to her competent help and encouragement. When in 1903 a vacancy occurred on the surgical staff of the Bristol General Hospital, Hey Groves was invited to become assistant surgeon, an almost unprecedented recognition of the surgical attainments of a G.P. But by this time Groves had attained high academic honours, having taken the B.S. degree with honours in 1904, the M.S. with gold medal in 1905, and the F.R.C.S. in 1905—a remarkable record for a man engaged in busy practice. The judgment of the election committee of the Bristol General Hospital was amply justified by his previous record, and still more so by his subsequent performance. Before long he had turned his attention to bone surgery and became one of the pioneers in bone-grafting. His judgment was sound, his technique

admirable. No one could be bolder when boldness was required, yet he could be as cautiously conservative as anyone upon occasion. In the war of 1914-18 he took a commission in the R.A.M.C.(T), and went to Egypt in charge of the surgical division of a general hospital during 1915-16. On returning to England he was attached as surgeon to the Beaufort War Hospital, Bristol. His friendship with and admiration for Sir Robert Jones were cemented by their common interest in orthopaedic surgery. It was in orthopaedic surgery that his reputation became world wide, and when the B.M.A. met in Bath in 1925 he was president of the Orthopaedic Section. In 1933 he travelled to Australia for the B.M.A. Meeting, where he was again president of the Orthopaedic Section and was honoured by being made a Fellow of the Royal Australasian College of Surgeons. In 1928-9 he was president of the British Orthopaedic Association. At the Royal College of Surgeons of England he achieved notable recognition. He was Hunterian Professor in 1914, Jacksonian Prize-winner in 1917, Arms and Gales Lecturer in 1917, Bradshaw Lecturer in 1926, and Hunterian Orator in 1930. He was a member of Council for 23 years, and became a Vice-President of the College.

Perhaps one of his greatest triumphs was the making of the *British Journal of Surgery*. The germ of the idea in 1913 was his, though it was fostered from the beginning by the late Lord Moynihan. Here is an appreciation of his work as Editorial Secretary of the *Journal* from a former member of the publishing staff:

"It was my good fortune to act as secretary to Mr. Hey Groves for nearly 25 years in his work with the *British Journal of Surgery*. An editor's task is not an enviable one but it would have been hard to find anyone more energetic and understanding as the editor of that journal which he founded in 1913, and which owes its present high position in the surgical world very largely to his industry and far-sighted policy. His kindly criticism of articles sent in for publication, his helpful letters to young surgeons submitting, perhaps for the first time, articles regarding the arrangement of which they were rather dubious, his advice about illustrative values, were all typical of his sincere resolve to maintain in surgical journalism the very highest standard. He was ever on the watch for articles dealing with 'everyday' surgery, and long tedious tables of statistics did not greatly impress him. His search for critical reviews of such subjects as tumours of the lung, surgery of the sympathetic nervous system, etc., brought in articles which have since been invaluable to research workers. He looked forward eagerly to the monthly meetings of the Editorial Committee which were held in the Examiners' Room of the Royal College of Surgeons (the very room in which the idea of the *B.J.S.* was born) his mind ever ready to answer any question arising out of the minutes or to accept suggestions for the betterment of the *Journal*. The presentation to him in October, 1933, of a beaten silver salver (the work of Omir Rimsden) was a symbol of the gratitude and affection which the Editorial Committee and subscribers felt for him and he prized both the gift and the spirit behind the gift very highly. Lord Moynihan, in making the gift said: 'This presentation is made to you on behalf of a number of subscribers to the *British Journal of Surgery* in recognition of your invaluable services during twenty years as Editorial Secretary. We offer you this salver and cheque as a tribute to your efficiency and devotion. You were one of those in whose mind was conceived the idea of founding in this country a journal worthy of the contributions to the art and science of surgery which England and the British Empire were making. Difficulties were many, and opposition and indifference were found in high places. In earliest days and throughout twenty years, with the exception of one year when you served in the Army overseas, our activities centred round you. All our plans, all our ambitions, all our efforts found in you a most willing, most competent, and tireless worker. Your industry, your wise judgement, your enthusiasm and unswerving rectitude, have been of value beyond reckoning in maintaining year after year our corporate efforts. To-day and by our simple gift we seek with our affection to assure you of our cordial recognition of your invaluable help.'

In Bristol Groves was professor of surgery for ten years, from 1922 to 1932, and his work was recognized by the University when the degree D.Sc. *honoris causa* was conferred upon him at the centenary of the Bristol Medical School in 1933. Belfast, too, made him an honorary LL.D. and the National University of Ireland an honorary D.Sc. When he first became professor he started clinical rounds in alternate weeks at the Hospital and the Infirmary, for he found the two institutions in something like opposition and rivalry, with the Infirmary students knowing nothing of the Hospital, and vice versa. But beyond these public endeavours to promote

harmony and co-operation one who worked with him for 18 years writes:

Possibly I know of some of his generous actions that few others are aware of. At least two successful medical men were enabled to complete their medical studies which otherwise they would, owing to financial difficulties, have had to abandon. He found out about their circumstances and paid the rest of their fees. Incidents he used to tell me about his own student days help to show the tenacity of purpose he had. He won a scholarship for Barts, and was sent to London to live with an uncle who resided at the far end of Hampstead. His uncle kept him, but did not allow him any pocket money. He had no money from home, and so he used to get hold of an odd arm or leg from the dissecting room and smuggle it back to Hampstead, and in the basement, by the light of candles, give grinds to younger students for a few shillings, but often he said there was a 'free' list for these grinds as well. Someone had to hold the door for if they had been found out they would have been sunk. Another incident was when a London surgeon asked him if he had ever seen London in the dawn, or before dawn broke. Mr. Groves said: 'I know the dawn in London as well as any surgeon you could name, I expect.' He said he was a devotee of Gladstone, and when he could he used to get into the House of Commons and listen all night to the Home Rule Bill debates, then walk back to Hampstead at 4 a.m., because, of course, there was no transport available at this time and he had no money for cabs. He said he did this many times. I cannot think of many modern students who would walk 4 to 5 miles in the chill of dawn to hear even Winston Churchill.

He was a prolific writer in the journals, and had published his well-known *Synopsis of Surgery*, *Surgical Operations for Students and Nurses*, *Fractures*, and with Fortescue Brinkdale *A Textbook for Nurses*. His recreations were golf, swimming, motorcycling and travel. How he loved travel, and what a companion he was! Not the least of the attractions for him was the Moynihan Surgical Club. He called his travels 'a busman's holiday,' but it was not only to study surgery and surgeons in new places that he loved travelling. The novelty of other towns and other lands enthralled him. He was a dependable colleague, a cheery and delightful travelling companion and a grand friend. To his widow, who survives him, we offer our deep sympathy. *Requiescat in pace*.

J. A. N.

Dr. CHARLES J. TRIMBLE C.B., C.M.G., one of the best known medical men in the Preston area, died on Oct. 8 at the age of 88. For very many years he had been a notable figure in general practice and to the older generation of Preston people he was the well-beloved and trusted physician. On his retirement from general practice he had devoted his extraordinary energies to administrative work, so that the younger generation of doctors knew him as an M.O.H., always ready with help and guidance cheerfully given. Ever careful of the clinical freedom of the practitioner, he enjoyed the trust and co-operation of every doctor in the neighbourhood. His interests were many and varied. His work in connexion with the Order of St. John of Jerusalem of which he was a Knight of Grace, was nationally recognized, and his lifelong association with the Territorials had won for him the richly deserved honour of Honorary Colonel of the 88th Field Brigade R.A. During the last war (he was 59 years of age in 1914) he served with distinction as O.C. of a base hospital in France and was mentioned in dispatches for bravery and administrative ability on three occasions, and at the conclusion of hostilities he received the honour of the C.M.G. For his services in the Boer War he was created C.B. For many years he served as a Justice of the Peace, was a Deputy Lieutenant for Lancashire, served on the county council, and was a freemason of 30 years' standing. D.J.D. writes: Of Irish birth, Dr. Trimble was a most charming personality. He loved life, enjoyed the company of his fellows and children adored him. He was most generous and was always anxious and willing to serve all who sought his aid. I was privileged to attend him during his last illness, he was ever grateful for any service given, and his interest in things medical remained acute even in the last month. The final chapter of his life presented a vivid, unforgettable picture. The unstinted devotion and kindly care of his daughter, who had been his lifelong companion, the constant unwavering attention of his successor as M.O.H., the loyalty of the officials who had served him in the past and perhaps above all, the generous welcoming smile and kindly handshake of a courteous and gallant gentleman. F.H. writes: The death of Col. Charles J. Trimble in his eighty-ninth year closes a life of activities which in their variety can seldom have been equalled by a member of the medical profession. In a career of such merit and of unusual extent it would be difficult to say which field of work was his

predominant interest. He served on all the medical committees of the Lancashire County Council, and through his wide knowledge of human relations rendered most valuable service. Perhaps the tuberculosis service, which developed mainly under his chairmanship, may be considered a fitting memorial to his public work. To all his undertakings he brought to bear a keen and powerful intellect, and by his enthusiasm and unsparing efforts ensured their success. Many high honours were conferred upon him, and during the last war he was awarded the gold life-saving medal of the Order of St. John in recognition of brave conduct and leadership during a period of great stress for the unit he commanded. By his friends and colleagues he will be remembered for his loyalties, for his cheerful and generous nature, and for his gift of kindly humour. Family doctor, medical officer of health, soldier, and administrator, in all these capacities he excelled, and his life is a fine example of devotion to duty and a record of noble service to his fellow-man.

C. E. V. R. writes: Dr. ALFRED COLES of Bournemouth will be remembered by his fellow-practitioners as a distinguished physician of the old Edinburgh school, who had a special aptitude for clinical pathology and haematology. To bacteriologists the name Coles will be familiar from his writings on optics, critical microscopy, psittacosis, blood parasites of man and animals, and in particular his lifelong efforts to demonstrate the value of the ordinary microscope for the study of virus elementary bodies. Coles was a genuine enthusiast, and, in company with Mrs. Coles, devoted most of the leisure hours of his retirement from practice to the hobby of microscopy. As a free-lance research worker he led an ideal existence; he cultivated the friendship of those he admired, and possessed an indefatigable desire for investigating the aetiology of infective diseases of unknown origin, sustained by his unbounded zeal for the study of microscopical objects of minute size. He performed his researches at his own expense and sought neither financial reward nor other advantage from anybody, but derived much amusement as a critical spectator from observing the efforts of others. Coles said and wrote what he believed to be correct; he made many interesting original observations in the field of microbiology and (like all true pioneers) made many pardonable mistakes. He was also a great authority on bird life and, with Mrs. Coles, spent many hours observing the migratory habits of these creatures on the South Coast shores. The death of Dr. Coles removes from our ranks a unique character, free and independent, a great doctor, and a born student of biology, to the knowledge of which he has made lasting contributions.

Medical Notes in Parliament

Legislation on N.H.S.

Mr. WILLINK was asked on Nov. 2 by Sir LEONARD LYLE what progress was being made in his discussions with the medical profession about the establishment of a National Health Service; and by what date he anticipated that he would be in a position to evolve definite legislative proposals for submission to Parliament. Mr. WILLINK replied that since he had stated the position to Dr. Howitt on July 13 the Representative Meeting of the British Medical Association had been arranged for early next month. Meanwhile, the Council of the Association had agreed to his suggestion that they should send representatives to elucidate points in their own draft statement of policy. Useful discussions for this purpose had taken, and were taking, place. He was not yet in a position to say when legislation would be introduced. He did not propose to cajole or compel the medical profession to join the Civil Service, or in any other direction.

Medical Work of UNRRA

UNRRA have appointed a medical liaison officer for each of the countries in which they expect to function. It will be the duty of these liaison officers to assess the need for further medical personnel. It is expected that the chief need of UNRRA for doctors will be for work with the displaced persons section of the administration. Apart from work with this section, it is thought that doctors who entered this country as refugees will best be able to assist by serving in the health organizations of their own countries rather than in UNRRA itself. Mr. RICHARD LAW gave this reply on Nov. 1. He said refugee Jewish doctors would be able to return to their own countries other than Germany.

Health in "Blitzed" Areas of Southern England

In a debate on Oct. 27 about repair of war-damaged houses in London and South-East England Mr. ROBERTSON said the race was between repairs and disease. Tuberculosis was increasing in Streatham, his division. Chemists could hardly deal with the prescriptions which poured in. People were living with continual draughts through the rooms or were living in one habitable room, with the furniture from upstairs piled into the other. Dr. HADEN GUEST asked whether the health situation was being carefully watched. During the last war, when housing conditions were better, a world-wide epidemic of influenza arose. Tuberculosis was not the only unfortunate thing which might happen. There was danger of some new plague from the ruins of the devastated homes.

Mr. WILLINK said that in the London region the total loss of houses was 109,000, and on Sept. 22 800,000 houses needed repair to make them reasonably comfortable. This did not include houses where a "field dressing" had sufficed or those where the damage was too serious to be tackled this winter. Mr. Willink did not allude to the dangers to health.

Medical Examination on Demobilization

On Oct. 31 Mr. PARKER asked the Secretary of State for War whether arrangements could be made for a thorough medical and dental examination of all men and women on demobilization from the Army. Sir JAMES GRIGG: Yes, Sir. Such arrangements will be instituted when the release scheme is brought into operation. It was later stated that similar arrangements would be made for the Navy and R.A.F.

Antitetanus Serum

On Oct. 31 Mr. A. EDWARDS asked the Minister of Health to what extent hospital staffs were obliged to inject antitetanus serum in all cases of accident, except where the patients refused to permit this; whether he was aware that the serum occasionally had disastrous effects, as at the Norfolk and Norwich hospital recently, where a patient died from anaphylactic shock caused by an administration of the serum; and whether he would intimate to those hospitals with which his Ministry had any connexion that it was inadvisable to make the administration of antitetanus serum a routine matter. Mr. WILLINK said that so far as air-raid casualties and other cases falling within the Emergency Hospital Scheme were concerned, hospitals were instructed that tetanus antitoxin in the doses prescribed in the instructions must be injected in all cases of injury. He was advised, on information supplied by the Medical Research Council, that the danger of anaphylaxis was very small, and he was not prepared to advise hospitals in the sense suggested in the last part of the question. The only cases of tetanus among air-raid casualties reported to his medical officers had occurred where no antitoxin had been given or where the instructions had not been fully observed.

Tuberculosis in the Services

On Nov. 2 Mr. JAMES GRIFFITHS asked how many persons graded A1 on admission to the Forces had been refused pensions on the ground that their disability—tuberculosis—was not due to their service. Sir WALTER WOMERSLEY regretted that the records did not enable him to give the figures asked. The large majority of cases of tuberculosis were accepted as due to service. Each application was considered in the light of the available evidence, including the member's medical history and the conditions of his service. Among the cases rejected it was not uncommon to find that, whereas the member on entry was graded I on clinical examination, he was subsequently found, by mass radiography, to be suffering from a quiescent lesion and to have been discharged to prevent the possibility of reactivation.

Committee on Artificial Limbs.—Sir WALTER WOMERSLEY announced on Nov. 2 the appointment of a committee to consider the design, development, and use of artificial limbs and of appliances connected therewith, under the chairmanship of Sir Brunel Cohen; the medical members are: Dr. A. A. Atkinson, Prof. T. P. McMurray, Mr. G. Perkins, and Prof. H. J. Seddon.

Casualties among Doctors.—On Oct. 31 Dr. Howitt asked the Secretary of State for Air, for War, and the First Lord of the Admiralty the number of casualties among doctors serving in the Navy, the Army, and the R.A.F. during the war up to the present time. The reply in each case was that it would not be in the public interest to give the information asked for.

Notes in Brief

Sir James Grigg said the present requirement that artistes who wished to entertain the Services abroad must be vaccinated and inoculated was one which must be maintained.

Medical News

Lord Moran and Prof. G. W. Pickering will speak on pre-medical education at a meeting, to which members of the B.M.A. are invited, of the London and Home Counties Branch of the Science Masters Association to be held at Mercers' School, Holborn, on Nov. 11, at 2.30 p.m.

The speakers at the second annual general meeting of the Research Board for the Correlation of Medical Science and Physical Education, which will be held at the Royal Institution, 21, Albemarle Street, W.1, on Nov. 15, at 3 p.m., will be the Minister of Health, Sir Alfred Webb-Johnson, and Brigadier F. A. F. Crew. The chair will be taken by Brig. F. D. Howitt, and the business will include an interim report by the board on "Medical Science and Physical Education and their Relation to Maternity and Child Welfare, Education and Recreation, and the Services."

Two meetings of the British Institute of Radiology will be held this month at the Reid-Knox Hall, 32, Welbeck Street W.1. On Nov. 16, at 8 p.m., an ordinary meeting will be followed by a symposium on "Physical, Biochemical and Therapeutic Aspects of Volume Dosage," at which one of the speakers will be Dr. F. Ellis. The following day there will be a meeting of medical members at 5 p.m.

A meeting of the Clinical Society of the Royal Eye Hospital will be held at the hospital, St. George's Circus, Southwark, S.E., on Friday, Nov. 24, at 5 p.m., when a talk will be given on "Foreign Service Experiences" by Major A. J. Cameron, Dr. F. Rowland Hill, and Major J. O. Oliver.

At an open meeting of the Scottish Eastern Association of the Medical Women's Federation on Friday, Nov. 24, at 8.15 p.m., in the B.M.A. Scottish House, 7, Drumshough Gardens, Edinburgh, Sir John Boyd Orr will give an address on "The Health of Mother and Child." Practitioners and senior medical students are cordially invited to attend.

Mr. R. Ogier Ward has been appointed surgeon to St. Peter's Hospital.

The Aylesbury office of the *Lancet* has now been closed, and all communications should be addressed to the London office, 7, Adam Street, Adelphi, W.C.2 (telephone, Temple Bar 7228).

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week measles notifications went up by 691, and those for scarlet fever by 24. The incidence of these diseases has risen continuously during the past two months. Whooping-cough, dysentery, and diphtheria also were more prevalent than last week, the increases being respectively 73, 33, and 13.

There were 355 more cases of measles in Lancashire last week, and 68 more in Cheshire. The increase in measles notifications has been more rapid in Lancashire than elsewhere in the country: during August 22% of the total cases were notified in this county, while in the past four weeks the percentage was 37; the largest returns were from Liverpool C.B. 258, Manchester C.B. 232, St. Helens C.B. 110—i.e., these three towns notified almost one-sixth of the total cases in the whole of *England and Wales*. Although the incidence of scarlet fever rose, the only large local variation was a fall of 76 in Lancashire. London had 15 more cases of diphtheria than last week, and Lancashire 39; half the total cases in the latter county were recorded in Liverpool C.B., which, with 61 notifications, had over one-tenth of the total for the whole country.

The rise in dysentery was due to an outbreak among 48 persons in Yorks West Riding, Wortley R.D. The other principal centres of infection were London 57, Lancashire 50, Surrey 38, Essex 28, Middlesex 26, Glamorganshire 26, Gloucestershire 16, Northamptonshire 12.

In *Scotland* the incidence of infectious diseases remained practically constant. The only local variation of note was an increase of 16 in the cases of diphtheria reported from Glasgow.

In *Eire* notifications of diphtheria rose sharply from 110 to 153; the disease is widespread, involving fifty-five areas.

In *Northern Ireland* a fall of 46 was recorded in the notifications of scarlet fever.

Week Ending October 28

The notifications of infectious diseases in *England and Wales* during the week included: scarlet fever 2,288, whooping-cough 1,061, diphtheria 554, measles 4,442, acute pneumonia 538, cerebrospinal fever 47, dysentery 362, paratyphoid 14, typhoid 9, acute poliomyelitis 14.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 21.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for (a) *England and Wales* (London included), (b) *London* (administrative county), (c) *Scotland*, (d) *Eire*, (e) *Northern Ireland*.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for (a) The 125 great towns in *England and Wales* (including London), (b) *London* (administrative county), (c) The 16 principal towns in *Scotland*, (d) The 13 principal towns in *Eire*, (e) The 10 principal towns in *Northern Ireland*.

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)

Live births	6,559	478	997	357	266	5,973	704	859	391	283
Annual rate per 1,000 persons living	—	—	20.3	23.2	5	—	17.4	26.4	5	—
Stillbirths	202	17	23	—	—	200	24	37	—	—
Rate per 1,000 total births (including stillborn)	—	—	23	—	—	—	41	—	—	—

* Measles and whooping-cough are not notifiable in *Scotland*, and the returns are therefore an approximation only.

† Includes primary form for *England and Wales*, *London* (administrative county), and *Northern Ireland*.

‡ Includes puerperal fever for *England and Wales* and *Eire*.

§ Owing to evacuation schemes and other movements of population, birth and death rates for *Northern Ireland* are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Antiology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

ANY QUESTIONS?

Tourniquets

Q.—In two fairly recent first-aid manuals the old direction that tourniquets should be relaxed every 15 minutes is repeated. The disadvantages, difficulties, and even dangers of this procedure in first-aid work are obvious. Both the manuals are otherwise excellent and I recommend them confidently to my classes. To which system—circulatory, peripheral, or central nervous—is the danger of allowing much longer intervals to elapse supposed to be due, and is there any evidence in support of the manual's direction?

A.—There is experimental proof (by Blalock and others) and clinical confirmation for the view that prolonged continuous application of a constricting tourniquet to a seriously injured limb greatly lessens the chance of survival not only of the affected limb but even of the very life of the subject of the injury. When applied for more than a short time the tourniquet produces an ischaemia which damages the tissues, and particularly the lining endothelium of the small capillaries, which on resumption of the circulation allow the fluid part of the blood to transude into the tissue spaces and thereby deplete the circulation and increase shock. There is also some evidence that toxic metabolites are formed in ischaemic tissues, and that these are later swept into the general circulation and do harm. It is good policy to do without a tourniquet when possible, and to apply it for the shortest time compatible with safety when it must be used. In a normal limb a tourniquet can usually be left on for thirty or forty minutes without any harm accruing—e.g., operations on the knee—but in dealing with a seriously damaged limb there is sound sense in permitting a temporary re-establishment of the circulation after a period of 15 minutes. This is not always possible and sometimes risks have to be taken, but the principle remains sound.

Tuberculin Testing

Q.—Would tuberculin testing of the general population, say, of a town of 60,000 persons yield any information that could be applied in the administrative control of tuberculosis?

A.—Tuberculosis testing of a selected community of, say, 60,000 persons of the general population would indicate the incidence of the infection but would give no information as to the morbidity of the disease. If all the negative reactors were retested at four- or six-monthly intervals until they gave a positive result, it could lead, by intensive search, to the discovery of the infecting agents. Such case-finding methods have been used with success in the U.S.A. and are valuable in the control of the disease among children. Both in adults and in children the development of the primary lesion can be observed and any necessary treatment prescribed if the time of the conversion of the skin reaction is known. A tuberculosis skin-test survey would also enable special attention to be given to the negative reactors who were, or contemplated, working or living in contact with open cases of tuberculosis.

Mixed Drinks and "Hangovers"

Q.—Why is it that the "mixing" of alcoholic drinks has more effect on an individual than if he sticks to one variety? Why do some drinks have worse after-effects than others, especially if mixed? What is the best treatment for a "hangover"? The last point does not seem to be dealt with very adequately in any literature, and is, I have found, of great importance when dealing with men who have to do a highly specialized job, sometimes after a "hectic" party.

A.—The first point to consider is whether the "mixing" of alcoholic drinks of similar nature—e.g., different types of cocktails—has a more inebriating effect than an equal number of any one of them. Is the resulting exhilaration from a "white lady," a "side-car," and a dry Martini greater than three like volumes of any one of these, even the weakest of the three? Frankly I do not know,

but suspect that there is no noticeable difference. If it does exist it can be explained only on the assumption that other constituents—e.g., volatile oils—vary in their powers of accelerating or retarding the absorption of alcohol from the stomach. I suspect that in the case of spirituous liquors one drinks more by being tempted by different flavours.

Presumably your correspondent is mainly interested in the harmful effect of "mixing" beer or wine with spirits. The Germans, who used to know a lot about drinking before they became a pest to their neighbours, were fond of quoting, "Bier auf Wein das darf nicht sein: Wein auf Bier das rate ich Dir." I believe, however, that there were numerous variants to suit the taste of the individual bibber. That the greater degree of drunkenness cannot be explained simply on alcoholic content seems clear, and one is forced to assume that other constituents of wines, beer, and spirits must play their part, though probably in relation to the process of absorption rather than to a direct effect on the central nervous system. Before committing ourselves to such a theory we ought to find out whether it is really true that such "mixing" is harmful. I know of no scientific approach to this age-old problem. This is strange in view of the fact that there would be no lack of volunteers! It is alleged that the "hangover" of "mixed" drinks is worse than that of a bout of "single-track" drinking. Again, if this is so the non-alcoholic constituents of the drinks are probably responsible. Some years ago Hurst attempted to demonstrate that liver damage followed a single bout of drunkenness, and that it caused the "hangover" symptoms. The evidence was inconclusive. The probability is that the symptoms are due to (1) the effect on the brain; (2) gastritis; (3) hepatitis. I believe the first is the most important, for the symptoms can be abolished with cocaine. This I do not advise. Every man has his own treatment for "hangover." My own, which is no worse than many others, is: (1) A bottle of Vichy water, or substitute, before retiring. Obviously only the seasoned and experienced toper will carry this out. (2) Half a pint of cold water containing a teaspoonful of sod. bicarb. stirred up in it, together with a tablespoonful of "Enos," on rising. (3) A cold bath. (4) Breakfast, no matter how revolting it may appear. (5) If the victim is not due to fly or drive a car, a small dose of "the hair of the tail of the dog," etc. Fernet Branca is the best "hair," though thoroughly disgusting. Amphetamine sulphate 10 mg relieves fatigue in a certain proportion of post-alcoholic sufferers, but depression later in the day usually cancels out the earlier benefit.

Coronary Thrombosis

Q.—A man aged 56 had, without apparent cause, a severe vomiting attack with substernal pain and pains in both arms. Coronary thrombosis suspected. The pains cleared completely in two days with rest. A specialist reports E.C.G. normal, heart normal, B.P. normal (150/100), and no sign of disease. After several weeks' freedom pains have now returned, coming at intervals of several days in scapular region, sternum, and arms.

A.—An attack of substernal pain with pain in both arms makes the diagnosis of coronary thrombosis most probable. An alternative diagnosis would be hard to find. It is not unusual for abnormal signs to be wanting at a subsequent examination, and even the electrocardiogram may be normal. Such negative findings are in general favourable. As to the pains which have now returned, an important question would be, Are they produced or worsened by exertion? If so, it is angina of effort. If not, further rest in bed may be desirable.

Obesity in a Young Woman

Q.—A young married woman aged about 24 years, about 5 ft. 4 in. in height and over 14 st. in weight, told me that twelve months previously she was under 11 st. Her breasts had become very large, pendulous, and painful. I gave her instructions as to diet, and ordered her some thyroid extract. The improvement was slight and she tends to relapse.

A.—A few more clinical details are really required to make the diagnosis certain, but the patient is probably suffering from a condition which seems to have become commoner of late, a combination of fat and fluid retention. The cause is not known, some believing it to be hypothalamic and others nutritional. There is no definite evidence to relate it to any endocrine gland. Those patients who can "stay the course" are greatly benefited by a diet low in carbohydrate and fat and as high in protein as present circumstances allow. They should avoid salt and limit their fluid intake to two pints a day. Diuretics such as mersalyl, urea, and ammonium chloride are helpful. Thyroid is useful even in those patients who are not hypothyroid, as it helps fluid excretion. It should, however, be pushed to the limit of tolerance or it is almost useless. If the dose is increased very gradually at intervals of a fortnight or so, any signs of intolerance will be mild and will rapidly abate when the drug is discontinued. Treatment may then be begun again with a slightly smaller dose. If this regime is followed, most patients lose weight very satisfactorily, but many are unwilling to cut out carbohydrates when there is no extra protein available.

Acne Rosacea

Q.—What is the basic cause of acne rosacea (brandy nose)? Is it due to the production and circulation of histamine or some other substance from a chronic gastritis?

A.—Rosacea, or acne rosacea, has no single basic cause, but rather depends upon the summation of a number of different factors, including a seborrhoeic background, gastro-intestinal dysfunction with hypochlorhydria or sometimes hyperchlorhydria, and possibly the absorption of histamine from the gastro-intestinal tract. Rosacea is also influenced by sex and age and by certain articles of food, of which tea, coffee, alcohol, and "hot" things are the most important, and by infection of the teeth and tonsils.

Drugs and Fibrositis

Q.—When rest and warmth relieve pain apparently due to neuritis can cure be hastened by giving vitamin or other treatment?

A.—The presumption is that the term "neuritis" is used here to indicate a painful affection of fibrositic origin. There is no evidence that rheumatic conditions of this kind are benefited by vitamins. Nicotinic acid has been used in the treatment of neuritis, but this is because it is a vasodilator, not because of its action as a vitamin. Apart from pain-killers, such as aspirin, drugs are of little value in fibrositis. Iodine has been used in various forms on the grounds that it relieves chronic inflammation, and cinchophen (atophan) or colchicum is recommended if the blood uric acid is raised. Other general remedies include removal of septic foci and treatment with vaccines, protein shock, or bee venom. All these, however, are much less likely to give relief than appropriate local treatment.

Farmer's Lung

Q.—A patient of mine is suffering from bronchitis. He has been employed for several years cutting hay in the pine fields (sheep cutter). Has any similar experience been noted of bronchiectasis arising in a person in the same or similar work?

A.—There is a condition, apparently due to the inhalation of the dust of mouldy hay, which is well known to country dwellers and could properly be called "farmer's lung." Dr Richard Fawcitt of Ulverston has done much work on this subject and in your correspondent will look up his paper in the *British Journal of Radiology* (June, 1938, 11) he will find a full account, including the information that bronchiectasis does occur in the later stages. See also W. N. Pickles, *Public Health* October, 1944, for a short description. The early symptoms are gradually increasing dyspnoea with hard, irritating cough and clear, sticky sputum. If the condition is present in the lungs a culture of the sputum, after exclusion of the patient from hay for some days and after repeated mouth-washing and gargling to prevent accidental contamination, will show various moulds, forms of *aspergillus* and *muco* being the most common. Fawcitt describes the x-ray picture as presenting a soft snow-flake mottling, widely distributed throughout both lungs, and later evidence of a patchy fibrosis with small cavities. It seems likely that the lungs of the above patient have become affected in this way after years of exposure to the dust of hay. A course of potassium iodide must be tried, but it is obvious that the condition has progressed too far for a cure to be expected and it would be unwise for the patient to continue in the same work. As a preventive, some form of respirator should be used, probably a gauze mask worn over mouth and nose would be sufficient. It is suggested that this patient's chest be x-rayed and the sputum examined for moulds. Dr. J. T. Duncan, Winchester College, Winchester, is investigating the mycology of this complaint and is anxious to have specimens of sputum.

Dyspareunia

Q.—What treatment would you suggest for a young married woman who complains of dyspareunia? The hymen is intact and does not appear to be unduly tough; the hymenal aperture admits one finger-tip. She is rather highly strung and was very apprehensive on examination, which seemed to cause her much pain. The husband is on active service, and she looks forward with mixed feelings of pleasure and fear of "being hurt" to his periods of leave. Is there any indication for surgical intervention?

A.—As is usual in these cases, the difficulty here appears to be nervousness and consequent vaginismus rather than an anatomical defect at the introitus. It is not stated how long the couple have cohabited, but if this woman "fears" her husband's return, then a natural cure is no longer likely. Treatment should not be further delayed, otherwise a cure will be more difficult to obtain. The nature of the trouble and the importance of muscular relaxation should be explained to the patient. She should be instructed in the use of vaginal dilators, which can be obtained in sets of three of different sizes. If the patient lies in the full dorsal position and

concentrates on abducting her flexed knees, the pelvic musculature will be relaxed; the smallest dilator, well lubricated, should then be passed. The object should be to teach her to pass the dilators herself, and when she can use the largest size it should be left in place for ten to fifteen minutes each day for about three weeks. A preliminary application of a local anaesthetic ointment is sometimes helpful in the early stages of the dilatation. Also a very nervous and shy patient can sometimes pass dilators herself more easily than can a doctor or nurse. When the husband returns he should be instructed in the proper approach to coitus. If need be the patient should use the largest dilator immediately before the renewed attempt at coitus. Unless the patient co-operates well and makes rapid progress, the above regime should be preceded by digital dilatation of the vagina (to admit three fingers) under general anaesthesia. In general this gives excellent results, but it is important to start the patient passing dilators within 24 to 48 hours after the operation—not to produce further stretching but to convince her that the "obstruction" has been removed and to restore her confidence. If the examination under anaesthesia reveals that the tissues are rigid and will not stretch easily, then enlargement of the introitus by plastic operation might be required, but this is exceptional.

If this physical approach to treatment is without avail, then the psychological condition of the patient should be explored.

Polyuria in an Infant

Q.—My daughter aged 5 months, bottle fed, weight 13½ lb., has a very marked polyuria and frequency. Nappies are soaked, very often as soon as put on, and this may be repeated every five minutes and the bed sheets and pram sheet are usually soaked. The urine is markedly acid to litmus, but does not contain albumin or sugar. A nappy left on for about an hour smells sometimes very strongly of ammonia and overnight this change proceeds further, with the smell of ammoniacal decomposition reminiscent of prostatic cases. Although sturdy and compact, she is small and has gained weight slowly, having suffered from casein intolerance, so that her diet has chiefly been Benger's milk mixture. Should alkalis or any other drugs be used in an attempt to combat the acidity of the urine? Would this affect the polyuria and frequency? What dosage would be recommended?

A.—It would be wise to exclude a urinary tract infection by the bacteriological examination of a catheter specimen of urine. Otherwise it would appear that the infant has what is sometimes called "compensated acidosis," often caused by excess of fat in the diet. It would be interesting to know if full-cream milk is being used with the Benger's, and also if cod liver oil is being given, and in what dose. Presumably in such cases fatty acids are diminishing the alkali reserve, and the body compensates by causing the child to pass urine which is either excessively acid or contains an excess of ammoniacal salts which decompose in the nappies in contact with the soda present. Often a mild urethritis or even cystitis is set up by irritation, and frequency results. On this basis it would be wise to restrict the fat in this infant's food, increasing the carbohydrate and substituting a vitamin concentrate for the oil, if given. Citrate in doses of 5 gr. three times a day should be given, and powdered boric acid used freely on the nappies and in the perineal region to mop up any free ammonia.

Epidemic of Boils

Q.—I should be glad to have suggestions on the prevention and treatment of widespread recurrent attacks of boils, extending over a period of months, in clean and apparently healthy people with normal urines and no other discoverable foci of infection.

A.—This question is rather misleading. Does it mean that staphylococcal infection, manifested by crops of boils, is spreading among a group of workers in close contact—e.g., typists in a large office? If so, there are two problems: (1) to prevent spread of the infection from case to case, and (2) to protect or cure the individual. If staphylococcal infection is spreading in an office, as it sometimes does, attention must be given to the atmospheric conditions—e.g., ventilation and humidity—which affect both the comfort and the health of the occupants. The staphylococci may persist in the dust of the room, which should, therefore, be thoroughly washed down and preferably disinfected with sulphur or formalin vapour. If skin infections are prevalent among the staff staphylococci will be present on the fingers of those who are clinically affected and also perhaps of those not obviously infected (symptomatic carriers). In this way, papers, pencils, typewriters, etc., become contaminated and may be the means of passing on the staphylococci. In these circumstances the regular use by all staff of a satisfactory skin antiseptic may help to limit the spread. Washing the hands with an antiseptic soap in a small quantity of warm water reduces the numbers but does not get rid of the staphylococci.

As regards the individual already infected, the affected parts and the surrounding skin should be kept covered with an antiseptic

dressing until the lesions are quite healed, for widespread multiple boils are usually due to auto-inoculation by contaminated fingers. A wet dressing of mercuric chloride 1:1,000 with an elastoplast covering does very well. If the boils are large and causing constitutional upset the patient should be kept off work and made to rest, for there is a danger of generalized infection. Penicillin is now available for the hospitalized patient. Recurrence of the boils may be prevented by the use of an autogenous vaccine, preferably containing staphylococcus toxoid, so that the individual's resistance is raised both to the toxin and to the organism itself. There is experimental evidence that antitoxic immunity is an important factor in limiting the spread of staphylococcal infection in the tissues.

Milk and Sugar-beet Tops

Q.—Does the feeding of cows on sugar-beet tops affect their milk composition either quantitatively or qualitatively? I ask this question with reference to babies fed on cow's milk.

A.—The feeding of cows on excessive quantities of sugar-beet tops or molassed beet pulp, or beet molasses may cause a fishy flavour and odour to appear in the milk. These beet by-products contain the nitrogenous base betaine, beet-tops containing an average of 0.3%. Betaine is metabolized by the cow primarily to trimethylamine oxide and rapidly excreted as such in the urine, but while the concentration of the oxide in the blood is high small amounts, of the oxide pass into the milk, and, if they remain there, react with the unsaturated acids of the milk fat to produce a fishy taint. If, however, sufficient time elapses before the next milking the subsequent lowering of the trimethylamine oxide content of the blood will be followed by the gradual diffusion of the oxide back from the milk to the blood, and the possibility of the occurrence of the taint is considerably lessened. The taint is avoided by limiting the amount of betaine fed to the cow and arranging a long interval between the feeding and the next milking. Not more than about 60 lb. of beet tops, given immediately after the milkings, should be fed each cow daily. Samples of fishy milk have been found to contain from 5 to 11 mg. of trimethylamine oxide per litre, and a similar amount of free trimethylamine resulting from the ready reduction of the oxide. Apart from these effects the feeding of sugar-beet tops to cows is unlikely to affect adversely the normal composition of the cow's milk.

Prefrontal Leucotomy

Q.—Has prefrontal leucotomy been performed to any extent on patients outside mental institutions? If so, does it have any effect on the intelligence, and is it probable that the patient would be enabled to earn his own living?

A.—Prefrontal leucotomy is most successful in relieving states of severe tension, whether protracted or episodic, and its uses are, broadly speaking, confined to four classes of illness: (1) depressive psychoses, in which convulsion treatment is contraindicated or has not proved successful; (2) obsessive-compulsive states of a disabling degree of severity; (3) some cases of florid schizophrenia intractable to other treatments, including insulin and electric convulsion therapy; (4) long-standing, violent conduct disturbances, which may be associated with schizophrenia, epilepsy, psychopathic personality, mental defect, etc. In the last group improvement is likely to be only symptomatic, although recovery has occurred. The operation has been, and may well be, performed in neurological units, general hospitals, or well-equipped nursing homes, so long as the patient's mentality and conduct do not require the special amenities of a mental institution. Most obsessive-compulsive states and some depressions fall into this category. It must be remembered, however, that leucotomy is a brain operation, requiring, if risks are to be minimized, the services of a neurosurgeon experienced in the special technique of the operation, and his regular team of assistants.

Gross intelligence defect is rarely if ever seen. On the other hand, discrimination of the finest degree is likely to be affected, and a more irresponsible attitude to life may occasionally develop. Leucotomy should not be recommended where patients occupy professional or highly responsible executive posts if there is a reasonable chance of recovery without operation; other work can usually be carried out as well as, and in many cases of long-standing obsessional personality definitely better than, before the illness.

Penicillin for Osteomyelitis

Q.—I have a patient recently discharged after recurrent operations for osteomyelitis. Is he faced with the prospect of continued operations, or does penicillin hold out a hope of arrest or cure?

A.—The penicillin treatment of chronic osteomyelitis is disappointing (see, for instance, I. M. Robertson, *B.M.J.*, April 15, 1944, p. 519). Penicillin is a valuable adjunct to radical surgery, but its administration, whether locally or even systemically, will not overcome an infection which is firmly established in bone.

LETTERS, NOTES, ETC.

The Neurotic Background

Dr. JOHN B. PRIMMER (Cowdenbeath) writes: Air Commodore Gillespie's excellent paper on psychological medicine and the family doctor will bear reflection, and should be taken to heart. The neurotic background is all too common. About thirty years ago, before psychotherapy had taken firm root, I inquired into the past history of a multipara. She was fair, fat, and forty, and complained of a plenitude of distressing symptoms that did not seem to fall into any particular pattern. Her frequent appearances and her loquaciousness necessitated a hold-up in a busy surgery. During a pause I diverted her thoughts from the present to a full discussion of her past. After much circumlocution she at last unburdened her soul and confessed that, many years before, she had been raped at a Sunday-school picnic! I did not try to elucidate any morbid details, but as a result of examination reassured her that there had been no untoward result, and that there was nothing organically the matter. Salpingitis, and certainly sterility, could be ruled out. No further treatment was necessary, and I saw her no more. With her husband she subsequently emigrated to a part of our far-flung Empire, where she reared more children. Fortunately I did not advise operation. At that time it was said that an ovary had a much chance of survival as a snowball in hell!

Non-tropical Elephantiasis

Dr. BRIAN P. HARRIS (Rottingdean) writes: As an alternative to operation for elephantiasis Dr. James Knott described a method of treatment in *Trans. roy. Soc. trop. Med. Hyg.* in 1937 or 1938 which I have tried with success in East Africa and which is roughly as follows. The affected leg and thigh are wound round with Turkish towelling from toes to groin, which is kept in position by a few thread stitches. A pair of wooden side-splints (Gooch's splinting is suitable) whose combined width does not completely encircle the limb is applied to opposite sides of the leg. Drawings with points facing outwards are fastened along the splints by pieces of adhesive strapping. A similar pair of splints is applied to the affected thigh. Hessian is now wound round leg and thigh from toes to groin, over the wooden splints, and is again held in position by a few stitches. Beginning at the toes, cord is now threaded round and round the limb through the hessian with a packing-needle and pulled tight. The limb is now surrounded by towelling, splints, hessian, and cord. The patient is allowed to walk about and considerable pressure can be exerted on the limb by tightening the cord and taking up the slack daily. (Oedema fluid exudes into the towelling.) After a fortnight or month the coverings are removed. Sufficient reduction in size of the limb may have been effected to enable a leather gaiter from toes to groin to be made for permanent wear. Or the splints, etc., may have to be reapplied with pressure for a further period. The method would appear to apply equally to non-tropical elephantiasis. The original paper should be consulted.

Red Vision after Cataract Operation

SIR STEWART DUKE-ELDER (London, W.1) writes: Your answer (Nov. 4, p. 614) as to the aetiology of erythropsia after cataract extraction is, to say the least, inadequate. A cataractous lens absorbs preferentially the short (blue) rays of the spectrum, a circumstance which probably explains the occasional and fleeting occurrence of "blue vision" after an extraction. Moreover, no over-correction of spectacle lenses will produce the visual effect noted. Contrary to the suggestion made, "red vision" after a cataract extraction is not very uncommon; it is also liable to occur whenever a sudden excess of light enters the eye, as after an iridectomy, maximal dilatation of the pupils, or prolonged snow-dazzle. So far as I know, no adequate explanation has been advanced. The fact that the red phase of an after-image is the most potent may have something to do with the matter; while the report by Edmund that the symptom disappeared rapidly on the administration of vitamin A in a night-blind subject may be interpreted to support Fuchs's view that in some way it is associated with the visual purple. Whatever it may be the explanation must be physiological rather than optical.

Alum-precipitated Pertussis Vaccine

GLAXO, LABORATORIES LTD. (Greenford, Middlesex) write: In your issue of Oct. 7, in answer to a query on whooping-cough prophylaxis (p. 486), you state that the alum-precipitated whooping-cough vaccine is not generally available in this country. This vaccine is, in fact, generally available and can be obtained without difficulty. We first prepared it in response to a request from a M.O.H. Later, as a result of further demands, we prepared further supplies but restricted its distribution to public health authorities. More recently, as we became assured of the value of this vaccine, we have made it generally available in phials of 5 c.cm. and 10 c.cm.

STUDIES ON HEPATIC DYSFUNCTION

II. THE VALUE OF SULPHUR-CONTAINING AMINO-ACIDS AND CASEIN DIGEST IN THE PREVENTION OF POST-ARSPHENAMINE JAUNDICE

BY

J. BEATTIE, M.D., D.Sc.

Bernhard Baron Research Professor, Royal College of Surgeons of England
AND

J. MARSHALL, M.B.

Major, R.A.M.C.

(From the Bernhard Baron Research Laboratories, Royal College of Surgeons of England)

Eller and Whipple (1942) observed that in protein-depleted rats chloroform anaesthesia was followed by fatal liver damage. This damage could be averted completely by the administration of methionine before anaesthesia. These observations suggested to us that the liver damage which occurs during an attack of post-arsphenamine jaundice might be averted by some similar treatment.

We have pointed out before (Beattie and Marshall, 1944) that in a clinic under the supervision of one of us the incidence of post-arsphenamine jaundice during the years 1942 and 1943 was over 50% of all cases treated entirely at the clinic. The incidence did not vary from month to month. However, the time of greatest incidence of the disease lay between the 13th and 19th weeks after starting arsenical therapy. In view of these observations it seemed worth while to attempt a series of experiments to determine if methionine, any of the other sulphur-containing amino-acids, or casein diets rich in methionine, would exert some demonstrable protective effect against post-arsphenamine jaundice during the time when the disease was most frequently developed. Apart from the scientific interest of such a study, a positive result would have some immediate practical value. It is important in antisyphilitic therapy with the arsphenamines to ensure an interrupted series of arsenical injections at weekly intervals for a period of at least six months except for a four-weeks' period beginning at the end of the 10th week of treatment. An attack of post-arsphenamine jaundice necessitates the withholding of arsenic during the period of icterus and for a few weeks or months thereafter, the chances of a cure of syphilitic infection are considerably diminished. Any treatment which would tend to reduce the incidence of post-arsphenamine jaundice, postpone it to late in the course of treatment, or, alternatively, so to reduce its severity as to enable the patient to continue to receive arsenical treatment, would be of value.

The Investigation

The experiments covered the whole of the year 1943 and the first three months of 1944. During this 15 months the incidence of post-arsphenamine jaundice occurred in the control groups in 36 cases (61%). The time of greatest incidence of the disease in these groups was between the 14th and 19th weeks of antisyphilitic treatment, when 18 cases occurred—82% of all cases. The control and treated groups consisted of patients who received all their antisyphilitic treatment in the clinic (M.L.H.). The experiments were designed so that protective treatment would begin just before the time of greatest incidence of the disease—i.e., at the 14th week. The members in each group were determined by the patients available, the quantity of the various preparations and amino-acids at disposal, and the inevitable loss of men from the groups as they transferred outside the area served by the clinic. It

was not possible to control the diet, as all patients were serving with their units and attended the clinic only as out-patients. It was noted that there was no significant difference in the incidence of jaundice among syphilitics from different units.

The routine antisyphilitic treatment used on all the patients in the control and treated groups consisted of 4 courses, each of 10 weeks, with a rest period of 4 weeks between courses. The weekly treatment consisted of an intravenous injection of 0.6 g. neoarsphenamine and an intramuscular injection of 0.2 g. bismuth in watery suspension. The first week of antisyphilitic treatment (A.S.T.) was reckoned to be the 7 days immediately following the first injection treatment. The weeks of treatment were reckoned consecutively from the first, and included the rest periods. Thus the 15th week of treatment was the week following the first injection of the second course.

Alternate patients arriving at the 14th week of treatment were chosen as controls and given no protective treatment. The remainder were allocated to one or other experimental group. In this way a continuous series of control and experimental groups was maintained for 15 months.

At the start of the investigation we had available a small supply of a dried casein digest prepared by spray-drying a papain-trypsin digest of pure casein. Owing to its unpalatable taste the powder was administered in capsules each containing 0.5 g. of digest. It was found that the practical upper limit of dosage was 20 capsules (10 g. digest) each day. These were given in 4 doses each of 5 capsules at 4-hourly intervals. This experiment was Series I.

To increase the amount of sulphur-containing amino-acids in the daily doses of digest we reinforced the dried casein digest with cystine. As it is well known that cystine can act as a "sparer" of methionine provided the minimal daily requirements of methionine are present in the diet, we thought that the reinforced digest might be more effective than the simple digest powder. To each 97.5 g. of digest 2.5 g. of cystine was added. Assuming that each molecule of cystine in the mixture would "spare" two molecules of methionine, the "maximum effective" methionine content of a daily dose of reinforced digest of 10 g. would be approximately:

Casein digest (97.5 g.)	=	312 mg. methionine
Cystine (0.25 g.)	=	155 mg. methionine
"Maximum effective" methionine content		467 mg. per day

It is probable that such an estimate exceeds the actual effective methionine content; but we had no means of assessing the latter. This experiment was Series II. It was necessary to determine if cystine alone was of value, and four different experiments with different dosages and covering differing periods of administration were carried out. These form Series III. Finally, when pure methionine became available this substance

even in doses of 0.6 g. per day. This formed the Series IV dressing element.

The scheme of each of the experiments is detailed below:—

Series I: 10 g. casein digest daily during the 14th and 15th weeks of A.S.T.

Series II: 10 g. reinforced casein digest daily from the 14th to 19th weeks (inclusive) of A.S.T.

Series III A: 0.5 g. cystine from the 14th to 16th weeks (inclusive) of A.S.T.

B: 1.2 g. cystine daily during the 14th to 16th weeks (inclusive) of A.S.T.

C: 0.6 g. cystine daily during the 14th to 19th weeks (inclusive) of A.S.T.

D: 1.2 g. cystine daily during the 14th week, followed by a single dose of 2.4 g. cystine at the time of arsenical injection on the 15th to 19th weeks of A.S.T.

Series IV: 0.6 g. methionine daily during the 14th to 19th weeks (inclusive) of A.S.T.

During arsenical treatment it had been observed that when some or many of the pre-icteric signs and symptoms of post-arsphenamine jaundice are present an injection of neo-arsphenamine (0.6 g.) almost invariably was followed by icterus within 7 days. When the injection is withheld most patients (80% or more) developed icterus within the same time. Biopsy findings made it clear that liver damage is usually well marked before icterus appears. For these reasons we considered that post-arsphenamine jaundice had occurred when some or all of the characteristic prodromata were present. In some patients, however, the prodromata were absent and icterus was the first sign of the disease. To avoid using the term "post-arsphenamine jaundice" when no icterus was present, we propose to use the term "liver damage" to include both icteric and non-icteric cases of post-arsphenamine jaundice. The general results are summarized in Table I.

TABLE I

Explanation of Graphs.—The detailed results are expressed graphically in Figs. 1-6. The vertical bars at weekly intervals indicate the injection of neoarsphenamine; the height of the bar is proportional to the dose of arsenical given. The horizontal shaded bar shows the duration of the protective treatment, and increases in its width are proportional to the daily dose given when this was increased. The narrow horizontal black bar indicates the appearance of typical prodromal signs and symptoms. Icterus is indicated by a doubling of the width of the bar. Duration of the illness is shown by the length of the bar. The broken line in Fig. 3 indicates treatment with reinforced casein digest.

The effect of the various treatments in deferring liver damage is summarized in Table II.

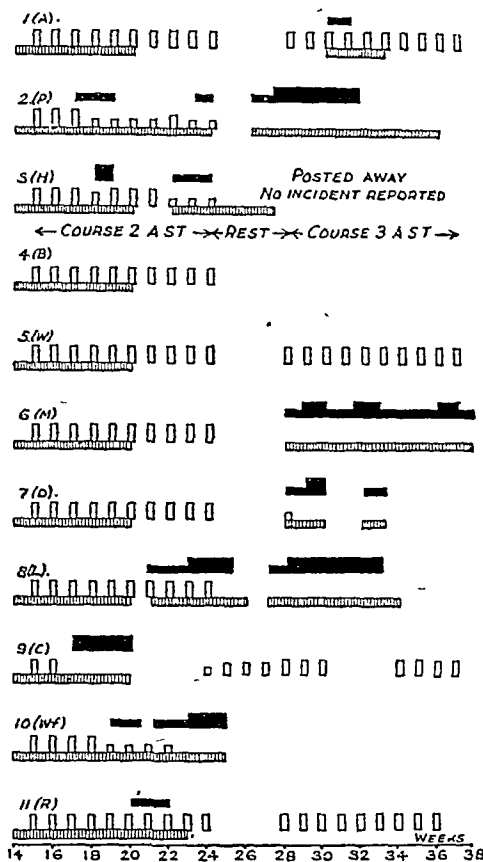

FIG. 1.—Series II.

Comment

In assaying the value of the "protective" treatments felt we had to provide answers to the following questions:

(a) Is the "protective" treatment of value in reducing the incidence of liver damage during the 15th to 24th weeks of anti-syphilitic treatment (A.S.T.)?

(b) Is there any evidence that the "protective" treatment shifts the incidence of liver damage towards the end of the second course of A.S.T.—i.e., towards the 24th week?

(c) Does the "protective" treatment prevent the appearance of icterus when prodromal signs and symptoms have appeared and arsenical administration is continued?

(d) Is the "protective" treatment to prevent the development of icterus effective only when arsenical injections are suspended or the dose is reduced?

FIG. 2.—Series III A.

The immediately effective treatments are apparently those given in Series III B and D, when no sign of liver damage appeared during the period of treatment. In Series III B, however, all 6 patients in this group had evidence of liver

damage within 21 days after the cessation of preventive treatment, while no such cases appeared in Series III D. The next most effective treatments seemed to be those in Series III A and Series IV, in which only one case in each appeared during treatment. Within 21 days three cases of liver damage occurred in Series III A and one in Series IV.

FIG 3—Series III B

As the numbers in each of these groups are too small to bear statistical analysis it is not unreasonable to add them together and to compare the findings with the control group. From the control group (36 cases) the number of cases for a smaller group of 28 cases may be calculated and the probable number of cases during certain weeks predicted. Analysis of a larger control sample (150 cases) has shown that the control group is in fact a fair sample and the incidence of liver damage in the various periods is representative. The analysis is given in Table III.

TABLE III—Cases of Liver Damage during Weeks of AST

	Total	1st Week	15th Week	16th Week	20th Week	24th Week
Controls (36)	14.7	6.2	7.7	0.8		
Treated groups (25) III A, B, D and IV	15	1	10	4		

In the groups where "protective" treatment was apparently effective the incidence of liver damage was not reduced during the second course of antisyphilitic treatment. This provided an answer to our first question. With regard to the second

FIG 4—Series III C

question, there is a tendency for more cases to appear later in the second antisyphilitic course than towards its beginning. In Series III A and B the protective treatment was prolonged over 3 weeks instead of over 6 weeks as in Series III D

and Series IV. If this treatment had been prolonged 6 weeks there is a possibility that the nine cases of damage which appeared within 21 days after the end of protective treatment might not have developed until the 20th-24th week period. In such an event the shift might have been more pronounced. Series III A and C are however

FIG 5—Series III D

practically identical in daily dosage of cystine (0.5 and 0.6 g) on either the length of time over which the cystine was given. Reference to Figs 2 and 4 shows that within the first 6 weeks at the beginning of the second course of arsenical treatment each of these groups had the same number of cases of liver damage. The prolongation of treatment at the same dosage for 6 weeks apparently in no way influenced the development of liver damage in Series III C. It is a fair deduction therefore that such a dosage of cystine is ineffective

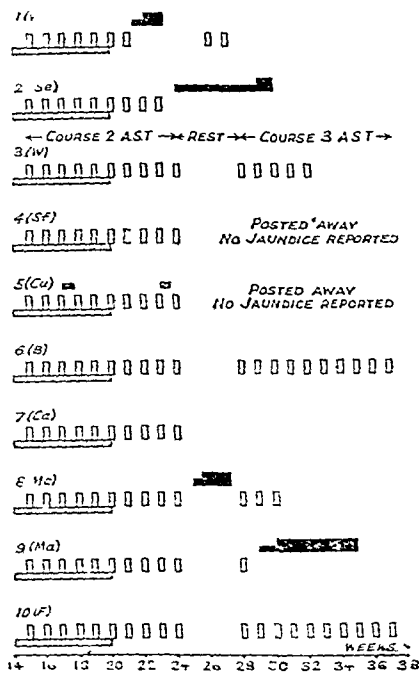

FIG 6—Series IV

Doubling the daily dose of cystine for a period of three weeks (Series III B) produced no cases while treatment was being given, but all the group had liver damage before the end of the sixth week from the start of the 21 day treatment

dressing periment is inconclusive in view of what has been boiks above regarding Series III A and C. It is possible that if treatment had been prolonged for 6 weeks a similar result to that recorded in Series III C might have been obtained; on the other hand, it is equally possible that no cases might have occurred.

Series III D treatment, in which a daily dose of 1.2 g. cystine was given during the 14th week and was followed by single doses of 2.4 g. cystine on the days on which arsenical injections were given (15th–20th weeks), was apparently effective, as no cases of liver damage appeared either during the period of "protective" treatment or during the subsequent 21 days.

Series IV seemed to show that small doses of methionine (0.6 g.) were almost as effective as the massive doses of cystine of Series III D. It should be noted that, in spite of continued full doses of arsenic, icterus did not develop in the single case of liver damage during "protective" treatment. The very significant delay in the appearance of liver damage in the remaining four cases is noteworthy.

Series I represents an attempt to increase the daily intake of methionine by using a casein digest. The results demonstrate clearly that an extra 0.3 g. of methionine present in the daily dose of digest for 14 days had no effect on the incidence or time of appearance of the post-arsphenamine jaundice. The Series II experiments, in which cystine was added to the digest, present some interesting features. During the period up to the end of the 24th week 5 patients of the 11 treated remained free from liver damage. One (R.) showed signs of liver damage at the beginning of the 20th week, but with continued "protective" treatment did not develop icterus, although full doses of arsenic were given. Two with prodromal signs and symptoms were treated by reducing the arsenical dosage and continuing the "protective" treatment. One of these (P.) did not become icteric, but a full dose of arsenic produced a reappearance of the prodromal phenomena. The other (Wf.), in spite of reduced dosage, eventually became icteric. A mild icterus in one patient (H.) was treated by reducing the arsenical dosage. At the end of 7 days icterus had disappeared and full arsenical treatment was resumed. The suspension of "protective" treatment for two weeks induced a reappearance of prodromal signs and symptoms. One patient (L.) showed no sign of liver damage until one week after the end of the protective period. Resumption of "protective" treatment, with full doses of neoarsphenamine, however, did not prevent the appearance of jaundice. He relapsed again after being without "protective" treatment for one week. Arsenic was not given during the relapse. Icterus appeared in one patient (C.) after two arsenical injections. Suspension of injections and continuation of the "protective" treatment were followed by disappearance of icterus in 3 weeks. Resumption of arsenical injections later without "protective" treatment provoked no relapse.

These results suggest that the addition of but a small quantity of cystine to the casein digest is just sufficient to protect some individuals from developing liver damage, others from the development of icterus, others also from icterus but only if the arsenical dosage is reduced; and others are not so protected. This scheme of "protective" treatment seems therefore to represent almost the balance between adequate and inadequate treatment. Assuming that the addition of 0.25 g. cystine acted by sparing methionine, it would represent the sparing of not more than 0.16 g. The total "effective" methionine supplement would therefore probably not exceed 0.4 g. per day.

Two possible explanations of these results must be considered. One protective compounds might be effective in rendering the neoarsphenamine non-toxic to the liver and presumably also to the spirochaete. Possibly post-arsphenamine jaundice is a partial deficiency disease in the sense that certain compounds, which enable the liver successfully to resist the toxic effects of virus infection combined with neoarsphenamine injections, are not present in optimal quantities in the wartime diet. Supplementation with these compounds presumably may be effective in altering the incidence, time of onset, or severity of the liver damage when it occurred.

Voegtlin (1925) showed that neoarsphenamine in the concentration found in the blood during antisyphilitic treatment

was not lethal to the spirochaete until it had been oxidized to arsenoxide. Arsenoxide is rendered non-lethal, however, if it is allowed to combine with a sulphhydryl-containing compound such as cysteine. Eagle (1939) suggested that arsenoxide killed the spirochaete by combining with sulphhydryl groups concerned in the respiration of the cell. Glutathione is one such compound. The probability is that arsenoxide is toxic to the liver cell through a similar mechanism. It is conceivable that cystine (being readily convertible to cysteine in the liver) might be utilized in this way to detoxicate the arsenoxide. In two of the cystine-protected series the times during which "protective" treatment was continued were identical. In Series III C; however, the cystine was given daily in doses of 0.6 g./day or 4.2 g./week, whereas in III D, with the exception of the first week, the cystine was all given on the same day as the arsenical injections in a dose four times the daily dose of III C but only slightly more than half the total weekly dose. In both groups the overall incidence of liver damage was unaffected. In III C the cases occurred at the usual time or were only slightly delayed. In III D the cases were very significantly delayed in onset (Fig. 5). Such a contrasting result can best be explained by assuming that cystine given in massive doses on the day of the arsenical injection is mainly effective by acting as a chemical detoxicating agent for the arsenoxide thus relieving the liver from the effects of arsenoxide for at least six weeks and enabling it to deal with later arsenical injections successfully for a limited period. There is only one other series in which the occurrence of liver damage was delayed to a comparable extent. In Series IV methionine was given in a manner corresponding exactly to Series III A, discussed above, but the results obtained were strictly comparable to those in III D. It seems impossible that methionine in this case could be acting as a direct detoxicating agent at a level of dosage where cystine was ineffectual. It therefore becomes necessary to assume that methionine, unlike cystine in large doses, is effective in the second of the two ways suggested above.

It must be made quite clear that Eagle's work was done *in vitro* and may therefore not be valid under *in vivo* conditions. The experimental evidence on animals is at present equivocal. In some measure this may be due to dietary variations which Martin and Thompson (1943) showed could introduce variations in the acute toxic effects of arsphenamine as great as 50%. The consensus of opinion, however, is that the sulphhydryl compounds, such as cysteine, can diminish the toxic effects of the trivalent organic arsenicals—neoarsphenamine and arsenoxide. Cystine apparently can only exert such an action when it is reduced to cysteine. This reduction of cystine to cysteine can occur in the liver.

The conclusion that cystine is mainly effective as a detoxicating agent, whereas methionine remedies a specific dietary deficiency, is strengthened when actual diet figures of these men are considered. The British Army Home Forces daily ration as issued contains 118 g. protein, of which 58% is of vegetable origin. In fact, we found that the maximum these men appeared to be eating was 100 g. of protein per day. This would give a sulphur intake of about 0.96 g. daily, representing about 2 g. each of methionine and cystine. It is well known that the borderline between adequate and inadequate quantities of the various essential food constituents may be narrow. If there is a suboptimal methionine intake in these men receiving arsenical treatment an increase of 25% might easily be sufficient to raise it to an effective level. On the other hand, the quantities of a sulphhydryl-containing compound sufficient to protect the liver by direct detoxication of the arsenic would have to be very much larger. One molecule of neoarsphenamine requires four sulphhydryl groups for detoxication. If all the administered cystine were converted directly to cysteine and all this cysteine were then combined with arsenoxide, the weekly dose of 0.6 g. neoarsphenamine would require 0.6 g. cystine. This would need to be available during the 24 hours following the injection, as it is known that the greater part of the spirochaetocidal action of neoarsphenamine, which we assume to be similar to its hepatotoxic action, occurs within this period. In view of the many ways in which cystine can be metabolized, apart from its conversion to cysteine, it is not surprising that the minimal effective dose of cystine should approach 2.4 g. when given

that the incidence was lower on Sundays and Mondays than on other days. It is hardly necessary to state that the departure from uniformity cannot be accounted for by treatment being withheld at the week-end. It is, moreover, too great to be readily attributed to chance. The suggestion is offered that the deficiency of perforations on Sunday and Monday may be due to rest at the week-end.

Incidence by Hours of the Day

Perforation of a peptic ulcer occurs with such dramatic suddenness and is marked by such intense pain that it is generally possible to determine the precise time of onset. In 951 perforations occurring in 884 patients treated at the Western Infirmary during 1938-43 the time of perforation was recorded in 816 (Fig. 10A). It will be noted that few perforations occur

during the night, and that during the day the incidence gradually rises to a maximum in the period 3 p.m. to 6 p.m., thereafter falling gradually. It is relevant to state that the usual meal-times of the working population in Glasgow are: breakfast 7 to 7.30 a.m., lunch 12 noon, supper 5.30 to 6.30 p.m. The incidence of perforations in relation to meal-times, is not clear and demands further study. It is noteworthy that the incidence is highest towards the end of the working day and lowest during the period of rest. This may be compared with the low incidence at the week-end and after the summer holiday period.

Incidence by Site of Ulcer

At two of the main Glasgow hospitals (Western and Victoria Infirmarys) we have classified perforations treated during the period 1924-43 according to the site of the ulcer. The classification has been made on the basis of operation notes recorded in the clinical case-sheets. In Glasgow it is the usual practice that operation notes are written (or dictated) in full by the surgeon responsible, and the records are generally detailed and precise. Consequently we have been able to establish the situation of the ulcer in 97% of cases.

The main difficulty has been in regard to ulcers situated at or close to the pylorus. In an emergency operation if the anatomical landmarks are obscured by inflammation or adhesions, it is impossible to determine the precise site of such an ulcer with certainty. As a result, in some cases (a small minority) the ulcer has been recorded as being situated "at the pylorus" or "close to the pylorus" with no more exact guide to its site of origin. Since these juxta-pyloric ulcers are closely akin to duodenal ulcers in appearance and behaviour (and very different from the typical lesser-curve gastric ulcer) we have grouped them with duodenal ulcers under the title "pyloro-duodenal". As their number is small (about 5% of the total) our conclusions on the relative incidence of gastric and duodenal ulcer are not affected materially by this arrangement.

It will be seen (Table II) that duodenal ulcer far exceeded all other types, accounting for 82.95% of the total. The

TABLE II.—Perforated Ulcer Incidence by Sites, 1924-43

Total	Gastric	Pyloro-duodenal	Anastomotic	Site not Stated
3,882	423 (12.70%)	3,220 (82.95%)	52 (1.34%)	117 (3.01%)

proportion of duodenal to gastric ulcer is about 13 to 2. Perforated anastomotic ulcers numbered 52, or 1.34% of the total—a remarkably high incidence considering that even in the heyday of gastro-enterostomy the proportion of all ulcer patients subjected to this type of operation must have been very small.

Perforated Gastric and Duodenal Ulcer: Incidence by Years (2 Hospitals; 20 Years)

Fig. 11 shows the incidence by years of gastric and duodenal perforations separately and, for comparison, the incidence by

years of all types of perforation together. It will be seen that the incidence of gastric perforation was not materially changed during the 20-year period, whereas the incidence of duodenal perforation has altered greatly. Indeed, the changing incidence of perforated ulcer as a whole merely reflects the growth of its duodenal component.

Site Incidence by Sex (2 Hospitals; 20 Years)

Table III shows the incidence in males and females of ulcers at different sites. It will be seen that males predominate in perforations of all types. The sex difference is particularly striking in anastomotic ulcers, all of which occurred in males.

TABLE III.—Site Incidence by Sex

Site	Male	Female
Gastric	442 (12.02%)	51 (25.00%)
Duodenal	3,076 (83.63%)	144 (70.59%)
Anastomotic	52 (1.41%)	0
Site not stated	108 (2.94%)	9 (4.41%)
All sites	3,678 (100.00%)	204 (100.00%)

It will be noted that there is a difference in the sex ratio of gastric and duodenal perforation. In males 12% of perforations were gastric while 83.6% were duodenal; the comparable figures for females were 25% and 70.6%. Statistical analysis shows that it is highly improbable that the difference in sex ratio has arisen through the play of chance.

Fatality from Perforated Peptic Ulcer

The fatality from perforated peptic ulcer is influenced, as we shall show, by many factors—the sex and age of the patient, the site of the ulcer, the season (winter or summer), the promptness of treatment, as well as (doubtless) the skill of the surgeon and the nature of the operative technique. Perhaps also there may be differences based on geography and race and nutritional standards.

We feel it necessary to emphasize the importance of these factors, for they have an obvious bearing when comparing the mortality rates given by different workers. Unfortunately, few reports in the past have provided the data necessary to make such a comparison with much confidence. For this

reason we make no attempt to compare the results reported here with those of other workers.

In the 7,156 perforated peptic ulcers contained in our 20-year series the deaths numbered 1,396,* or 19.5%. During the 20 years the fatality rate has fallen from 25.7% in 1924 to 14.1% in 1943 (see Fig. 12). The fall has not been a steady

ne, but the trend as a whole is quite clear, and statistical analysis shows that it is unlikely to have occurred as a result of chance. It should be noted that this improvement has been achieved despite an increase in the age incidence. Probably is attributable mainly to increasing promptness of treatment.

It is relevant to state at this point that in over 90% of cases in our series the operative treatment has consisted in simple closure of the perforation, without gastro-enterostomy. Primary gastrectomy is not practised.

Deaths by Age Groups in Males and Females (3 Hospitals; 20 Years)

Fig 13 shows the fatality rate in males and females at various age groups. Males have been taken in 5-year groups; females, owing to the smaller numbers, in 10-year groups.

It will be seen that the fatality rate increases with age and that in all age groups the fatality rate in females exceeds that in males. Over the whole series the fatality rate for males is 18.6%, for females 36.4%. In males the fatality rate remains below 10% until the age of 30 and below 20% until the age of 50, after which it rises rapidly. In females the rise occurs earlier and is more pronounced. The higher fatality rate in

* This figure and those given elsewhere throughout the report include all deaths occurring at any point after perforation while in hospital. It is relevant to state also that our series includes cases omitted moribund and not subjected to operation; it excludes cases diagnosed as "leaking ulcer" but recovering without operation.

females is not due to the larger proportion of gastric ulcers occurring in that sex, nor do our records indicate that it is due to any difference in the promptness with which treatment is instituted.

Deaths by Season (3 Hospitals; 20 Years)

Table IV gives the deaths for the winter and summer months. It will be seen that the rate is considerably higher in winter than in summer. Statistical analysis shows that the difference

TABLE IV.—Perforated Peptic Ulcer. Deaths by Season (Both Sexes)

	No. of Cases	Recovered	Died
Winter (Oct.-March)	3,666	2,901	765 (20.9%)
Summer (April-Sept.)	3,490	2,859	631 (18.4%)
Total	7,156	5,760	1,396 (19.5%)

$$\chi^2 = 8.907. \quad n = 1. \quad P = \text{less than } 0.01.$$

is unlikely to have occurred by chance. Nor do our records provide evidence that the disparity can be accounted for by seasonal variations in the age incidence or sex incidence or in promptness of treatment. It may well be attributable to the increased risk of pulmonary complications in the winter months.

Deaths by Site of Ulcer (2 Hospitals; 20 Years)

In males the fatality rate for perforated gastric ulcer is much higher than for duodenal, and the difference is far more than can be accounted for by differences in the age incidence.

TABLE V.—Deaths by Site of Ulcer

Site	Males			Females		
	Recovered (No.)	Died (No.)	%	Recovered (No.)	Died (No.)	%
Gastric	316	216	28.5	32	19	37.3
Duodenal	2,625	451	14.6	106	38	26.4
			$\chi^2 = 8.907$ $P = \text{much less than } 0.01$			$\chi^2 = 2.042$ $P = c. 0.18$

In females also the fatality rate is higher in gastric than in duodenal perforation, though, perhaps owing to the fewness of cases, the difference is not statistically significant. Thus perforated gastric ulcer is a more dangerous disease than perforated duodenal ulcer. Our records give no indication that this is due to the promptness with which the two types are submitted to treatment. It may well be due to the fact that in gastric ulcer the perforation is generally of larger size and permits greater escape of more heavily infected contents.

Deaths by Delay in Treatment (1 Hospital; 6 Years)

In 939 perforations occurring in 872 patients admitted to one hospital (Western Infirmary) during the period 1938-43 the fatality rate has been assessed by the delay in treatment. In 813 of these cases the number of hours between the time of perforation and operation was recorded. The time interval

658, Nov. 18, 1944

ACUTE PERFORATED PEPTIC ULCER

BRITISH
MEDICAL JOURNAL

ranged from half an hour to 3 days. It will be seen that in a large majority of cases operation was performed within 6 hours of perforation. This promptness of treatment is doubtless due partly to the fact that the area served is predominantly urban, but much credit must also be given to the diagnostic acumen of the practitioners in this area. Fig. 14 shows that in this series the fatality rate rose progressively with delay in treatment. This, of course, confirms general experience and the reports of all previous observers.

Summary

Figures are reported relating to the incidence of perforated peptic ulcer in an area in the West of Scotland with a population of over 2 millions. The more notable findings are as follows:

1. From 1924 to 1938 there was a progressive increase in the incidence of perforations. During the war the steady increase has been interrupted by a marked rise in 1940-1, followed by a return to a lower level. These changes almost entirely concern duodenal ulcer.

2. The 1940-1 rise was not correlated with air raids in this part of the country. It is suggested that, in addition to anxiety about the war situation, overwork and perhaps undernutrition may have exerted an influence.

3. The sex ratio has undergone little change during the 20-year period. The rise in 1940-1 and the fall in 1942-3 were confined to men. In women during the war years the general pre-war trend was maintained. This finding is somewhat surprising in view of the great changes which have taken place since 1939 in the habits and working conditions of women.

4. Perforation is rare in childhood; its incidence rises rapidly in adolescence and attains a maximum between the ages of 30 and 40 years. Since 1924 there has been a rise in the mean age which does not appear to be due entirely to ageing of the population. The mean age is higher in females than in males.

5. Perforations are unduly common in December and relatively uncommon in August, September, and October. This low incidence in the summer months may possibly have a nutritional basis or may be related to the holiday season.

6. Perforations are less frequent on Sundays and Mondays than on other days. This may perhaps be related to rest at the week-end.

7. Perforations are unduly common between 3 p.m. and 6 p.m. and comparatively uncommon during the night and morning. The relation of these phases to meal-times is not clear and requires further study. There may be a correlation with periods of stress and rest respectively.

8. The fatality rate from perforations increases with age and with delay in treatment. It is greater in gastric than in duodenal ulcer, in females than in males, in winter than in summer.

This survey has been carried out under the auspices of a committee of the Nuffield Provincial Hospitals Trust appointed in Glasgow for the study of sickness records. Thanks are due to our surgical colleagues and the hospital authorities for furnishing us with the information on which this survey is based, and particularly to the medical superintendents of the three main voluntary hospitals, who have given us every facility for extracting the hospital records. Our task has been greatly lightened by the generous help we have received on all sides. We acknowledge also our debt to Prof. J. W. McNee, of whose staff one of us is a member.

Extracting clinical records often proves disappointing, but in this instance we have been gratified at the amount and the detailed character of the information available, and we have pleasure in recording our appreciation of the care devoted by our colleagues, year in and year out, to this routine task of hospital work.

That there is a real demand for a contributory hospital scheme for those who desire treatment in hospital private wards and nursing homes is shown by the progress made by the Hospital Service Plan under the chairmanship of Sir Bernard Docker and sponsored by King Edward's Hospital Fund for London. This plan has grown steadily since its inception barely two years ago, and the secretary of the London Association for Hospital Services (10, Old Jewry, E.C.2) now announces that the maintenance refund rate is to be increased from £6 a week to £6 6s., thus indicating a desire among the higher-salaried public to make provision for their dependants and themselves in the event of serious illness. The increased refund is payable to subscribers admitted to hospitals after the end of October.

EXPERIENCES WITH THE GIANT MAGNET AND METALLIC INTRAOCULAR FOREIGN BODIES IN RECENT BATTLE CASUALTIES

BY

It is perhaps important to publish the following case just now, and we do so at the suggestion of Brig. Sir Stewart Duke-Elder.

Case History

On July 15, 1944, L/Cpl. E., a land-mine battle casualty from Normandy, was admitted to No. 4 Canadian General Hospital. He had been blown up on July 3, and was "pulseless" when picked up and transfused that evening. From toes to vertex he was spattered with wounds of various sizes. All were superficial except one in the abdominal wall, one of the left hand, and a penetrating injury of the left eyeball.

The first two wounds were operated upon in France. When received at No. 4 Canadian General Hospital the patient was in good condition. He had received intramuscular penicillin, 50,000 units five-hourly, starting on July 8, to a total of 500,000 units; it was then stopped. On the 18th it was given again—15,000 units every three hours to a total of 150,000 units.

H. A. G. D. located a small foreign body impacted in the retina about 3 d.d. down and in from the disk. The entrance wound was minute, near the limbus towards 9 o'clock. There was haemorrhage of the retina near the track of the missile, but lens and vitreous were clear. The vision was 20/20. A radiograph showed a single minute opacity corresponding in position to the visible F.B. H. A. G. D. had the case transferred to the S.E.C. Ophthalmic Centre for extraction, since his magnet was not very powerful, and assisted at the subsequent surgical procedures.

On July 15 operation was performed under novocain infiltration. Good rotation was ensured by dividing the mesial rectus. A 3-mm incision was made in the sclera through a linear diathermy coagulation, between points of fine silk suture. The incision was seen to be about 1 mm. from the F.B., which was partially hidden by coagulum. Six short applications of the giant magnet with the tip of a beak-shaped terminal on the wound produced no movement. It was considered inadvisable at this time to extract the particle with forceps, for several reasons which need not be discussed here. The patient was retained for further consideration.

The next day, when we were dealing with a minute metallic F.B. in the vitreous of a German prisoner of war by the posterior route, Major H. W. Applin, who was collaborating, observed a slight rocking of the F.B. at the end of about the tenth short application, as the current went on and off. Thereafter the particle made larger excursions from the centre of the vitreous towards the wound and was delivered through the choroid (which had not been incised) at the thirty-fifth application. The immediate post-operative progress in this case was uneventful; the eye remained quiet, the vitreous clear, and the vision 6/6.

This experience encouraged us to continue with magnet extraction in the case of L/Cpl. E., since, meantime, some metallic particles collected from scabs on his legs had proved magnetic, and had given a positive Prussian-blue reaction when dissolved in nitric acid. On July 28 the sclera was exposed down to the previous wound and the curved terminal placed against it towards the side away from the F.B. The magnet was then used in short bursts of about 4 seconds (on a few occasions as long as 15 seconds) for 75 applications. The current was probably flowing for not more than a total of 10 minutes. During this time the F.B. was observed to rock in its bed of coagulum, gradually come out of it, and lie across the wound. The magnet was then too hot to manipulate, and it was considered that its insulation was in danger. The patient was returned to bed.

On Aug. 2, under continuous pentothal, the mesial sclera was freely exposed, the internal rectus being divided again to give free access. The scleral suture was removed from the original wound, on which the beak-shaped terminal was placed. The wound elevated slightly at the first magnet application, and the particle, less in size than the head of a half-inch pin, came out at the sixth trial without any haemorrhage or vitreous showing.

The post-operative course has been uneventful. The vitreous remained clear and the vision good—6/9 with lens.

Commentary

It has long been known that intermittent applications repeated at a number of sittings will succeed in moving a feebly magnetic particle (see Crawford R. A. D. *Brit J Ophthalm.* 1943, 27, 227), and no doubt others have had similar experiences to ours with recent brittle casualties. It seemed to us and to Major Applin that it may not be generally realized that a small magnetic FB or a larger metallic magnetic particle may behave as a non-metallic FB for a considerable number of magnet applications and be labelled as such. Moreover, with such particles the magnet test of production in a cocamized eye is useless.

There are further lessons to be learned from this case and other recent cases we have dealt with.

1. The posterior route is ordinarily best to posterior segment FBs.

2. The shortest route to the exterior is probably always best, provided it does not drag the particle over or through an intraocular part or structure of relatively greater importance than that in which it is lodged.

3. A beak-shaped magnet terminal is almost essential for work well behind the equator. A blunt cone-shaped terminal is sometimes a danger especially with highly magnetic large bodies, unless they are situated in the anterior segment, since the field is too diffuse to direct the delivery accurately.

4. The removal of small metallic intraocular FBs of feeble magnetism which it is desirable to remove as in the case of iron compounds, is sometimes determined by the patience and perseverance of operator and patient and the lilt of the magnet and rectifier—possibly oftener than we have thought heretofore.

5. It is perhaps stating the obvious to say that exploration of intraocular FBs lodged superficially on the skin of face or body or in the conjunctiva, as to their composition and magnetism, is desirable.

6. To those accustomed to the localization of civil hospitals in peacetime the slower and less accurate methods necessitated by war conditions constitute a great handicap.

7. The fact that frequent applications of the giant magnet increase the magnetism of feebly magnetic alloys should influence technique.

8. The application of a surface diathermy terminal to the sclera in the neighbourhood of a metallic intraocular FB is likely to produce an uncontrollable reaction emanating from the FB. For this and other reasons (e.g. the greater difficulty of withdrawing a magnetic particle from a bed of coagulum) it is probably better technique to apply diathermy to the neighbourhood of the scleral wound after the FB is removed.

9. If prolonged applications of the Army portable giant magnet are required, as in the case described above, it is almost essential to place it on an adjustable stand with a tilting top beside the operating table.

LATENT MASTOIDITIS IN INFANCY

W. H. PATTERSON, M.D., D.C.H.

Medical Superintendent, Booth Hall Children's Hospital, Manchester

G. STEWART SMITH, M.A., M.D.

Director of Pathological Services, Manchester Municipal Hospitals

The frequency with which pus is found at necropsy in the middle ears and mastoid cavities of infants is now generally recognized, but the exact part it plays in the causation of death is still controversial. The present paper is based on an analysis of 120 consecutive necropsies in which the middle ears were specially examined. It is felt that observations on a comparatively small series might be of value in reaching a solution to what is admittedly a difficult clinico-pathological problem.

The Literature

The literature is extensive, but the conclusions reached by the various authors on the significance of latent mastoiditis in infancy and early childhood are by no means unanimous.

In this article only a representative few of these papers will be considered. First Trotsch of Wurzburg in 1867 recorded the frequency with which he found purulent otitis media in infants aged from 16 hours to 1 year. Parrot (1877), in Paris, was surprised to often find pus in the middle ear of infants at necropsy. In his lectures on "l'athrepsie" he expressed the opinion that there was close association between athrepsia and otitis media. "Soit comme maladie primitive, soit comme complication." Johnston, Brown, and Tisdall (1930) in a clinical study of 171 cases of intestinal intoxication found otitis media in 109 (63.7%), the predominant organism being the streptococcus which has also been recorded as the chief causative organism in American reviews of the subject. They point out differences between the symptoms of gastro-enteritis and those of classical primary mastoiditis, and conclude that intestinal intoxication is not due to masked infection in the middle ears and mastoid antra. Findlay (1932) and Yampolsky (1933) hold the same opinion. Melle (1934) reported on the examination of mastoids in 300 consecutive necropsies in children. In 140 no abnormality was found in middle ears or mastoids, though of this number 62 had died of some alimentary condition. In the remaining 160 pus was found in the middle ear or mastoid. The cause of death in 73 of these had been alimentary intoxication or chronic malnutrition. The remaining 87 of the "pus in mastoid" group had died of causes other than alimentary. In other words, pus in the middle ear or mastoid was not found more often in patients dying of acute alimentary intoxication or chronic malnutrition than in those dying of any other cause. He stated that "from a clinical point of view, and from one's observations at post-mortem I can see no justification for blaming the mastoid as the primary cause of an acute alimentary intoxication."

Le Mee (1937), discussing Parrot's findings, suggested that the condition was a "post-mortem empyema" and the mechanism one of elementary physics. Cooling of the air in a cavity results in a reduction of pressure, and suction of adjacent fluid (in this case from the pharynx) takes place. Consequently if looked for, pus may be found not only in the middle-ear cavities but also in the sinuses of infants. Le Mee thought that the finding of pus in the middle-ear cavities of infants had not the same significance as in the child. Ebbs (1937) examined at necropsy the ears of 880 children aged up to 14 years who had died from a great variety of medical and surgical conditions. Pus was found in the middle ears of just over half of these patients. His series included 603 infants under 1 year, and 61% of them had purulent otitis media when examined after death. A clinical history of "gastro-enteritis" was obtained in 238 infants under 2 years and 81.4% of these had pus in the mastoids. Further, he found at necropsy that 71.6% of 134 so-called "primary pneumonias" and 70% of secondary pneumonias had otitis media. Ebbs concluded that "otitis media [as found in his series] had played a very large part as the aetiological, complicating or final cause of death in a great many of these children."

Cooper (1937), investigating infantile diarrhoea clinically in 300 infants, found parenteral infection in 122. Though otitis media was by far the most common infection, "it did not seem to prejudice the outlook." McConkey and Ross Couper (1938) found that of 1,324 infants admitted to hospital, 195 had otitis media or otitis media and mastoiditis, and they thought that the presence of these was responsible for diarrhoea and vomiting in a certain proportion of cases, especially in the toxic groups, caused by "a pent-up infection in the middle ear" and lack of drainage. Campbell and Cunningham (1941), with 574 cases of gastro-enteritis, concluded that "only those parenteral infections found in the early days of illness could be regarded as playing a part in causing the disease."

The question of the association between infantile diarrhoea and vomiting and middle-ear infection has been raised again by Leathart (1943) who believes that "many infants dying from diarrhoea, vomiting, and dehydration have had in addition an unsuspected bilateral mastoiditis two or three weeks before death." He attributes the condition to milk, vomit, or infected mucus entering the Eustachian tube in children either too young or too ill to sit up and accordingly nursed while lying on their

LATENT MASTOIDITIS IN INFANCY

BRITISH
MEDICAL JOURNAL

backs. He is convinced that all progressive cases require operative treatment.

The Present Investigation

The patients in this series were mainly infants, and the term "mastoid" is used to include the middle ear and mastoid antrum. Under the age of 2 years there is no sharp division between them, and the mastoid cells are as yet undeveloped.

Except for some patients who died within a few hours of admission to hospital, most survived long enough to allow of full clinical investigation. Careful analysis of the clinical picture revealed no new facts. It is worth noting that 27 of the patients in whose mastoids pus was found post mortem had normal or subnormal temperatures throughout the course of their illness. There was no correlation between leucocyte counts and the presence of mastoid pus as demonstrated after death. Quite low total leucocyte counts were recorded in some cases which had pus in both mastoids. This fact, however, cannot be used as an argument that the mastoid suppuration was "inactive," because total leucocyte counts in infants are often unreliable indices in differential diagnosis.

Many of the "positive" cases had adequate courses of one or other of the sulphonamide drugs, but the clinical course in these patients was unaffected even temporarily. Although sought for in all patients, otitis media was discovered in only 12 patients before death. Pus was found in 71 after death, bilaterally in 38. Of the 120 patients, 115 were under 2 years of age.

5 weeks to 6 months ..	46	26
7 to 12 months ..	10	6
1 to 2 years ..	9	8
3 years and over ..	2	3
All ages ..	71	49

As a result of the clinical and pathological diagnoses the cases have been divided into four groups, three of which are fairly well defined, while the fourth contains a variety of conditions.

Group 1: Diarrhoea and Vomiting.—The 49 cases in this group were diagnosed clinically as "gastro-enteritis," and the other pathological findings, mostly inconclusive as regards inflammatory changes, left one with no alternative than to support the clinical diagnosis. Pus was found in the mastoids of 35 of these.

Group 2: Respiratory Conditions (Bronchopneumonia, Bronchiectasis, and Atelectasis).—Of the 30 patients in this group mastoid pus was present in 17, while in 13 the mastoids were clear.

Group 3: Marasmus and Athreptic Conditions.—Six of the 12 cases had pus in the mastoids.

Group 4: Miscellaneous Conditions.—There were at least 20 different causes of death in this group of 39 patients, and here 13 had positive mastoid findings.

Bacteriology

At necropsy each mastoid cavity was swabbed separately and the swabs were examined microscopically and culturally. Attempts have been made by various writers to determine the significance of the bacteriological findings in the pus in cases of latent mastoiditis, particularly so in the symptom-complex of diarrhoea and vomiting of infancy, investigation of the faecal flora of which so often gives negative results. Floyd (25), Jeans and Floyd (1926), and Marriott (1925) found haemolytic streptococci to be the predominating organisms in mastoid pus in this condition, and Marriott went so far as to suggest that the infantile diarrhoea and vomiting syndrome was probably a specific intoxication due to haemolytic streptococci, which were found in all his cases. Spahr (1929) concluded that where intestinal organisms were found in cultures of the mastoid pus the prominent symptoms were diarrhoea and vomiting, and that other organisms, though frequently met with, did not give rise to these symptoms. The findings in our series are set out in Table II.

It will be seen that the bacteriology was extremely varied, not uncommonly two or three different organisms being present in one mastoid. There were no characteristic findings in any

group, and our results do not support the conclusions of Marriott or of Spahr (loc. cit.). In none of the groups did streptococci predominate, and in the three larger groups, pneumococci, either alone or along with other organisms, were most commonly found. Pneumococci were four times as numerous as streptococci in the whole series, and in the diarrhoea and vomiting group were present in 54% of the cases in which there was pus. Crooks and Signy (1936) found the pneumococcus to be the most frequent causative organism in nasal sinusitis in childhood. It is interesting to note that pneumococci were seen in the mastoid pus of one patient with tuberculous meningitis and in one case of meningococcal meningitis. *Bact. aertrycke* was present in one case with diarrhoea and vomiting, but was not isolated from the faeces, and *Bact. coli* was present in three cases in the same group.

Discussion

This investigation was carried out primarily to try to reach some conclusion as to the place "latent mastoiditis" occupies in relation to the diarrhoea-and-vomiting syndrome in infants. Although we have been able to confirm the frequency with which pus is found in the aural cavities at necropsy in these cases, it is almost as common in a wide variety of conditions.

Acute otitis media is one of the commonest diseases of infancy. It is often undetected, sometimes for want of looking, and frequently because the symptoms and otoscopic signs are not as characteristic as in older children and adults. The infant tympanic membrane is tough, and spontaneous perforation is often later in following acute middle-ear suppuration than in older children. Apart from this, however, the anatomy of the infant's aural cavity is such that acute septic processes in it should rarely remain "latent" for long. The otologists teach that, while it is the "chronic ear" in children and adults which develops complications, it is in the acute stage that the infant is most liable to develop local extension of the suppuration. It is generally accepted that acute middle-ear infection in infancy implies involvement of the antrum in most cases. At this age the antrum is quite superficial, and its outer wall may even be deficient where the squamo-mastoid suture lies over it. Subperiosteal abscess should be, and in fact is, a very common complication of mastoiditis in babies. Again, the presence of the unossified petro-squamous suture in the infant presents an easy pathway direct from middle ear to middle cranial fossa. Extradural abscess and meningitis are ever-present dangers, and not rare complications, of acute otitis media in infants.

We think it is an important point that, except for one case of meningitis due to *H. influenzae*, none of our patients had any of the local complications which might reasonably be expected if the pus found in the mastoids was the result of an acute primary active process, and, moreover, so virulent as to cause death from toxæmia and dehydration. Death did

not occur too soon for complications, because the majority survived for over two weeks.

The clinical records in our Groups 2, 3, and 4, where pus was found in the mastoid after death, do not reveal that diarrhoea and vomiting were a feature of the illness, as might be expected if the association of mastoiditis and diarrhoea were that of cause and effect. Indeed, while the "parenteral" infection is well recognized as often being associated with vomiting and diarrhoea in infants, "gastro-enteritis" is not a common associate with, say, a pneumococcal empyema or a staphylococcal osteomyelitis, even when undrained. Why should the same infection in the mastoid cause such profound results?

The shorter, wider, and more patent Eustachian tube is often evoked to explain how milk-infected mucus, etc., can find its way to the middle ear. It seems to us that the reverse holds—namely, that "pent-up" pus is less likely to be present in the middle ear of infants than in older patients, because some drainage can take place through the tube into the pharynx. In fact, this is possibly one of the reasons why classical drum signs are often absent in infants with acute otitis media.

Infants have fairly well developed antral, ethmoid, and sphenoidal sinuses. While clinically recognizable "sinusitis" is not common in infants, it would seem logical to suspect these also as being the seat of "pent-up" infection. Ebbs (1937) has shown that pus can be found in one or more sinuses at necropsy in a by no means negligible number of patients. In the age group he investigated the findings were positive in 30.6% of 496 cases examined. We agree with Findlay (1932) that the climax of the "focal sepsis" theory was surely reached when Odeneal (1928) stated that the nasal accessory sinuses are infected in 50% of cases of gastro-enteritis, and that if myringotomy and mastoidectomy do not cause improvement in the infant's condition the sinuses should be opened and drained!

The diversity of organisms found in our cases and in other investigations makes it difficult to believe that such a constant syndrome as infantile diarrhoea and vomiting can be the result of such infection. Finally, the highly infectious nature and the mode of spread of gastro-enteritis in infants' wards in hospital form, we think, one of the strongest points against latent mastoid infection being the key to the aetiology of this condition.

Summary

In a series of 120 necropsies in infants and young children pus was found in the mastoid cavities of 71.

Though the highest incidence was in patients with a clinical history of "diarrhoea and vomiting," it was found almost as often in a wide variety of conditions.

Clinical, post-mortem, and bacteriological findings suggest that so-called "latent mastoiditis" is not an aetiological factor in the diarrhoea-and-vomiting symptom-complex.

The Club for Research on Ageing has received from Lord Nuffield a donation of £3,000, which will enable Dr. V. Korenchevsky to continue his gerontological investigations for a period of three years. Clinical trials of the effects of vitamins on aged persons at the Tooting Bee Hospital will be finished at the end of this year. These were rendered possible during the last two years by substantial grants from Lord Nuffield and the Nuffield Foundation. The Club expresses its heartfelt thanks for these benefactions, and is also very much indebted to the London County Council for most valuable co-operation.

SECONDARY ABDOMINAL PREGNANCY

BY

FRANCIS E. STOCK, M.B., F.R.C.S.

Medical Officer, Colonial Medical Service, Nigeria

Secondary abdominal pregnancy is a well-recognized but uncommon complication of pregnancy, and numerous cases have been described in the past. The case here recorded is of interest in view of the complications which had arisen by the time the patient was brought for treatment.

Case Report

On April 22, 1944, a Kanuri woman aged about 30 was brought to the African Hospital, Maiduguri. She complained of twelve months' amenorrhoea, increasing abdominal swelling for the same period of time, and for the last month a purulent discharge from the umbilicus. She did not complain of pain, but on questioning stated that she had suffered from an attack of abdominal pain three months previously, at the approximate time when her pregnancy should have terminated. She did not admit to having had any pain at an earlier period of the pregnancy. On examination the woman was seen to be extremely ill and considerably dehydrated. Her temperature was 99° F. and pulse rate 120 a minute. There was a swelling in the abdomen which appeared to be a pregnant uterus up to the level of 3 in. below the ensiform cartilage. There was a purulent discharge from the umbilicus, from which a portion of a foetal foot was protruding. Traction on this produced the whole foot as far as the ankle-joint. The skin of the foot was somewhat macerated. Over the whole of the left side of the abdomen were well-marked gas crepitations, which extended to well beyond the niple line. There was a copious and offensive vaginal discharge.

The woman was taken to the theatre immediately, and under light chloroform anaesthesia the small opening in the umbilicus was enlarged upwards and downwards for about 2½ in. each way. This revealed a large cavity full of pus and lined with thick granulation tissue. A macerated foetus was extracted and the cavity washed out with saline, hydrogen peroxide, and finally eusol. There was no umbilical cord attached to the foetus or to any part of the gestation sac, and the foetal umbilicus was closed. The gestation sac was not within the uterus, and there was no opening out of the sac other than that through the umbilicus, which had been enlarged at the operation. The anterior wall of the gestation sac consisted of the anterior abdominal muscles and skin only. The wound was loosely sutured by silk-worm-gut stitches through all the layers, and a large drainage-tube was left in the cavity.

The patient was returned to bed and given anti-shock treatment. Rectal saline was administered several times in the first 24 hours and was retained well. To counteract the general infection and the gas infection of the abdominal wall 20 c.cm. of 10% soluseptasine was given immediately and 10 g. of sulphamamide daily by mouth for the first two days. Antitetanus serum, 3,000 units, was given on admission, but no anti-gas-gangrene serum was available. The sulphamamide was reduced to 5 g. daily on the third and fourth days and then to 4 g. daily for the further four days. The cavity was washed out at first thrice daily with hydrogen peroxide followed by eusol, and the vagina was douched twice daily with weak potassium permanganate. Recovery was far more satisfactory than could reasonably have been expected. The toxæmia diminished rapidly and the gas crepitations had disappeared within 48 hours. The tube was removed on the fifth day and the stitches on the eighth. By this time the wound was being syringed out once daily and the discharge had decreased considerably. The vaginal discharge had almost ceased. During this week routine examinations of the blood and faeces resulted as follows. Blood: no malaria parasites seen; haemoglobin 40%. Faeces: ova of *Ancylostoma duodenale* and live *Trichomonas intestinalis* were both present in considerable numbers. Treatment of the anaemia was instituted immediately, and at a later date the ancylostome infection was treated successfully with oil of chenopodium.

Convalescence was naturally slow, for the patient had been very debilitated. On May 1 she developed a bed-sore over the sacrum which took six weeks to heal. The abdominal wound healed slowly and a sinus persisted which required to be laid open and packed with bipp. She was discharged from hospital on June 17, by which date the abdominal wound was healed. The haemoglobin was then 65%, and there was no evidence of hookworm infection.

Discussion

Secondary abdominal pregnancy—i.e., continuation of pregnancy within the abdominal cavity following rupture of a tubal pregnancy—is described as being of two varieties—intra-peritoneal and intraligamentary, depending on whether the tube

ruptures into the peritoneal cavity or between the layers of the broad ligament. In the intraperitoneal variety the gestation sac is formed mainly by inflammatory tissue laid down on the outside of the amnion. In the intraligamentary variety, as the sac enlarges it displaces the peritoneum upwards and, if lying anteriorly, will strip the peritoneum from the anterior abdominal wall. The pregnancy may continue for a normal period of nine months, after which time a false labour occurs and the foetus dies. After the death of the foetus, if the sac remains sterile, the foetus will become inspissated and in the course of years be converted into a lithopaedion. Infection of the sac is apt to occur at any time from the bowel, uterus, or vagina. In such cases fistulae may form between the sac and one of these other structures. Infection from the bowel is probably more likely to arise in the intraperitoneal variety, for in this type the bowel is adherent to the sac wall.

In the above case the pregnancy was probably of the intraligamentary variety. Furthermore, it is probable that the infection had come from the vagina; for, although no fistulous opening was seen, it is likely that a small opening did exist. It is almost certain that at the time of the false labour some vaginal interference had been attempted by the patient's friends and relations. Any such interference would have taken place under the most septic conditions. The presence of a vaginal fistula would account for the profuse and offensive vaginal discharge, which cleared up at about the same rate as the discharge from the gestation sac.

Summary

A case of secondary abdominal pregnancy, complicated by infection of the sac and rupture through the umbilicus, is described.

A short reference is made to the types of intra-abdominal pregnancy and to the ways in which these may terminate.

The case described is classified as the intraligamentary variety, and the probable source of infection is indicated.

Medical Memoranda

Gas Gangrene after Amputation under Refrigeration Anaesthesia: A Warning

Many surgeons are adopting the freezing method to anaesthetize a limb before amputation. There is no doubt that in certain cases, notably diabetic gangrene, this has distinct advantages. The following case shows that unsuspected danger may lurk even here.

On July 23, 1944, I performed an amputation of the right leg through the middle third for spreading diabetic gangrene of the second and third toes. The patient was a man aged 75, in good general condition. The operation was performed with routine pre- and post-operative refrigeration technique, and first of all went well. Forty-eight hours afterwards, however, he became very ill, and on examination presented the clinical picture of a well-established gas-gangrene infection of the stump. The condition appeared to be beyond surgical scope, and the patient died 12 hours later in spite of the administration of large doses of anti-gas-gangrene serum. Cultures of the muscles during life showed *Cl. welchii* with typical stormy clot formation. In seeking the source of infection we had the ice examined. A bacillus showing the cultural and biochemical features of *Cl. welchii* was isolated. Subsequent examination, on different days, of two further specimens of ice, taken from the centre of a new block immediately on delivery with strict aseptic precautions, gave the same result.

Numerous amputations had previously been done at the hospital, using ice from the same source, with no untoward result. It thus seems that any surgeon proposing to use the method should first make sure the ice supplied is free from pathogenic bacteria—especially spore-bearing varieties. Most of the ordinary pyogenic bacteria probably succumb to the usual skin-cleansing on the theatre table. Ice may be contaminated from its container or during transit from the factory (although better than in Continental cities, there are still a few open ice-carts about, and still a few horses to enrich the dust of London streets); but in this case the contamination has been proved to be in the ice. The matter is being taken up by the makers and will shortly be put right, no doubt.

SURVEY OF BIOCHEMISTRY

Annual Review of Biochemistry. Vol. XIII. Editor, James Murray Luck; Associate Editor, James H. C. Smith. (Pp. 795, 31s 6d.) California Stanford University Press; London: H. K. Lewis and Co.

With 90 more pages than the previous volume (reviewed in the *Journal* on July 22, 1944) the new one again presents certain now valued and expected features, along with the pleasant air of novelty imparted by certain of the more specialized chapters. Anglo-American collaboration is, as before, in evidence: three of the chapters are by British experts, one by a Canadian, one by a Puerto Rican scientist, and the others by authors in the United States. The editors have continued their established practice of changing almost all the contributors, even for those subjects that are repeated year by year—a practice that editors of annual reports and reviews elsewhere might bear in mind. Thus D. E. Green and P. K. Stumpf take over biological oxidations and reduction from F. Lipmann; W. Z. Hassid the chemistry of carbohydrates from H. S. Isbell; H. Neurath and J. P. Greenstein the chemistry of proteins and amino acids from L. F. Hewitt, R. A. Kekwick and A. S. McFarlane; E. A. Evans jun. carbohydrate metabolism from H. J. Deuel jun.; R. H. Barnes and E. M. MacKai fat metabolism from G. O. Burr and R. H. Barnes; C. P. Bernt the metabolism of proteins and amino acids from H. Borssool and J. W. Dubnoff; J. C. Keresztesy the water-soluble vitamins from R. J. Williams; W. C. Russell the fat-soluble vitamins from K. Hickman; W. H. Sebrell nutrition from C. S. Lanford and H. C. Sherman; F. J. Richards the mineral nutrition of plants from D. I. Arnon. For a reason that close examination of both texts has failed to reveal, the chemistry of the lipids, discussed last year by S. J. Thannhauser and G. Schmidt, is this year replaced by the chemistry of the lipids from the pen of J. B. Brown. If the two terms are interchangeable, one is superfluous; if they are to be differentiated, perhaps the editorial board would decide and declare how. This year's article, it should, however, be said, is as interesting as last year's. Again, R. A. McCance and E. M. Widdowson have chosen in the present volume to write on "Mineral Metabolism," whereas in Volume XII L. A. Maynard and J. K. Loosli took the same terms of reference under "Mineral Nutrition." "The Chemistry and Metabolism of the Compounds of Phosphorus" is this year contributed by A. A. Green and S. P. Colowick, in place of last year's analogous review of sulphur compounds by J. C. Andrews.

So much for the staple foods: there are as well a number of attractive side-dishes. T. Mann and C. Lutwak-Mann on non-oxidative enzymes; H. S. Loring on nucleic acids, purines, and pyrimidines; D. Burk and R. J. Winzler on the biochemistry of malignant tissue; E. L. Tatum on the biochemistry of fungi; D. Glick on histochemistry—all these provide scientific titillation for those palates with a taste for the theoretical or laboratory side of biochemistry, as does the chapter on steroids by F. C. Koch. (Incidentally, it is good to see this term, first proposed by the British scientists R. K. Callow and F. G. Young, now generally adopted.) Others more concerned with the possibilities of therapeutic application will turn with appetite to "The Alkaloids" by R. H. F. Manske; "Synthetic Drugs—Antispasmodics" by F. F. Blicke; "The Chemistry of the Hormones" by H. Jensen; while the more botanically or agriculturally minded will find satisfaction in C. F. Huffman's and C. W. Duncan's chapter on deficiencies of farm animals, in "Chloroplast Pigments" by H. H. Strain, "Growth-regulating Substances in Plants" by J. van Overbeek, and "Photoperiodism in Plants" by K. C. Hamner.

A feature of interest about the authors of this volume is that they are drawn from all types of scientific institutions—Governmental, academic, and industrial. Naturally the academic workers predominate, even when allowance is made for the fact that the staffs at many State colleges in the United States are, strictly speaking, Governmental employees. It is, however, worthy of note that five of the experts (out of

the 34) contributing to the book are on the scientific staffs of manufacturing companies in the chemical or allied industries. Altogether, as hitherto this review strikes awe and admiration into the reader's heart, awe at the mass of data necessary to establish even the smallest fundamental advance in science, admiration for the energy and enthusiasm of editors and reviewers who provide a running record of the data, with commentary, a process as essential to the advance as the accumulation of the data themselves. This volume is indispensable, like its predecessors.

AN ADVENTUROUS LIFE

A Man who Found a Century By Dr A. Nakashian (Pp 9 12s 6d net.) London George Allen and Unwin Ltd

The country which the author of this dramatic tale found is the USA. He reached it after a most adventurous life of strenuous endeavour, imprisonment fleeing from danger, and Armenian massacres. His father was an Armenian carpenter, and at an early age the author came under the Christian influence of American missionaries. They had at that time begun to take a leading part in introducing liberal education in the Near East, especially among the Moslems. Their work among Mohammedans was difficult, death being the penalty for accepting the Christian faith. So the missionaries turned to the Armenians, who were religious by nature and had already an established Orthodox Church. The geographical position of Armenia made it a target for attacks from Persians, Mongols, Romans, Saracens, and Turks. Armenia was the highway between Europe and Asia and the battlefield on which all races had fought for twenty centuries.

Young Nakashian first graduated from an American college and hospital at Aintab, and from there went to the American University at Beyrouth. He became M.D. in 1894 and then had to go to Constantinople to take the State examinations of Turkey before the Imperial Faculty, entailing a further course of five years. His professional career from the time he started medical and surgical practice was one long series of thrills among sheiks, rich merchants, robber chiefs, and Kurdish outlaws. After being imprisoned by the Turks and escaping from the massacres of Armenians, he eventually became a doctor in the Turkish Army in the last war. Finally he left that tottering empire for the United States where he is now settled as a citizen.

The tale is exciting throughout and bears the imprint of truth, even though much of it is stranger than fiction.

ENDOMETRIOSIS

A Study of Endometriosis, Endosalpingiosis, Endocervicosis and Peritoneo-ovarian Sclerosis, and Related Studies By James Robert Goodall, M.D., C.M., D.S., F.R.C.O.G. (Pp 140 illustrated 3s.) London J. B. Lippincott Company

Twenty years ago few medical students were taught anything about endometriosis. We now know that this condition is one of the more common causes of pelvic disorders requiring major surgery. Though its clinical manifestations are varied and numerous and its pathology is far from fully understood, none the less it is being diagnosed with progressively greater accuracy. Much of this advance in knowledge is due to the work and writings of Dr Goodall, whose new book *A Study of Endometriosis* is assured of a warm welcome in all English-speaking clinics. Dr Goodall gives a comprehensive survey of endometriosis in all its forms, and describes in addition related pathological entities which he terms endosalpingiosis, endocervicosis, and peritoneo-ovarian sclerosis. At this stage of our knowledge it is inevitable that facts and theories should be closely associated, but the author has endeavoured with success to avoid unjustifiable dogma on the one hand and the confusion of facts and opinions on the other. He describes endometriosis, endosalpingiosis, and endocervicosis as invasive diseases of urogenital origin, and subdivides endometriosis into two main groups—mixed and stromatous—either of which may occur within the uterus or as an extra-uterine manifestation. An acute stromatous endometrioma is also described. This would be diagnosed as a sarcoma by most pathologists, many of whom may not be entirely convinced of the error of their ways even after reading the author's views on the cases he presents. The description of extra-uterine endometriosis is particularly good. One small point of criticism is with the

statement that in bowel endometriosis as carcinoma of the bowel there is never any uterine discharge. This is not correct, for an endometrioma of the colon may reveal its presence by periodic rectal bleeding associated with the menses.

In the next edition it is to be hoped that the author will make clearer his views on three important issues. It would appear from his description of endometrial endometriosis that he would include under this heading cases of Schroeder's disease or metropathia. The idea has some appeal, but it would be helpful if Dr Goodall would state his views on this subject more definitely. His description of endosalpingiosis recalls the work of Frankl of Vienna, on the subject of nodular salpingitis following recurrent tubal infection, usually of gonococcal origin. No reference is made to this work, and it would be helpful to know if Dr Goodall is describing the same condition, believing the aetiology to be different from that suggested by Frankl. Finally the reader is left with the impression that all blood cysts of the pelvis are of endometrial origin. King, of Melbourne, many years ago advanced impressive arguments for considering that this was not so. No reference is made to his work, and it would be interesting to know what Dr Goodall's views are on this subject.

Mention must be made of the excellence of the illustrations, which are so good that it is even a pleasure to turn the book upside down to study Plate IV. This book is sure to stimulate much further research, and the author is to be congratulated on the very high standard of his work.

Notes on Books

MAY and WORTH'S *Diseases of the Eye*, which first appeared as May's *Manual of Diseases of the Eye* in 1900, and of which the present volume is the 9th English edition, is a hardy veteran among the smaller textbooks on ophthalmology. By means of extensive revision the present editor, Mr M. L. Hine, has succeeded in incorporating the more significant modern work in a text that has obviously proved satisfactory. Inevitably there is a certain unevenness in the style, but the volume remains as acceptable as ever as an elementary guide. It is published at 16s. by Baillière, Tindall and Cox.

A second edition of *Functional Disorders of the Foot*, by FRANK D. DICKSON and REN L. DIVELEY, has now been published (J. B. Lippincott Company, 30s.). There is very little change from the former issue, one or two new surgical procedures are described—e.g., the Young operation for pes planus, and excision of the digital neuroma in metatarsalgia. There are also two new chapters relating to foot troubles in industry and the Services. The paper is of rather poorer quality than that previously used, probably a wartime measure, in consequence some of the x-ray pictures have failed to reproduce as clearly as in the first edition.

Preparations and Appliances

RETRACTOR FOR PROSTATIC POUCH

Mr CHARLES E. KINDERSLEY, F.R.C.S., surgeon to the Royal United Hospital, Bath, writes:

The retractor illustrated has been made for me by Messrs Down Bros., its purpose being to retract the trigonal area and prostatic pouch so that the pouch can be inspected after the

enucleation of the gland. The curves are adapted to those of the pelvic cavity, and I have found it extremely useful in making the final inspection of the cavity.

THE RISE IN PEPTIC ULCER

It is difficult to say anything fresh about the clinical aspects of peptic ulceration. Except for having learned the risks of alkalosis and avitaminosis we know no more about the aetiology and control than when Sippy introduced his treatment by diet and alkalis in 1915. Since that date however peptic ulcer has grown from a clinical problem to a social problem, owing to a secular change in incidence. A rise was already suggested by the large number of cases of haematemesis which came under study in the decade preceding this war. It was hardly possible to doubt the fact of this rise when the present army was recruited and large numbers of men were found to be suffering from peptic ulcer. It was officially stated in May 1942 that 17% of the total discharges for all diseases from the Army and the Royal Air Force and 13.8% from the Royal Navy were on account of digestive disorders. The majority of these men were suffering from peptic ulcers, and 90% of the ulcers had given rise to symptoms in civil life, before the man joined the Services.¹ In wartime industry men have broken down with peptic ulcer under the strain of long hours or changing shifts, and while the Services can discharge the man with a peptic ulcer the industrial medical officer cannot deal with the situation so simply. No such phenomenon was noted in the last war, either in the armed Forces or in industry, and the only explanation seemed to be a considerable increase in the incidence of peptic ulcer in the years between the two wars. Nor is the increase confined to this country, as is shown by the provision of special dietetic facilities for workers with peptic ulcer in Russian factories and the formation of special units for German troops suffering from digestive disorders.

Nevertheless, in the absence of morbidity statistics, it was still possible for sceptics to doubt the increase in peptic ulceration and compare it with the loose talk about the increase in cancer which had not been substantiated on careful investigation. An analysis of death rates from peptic ulcer in Great Britain was published this year by Tidy,² who came to the conclusion that there was little or no rise between 1912 and 1920, but a sharp rise between 1921 and 1930, the curve then flattened out and remained at the same high level. Tidy thought that the rise was almost entirely due to an increased incidence in males over 40. He found certain differences between England and Scotland, more particularly a rather belated increase in the incidence of gastric ulcer in Scotland. When these results were presented at a meeting of the Association of Physicians³ they were criticized on the ground that certifi-

cation is liable to be affected by changing fashions and improved diagnostic procedures. This type of criticism has recently been answered by Stocks,⁴ who points out that death certification is generally more accurate than certification in life, and that the statistician is interested in long-term trends which are unlikely to be gravely affected by mis-diagnoses and mis-statements. In any event it seems impossible to offer any serious criticism of the factual value of the data on perforation which have been presented by Prof. Illingworth and his colleagues in the article of which the second part appears in our present issue. This is a remarkably thorough piece of investigation which was made possible by the circumstance that the Glasgow region forms a natural catchment area from which practically all cases of perforation flow into a small group of hospitals in the city. It was aided by the high standard of surgical records in these hospitals, which will be the envy of other regions which have tried to compile morbidity statistics. It is clear that perforation of a peptic ulcer was almost unknown in Glasgow until the last decade of the nineteenth century. Since then it has increased in almost exponential fashion to attain a sudden peak in 1940-1, since when the rate has fallen. The main analysis deals with the twenty-year period 1924-43, during which the changes almost entirely concern duodenal ulcer, gastric perforation having remained stationary. The sex ratio has undergone little change, having remained at about 19 males to 1 female throughout. Apart from the rise from a total of 191 perforations in 1924 to 615 perforations in 1941, there are two observations to which we may draw attention. The first is that perforation seems to be related to fatigue, being less common after the summer holiday and the week end, and more common in the late afternoon, the second is that the fatality rate increases sharply with age.

It is difficult to believe that merely the perforation rate has increased in the Glasgow region, and not the total incidence of peptic ulceration. Nevertheless the papers of Tidy and of Illingworth and his colleagues both point to the need for statistics of the total incidence of peptic ulceration in our population and not just of the fraction which perforates or dies. This implies "filling in forms," which is unpopular with men overworked in practice, but it is the only way in which morbidity statistics can be collected. At present it would be fair to say that we do not know how the incidence of peptic ulceration is affected by climate, occupation, or income level. Such knowledge is desirable in view of the two current theories of causation. These may be defined as the psychological and the nutritional, and both ultimately attribute the blame to our so-called civilization. Donnington has described the characteristic diseases of civilization as psychoneurosis, exophthalmic goitre, hyperpiesia, and peptic ulcer. He attributes their increase to the greater emotional strain of civilized life, and the tendency for feelings to be individual rather than communal, and to be pent up rather than exteriorized. He pictures this pent-up emotion welling up, as it were, in the hypothalamus and expressing itself through the autonomic nervous system and the viscera.

¹ Hurst, A. F., *Medical Diseases of War*, 4th ed. London, 1944.² *British Medical Journal*, 1944, 1, 677.³ *Quart. J. Med.*, 1943, 36, 260.

His theory receives support from Wolf and Wolff,⁵ who have made careful observations on a man with a large aperture in the stomach. They found that prolonged emotional disturbances, and in particular internal conflict with unfulfilled desire for aggression and fighting back, were accompanied by marked and prolonged increases in gastric motility, secretion, and vascularity, with reddening and engorgement of the mucosa. It would be generally agreed that nervous tension and fatigue at any rate favour perforation and haemorrhage, and the results of Illingworth and co-workers are in harmony with this view. The importance of diet in the aetiology of peptic ulcer has been unequivocally demonstrated by McCarrison⁶ both in the field and in the experimental laboratory. Peptic ulcer is very common in the south of India; it is in fact 58 times as common as in the north. On putting groups of rats on the well-constituted diet used by the Sikhs, and on the defective diets used by the poorer classes in Madrassi and Travancore, McCarrison obtained the following results: first group (Sikh diet), nil; second group (Madrassi diet), 11%; third group (Travancore diet), 29% incidence of peptic ulcer. These are remarkable findings, and it is obviously desirable that we should have statistics which would enable us to relate the incidence of peptic ulceration to nutritional status. Many would doubt whether the correlation between peptic ulceration and general poverty of the diet in this country is as close as it appears to be in India. Many would doubt again whether fatigue, nervous tension, and unfulfilled aggression have increased to an extent commensurate with the rise in peptic ulceration.

There are of course other important aspects of peptic ulcer when it is viewed as a social problem. Both water-borne and air-borne infections have been declining as a result of improved social conditions, and developments of chemotherapy have greatly increased our control of bacterial disease. During the last few years virus diseases, like yellow fever and typhus, have yielded to new prophylactic measures, and we can probably look forward with confidence to the eventual conquest of infectious disease. The population is shrinking and ageing, and we are coming to the stage where we are getting rid of acute disease, where our patients live to be older, and where their illnesses by the very fact of age are less tractable and of longer duration. The mortality of both haemorrhage and perforation of a peptic ulcer is directly proportional to the age. Changes in type of disease and in age of population are combining with a real increase of incidence to make peptic ulcer one of the most important diseases in our country. Similar morals could be drawn from a study of rheumatism or mental disease. In planning a medical service and making our hospital provision we must make sure that we are providing for the present war against disease and not the past. There is a tendency in some quarters to speak as if "long-term sickness" could be divorced from general medicine; the lesson from peptic ulcer is that long-term sickness may well be the most important problem of the coming years.

MEPACRINE AND MALARIA

After the great researches of Ehrlich and his successors which led to the discovery of the various arsenical and other compounds used in the treatment of syphilis and sleeping sickness the progress of chemotherapy seemed to halt, and during most of the nineteen-twenties no further notable advance took place. One fresh product—pamaquin (plasmoquin)—appeared which promised new things in the treatment of malaria and was remarkably effective in the laboratory infections of canaries with *Plasmodium relictum*. When applied in human malaria it proved to have only slight curative action and to be very toxic; its discovery, although encouraging, was of little real value to clinical medicine. A much more substantial contribution to medical science was made about 1932, when from the I.G. Farbenindustrie came an account of the antimalarial action of a new substance first called "erion," then "atebrin," and now officially designated as "mepacrine" in the *British Pharmacopoeia* and as "quinacrine" in the *United States Pharmacopoeia*. Mepacrine is composed of an acridine nucleus with a long side-chain ending in a substituted amino group; it is strongly basic and acts in many ways like a yellow dye, tending to stain the skin that colour when it has been taken by mouth in large quantities. According to the original statement of the manufacturers its action against malaria was as powerful as that of quinine, and this was confirmed during the malaria epidemic of Ceylon in 1935, when mepacrine was first tried out on a large scale. From the experience gained in this epidemic and from field trials organized in Malaya and elsewhere, it became generally accepted that mepacrine was about as effective as quinine in the treatment of acute attacks of malaria. It had an advantage over quinine in that it was less apt to cause vomiting and less likely to be followed by blackwater fever; but, on the other hand, its action was rather slower, and in a small proportion of cases it might cause alarming symptoms resembling those of epilepsy or mania. It also had the disadvantage that its prolonged use tended to stain the skin yellow. In the remaining years before the war each compound had its own champions. Some persons and communities relied almost exclusively on quinine and regarded mepacrine with suspicion, but this may have been due mainly to conservatism and tradition. Other groups vaunted the great superiority of mepacrine; but these were mostly German, and their preference often seemed to be based more upon nationalist than upon medical grounds. In parts of the Tropics such as East Africa, where there were large German settlements, a yellow discoloration of the skin began to acquire the significance of a demonstration of patriotism, apparently without any qualms about the resulting non-Nordic appearance. Among more detached observers the general view prevailed that mepacrine and quinine were about equal in their merits and demerits.

With the coming of the second world war and the Japanese onslaught on Occidental possessions in the Far East and the Pacific the problem of the prevention and treatment of malaria became of the utmost importance. The broadcast of the Australian Premier is now well known in which it was stated that 80% of the Australian Forces

⁵ *Human Gastric Functions*, New York, 1943.

⁶ *Nutrition and National Health*, London, 1944.

first found in New Guinea were laid low with malaria, and the importance of disease (50% malaria) in causing far more casualties than the enemy had done was similarly disclosed in Mr. Churchill's description of the recent campaign in Burma. But while the dangers of malaria had grown, the supply of antimalarial drugs had diminished. The world's supply of quinine came almost entirely from Java, owing to the workings of a monopoly, which, for reasons the ordinary person could not understand, was never challenged by the development of alternative sources. And with the capture of Java by the Japanese the supply of quinine was reduced at one stroke to almost negligible amounts. In these circumstances the Allied nations turned, somewhat unwillingly, to mepacrine, and immense efforts were made on the one hand to expand its manufacture and on the other to explore its full capabilities and limitations. The whole story of this aspect of military medicine cannot be told until hostilities have ceased but some of the important conclusions reached are shown in the resolutions which have been adopted by the American and British official bodies for the promotion of research on malaria and its treatment: these are recorded elsewhere in this issue. Both bodies have come to the same conclusion that mepacrine, far from being an inferior substitute for quinine, is in some ways more effective. So far as vivax malaria is concerned the two compounds are about equal in either preventing or treating acute attacks, but neither compound can stop the appearance of relapses after administration of the drug has been discontinued. When employed against falciparum malaria, however, mepacrine if properly used, will completely suppress or cure the infection, the action of quinine in this respect is less certain. With correct administration the toxic effects of mepacrine are not so much greater than those of quinine as to hinder its use. Both American and British bodies therefore declare that, even if quinine were available, its distribution to the armed Forces instead of mepacrine would not be advantageous and might possibly be disadvantageous. Apparently one of the debts we shall owe to dire military necessity will be this realization of the superiority of the synthetic antimalarial over the naturally occurring alkaloid.

The gratification felt at the satisfactory way in which we have met the catastrophic loss of quinine from Java is somewhat marred by the humiliating thought that the solution of the problem lay in taking advantage of German enterprise and persistence. Although the work of Ehrlich showed the great possibilities of chemotherapy, this new branch of science long continued to lack effective support in this country. The war has given the British pharmaceutical industry a big opportunity to embark upon long term projects of research and development. There is no shortage in this country of brilliant workers with a high capacity for original thought, and the material resources are not lacking to give them the support and security they need to bring their thought to fruition. What we want to see is the harnessing of all the energies, mental and material, that will help this country to keep the lead in chemotherapy that penicillin had given it. If we criticize the pharmaceutical industry for its lack of imagination in the past we must also criticize the State for its cheese-paring attitude towards the State-supported Medical Research

Council, which receives from the Treasury an annual grant of £220,000. Unfortunately in a commercial community the State finds it more tempting to subsidize business than to subsidize brains, in the foolish belief that the prosperity of a country depends more upon the former than the latter. If this suicidal policy is continued in the post-war world then we shall find ourselves outstripped by those countries which have a larger vision.

SULPHONAMIDES AND AGRANULOCYTOSIS

Agranulocytosis is among the rarer complications of sulphonamide therapy, but the risk of such a serious sequel has prompted the general advice to check the white cell count at regular intervals in any patient on sulphonamides for more than one week. It is commonly held that the danger of agranulocytosis is proportional to the total dosage of drug given but the complication has occurred after total dosage of 18 g and an average daily dose of 2.3 g in a collected series of 20 cases.¹ On the other hand, many patients have been given amounts up to 100 g or more without any untoward effect. More important than large dosage is the duration of treatment. Agranulocytosis has rarely been reported in patients who have had less than nine days' treatment, and this observation, together with the relatively small dosage that may induce the phenomenon, suggests that agranulocytosis is an allergic rather than a toxic manifestation of sulphonamide therapy. It would thus take its place among other allergic reactions to the sulphonamides—e.g., drug rash, drug fever, and perhaps renal complications. The best treatment for agranulocytosis is still a matter for controversy, and it is often difficult to say if any particular treatment—fresh-blood transfusions, pentnucleotide, liver extract—has contributed to the patient's recovery. Sternal puncture may be a useful prognostic guide, if many immature granulocytes are found in the bone marrow when none is present in the peripheral blood the chances of spontaneous recovery are good.

A new attack on the problem is suggested by the experience of Nixon, Eckert, and Holmes.² Believing that a patient with agranulocytosis may succumb to secondary bacterial infection because of the absence of phagocytes, they recommenced sulphonamide therapy in three patients—one with scarlet fever and two with primary atypical pneumonia—who had developed agranulocytosis after a primary course of sulphadiazine lasting for two weeks or more. Granulocytes disappeared from the peripheral blood between the 15th and 20th days after treatment was begun, and was accompanied by secondary fever and the typical ulcerative throat lesions. After an interval of a few days sulphadiazine was started again in amounts sufficient to give blood levels of 5–10 mg per 100 c.c.m. (In one case it was at first given intravenously, and the blood concentration of the drug rose to 20–25 mg per 100 c.c.m.) Within 5 to 10 days granulocytes began to reappear in the blood, pyrexia disappeared, and all three patients made good recoveries. Although other ancillary treatments were used, the authors believe that the second course of sulphadiazine was responsible for the ultimate cure by preventing an overwhelming secondary infection. While this may be true, it is also possible that the second course helped to desensitize the patient to the sulphonamide, for it is now becoming accepted that continuance with sulphonamides may desensitize the patient to specific allergic reactions such as drug rash and drug fever. Another point not appre-

ciated enough is that granulocytopenia resulting from severe bacterial infection is not in itself a contraindication to sulphonamide therapy. Treatment in such cases is often followed by a marked rise in the granulocytes as the infection is brought under control.

HEALTH SERVICES IN NORTHERN IRELAND

The Northern Ireland Minister of Health and Local Government has appointed the following to be a Health Advisory Committee for Northern Ireland: Mr. William Allen, Mr. Leslie Arndell, M.Sc., Mr. William J. Bailie, Miss M. A. Beaton, Dr. B. R. Clarke, Alderman Thomas L. Cole, Lieut.-Col. John M. Foreman, L.D.S., Lieut.-Col. A. R. G. Gordon, M.P., Councillor James Hamilton, Dr. J. Stuart Hawnt, Dr. J. M. Hunter, Dr. George G. Lyttle, Miss Dorothy Melville, Dr. F. P. Montgomery, Councillor Patrick Murphy, Dr. J. H. McBurney, Mr. H. I. McClure, F.R.C.S., F.R.C.O.G., Mr. Howard Stevenson, F.R.C.S., M.P., Prof. W. J. Wilson, M.D., Mr. C. J. A. Woodside, F.R.C.S. The Council, of which Mr. Howard Stevenson has been appointed chairman, is to advise the Minister of Health upon the general administration of the health and medical services. Mr. John A. Oliver, of the Ministry of Health and Local Government, will act as secretary. The members of the Council have been appointed in their personal capacity to advise the Minister on the strength of their knowledge and experience. Mr. Howard Stevenson is one of the representatives of Queen's University of Belfast in the Ulster House of Commons. He was chairman of the Select Committee on Health Services which reported this year.

FOOD YEAST

Food yeast, which has recently attracted the attention of the biochemist and nutritionist, has now interested the Colonial Office, who have formed a company, Colonial Food Yeast, Ltd., to grow it on a commercial scale in Jamaica. The object of growing the food yeast is threefold: to provide a cheap source of protein and vitamins for the native populations in the Colonies, to find new uses for sugar and molasses, and to help the sugar industry in Jamaica. The low level of nutrition in the natives of many of our Colonies has long been a scandal, and it is good news to hear that the conscience of the Colonial Office has at last been quickened. The nutritional, research, and commercial aspects of food yeast are set out in a booklet.¹ Food yeast is the dried yeast *Torulopsis utilis*, which for nutritional purposes is preferred to ordinary bakers' or brewers' yeast (*Saccharomyces cerevisiae*) owing to the ease and economy of manufacture and its superior flavour and palatability. It contains a considerable quantity of high-class protein and vitamins of the B complex, of which it is one of the richest sources: 100 grammes or 3½ oz. provide 43 grammes of protein, 2 mg. of vitamin B₁, 5 mg. of riboflavin, and 40 to 45 mg. of nicotinic acid—more than the daily optimum intake of these three vitamins. Its vitamin B₁ content is much less than that of brewers' yeast, which contains 16 mg. per 100 grammes. This is balanced by its high riboflavin content. Food yeast contains the essential amino acids in kind and proportions similar to those found in a good mixed diet. It contains in particular a large amount of lysine, which is deficient in a diet made up chiefly of cereals. Being much cheaper than animal protein—the cost ex factory is hoped to be 6d. a lb—it offers an excellent means of improving the dietary of populations existing on impoverished diets. Actually

the idea of fortifying food with yeast is not new. The Germans used it in 1914–18 as a source of protein for human consumption, and it is believed that they have been making thousands of tons of it annually in this war.

The source of the carbohydrate for the nutrition of the yeast will be molasses, sugar juice, or raw cane sugar from Jamaica, where the factory for the production of the yeast will be erected. It is hoped that it will thus provide an outlet for the by-products of the Jamaican sugar industry: an output of 12 tons of dried yeast a day is aimed at. Food trials on the nutritive value of food yeast have been made. The proteins appear to be as good biologically as those in milk. In one test a group of school-children receiving a third of an ounce of food yeast a day with school milk showed a greater increase in weight than those of a control group receiving milk but no yeast. Food yeast has distinct possibilities in the field of nutrition at home as well as in the Colonies. Its introduction into soups, stews, gravies, etc., not only would improve their flavour but would considerably enhance their nutritive value. It can also be introduced into bread and would afford a better and cheaper method of "fortifying" white bread than the addition of synthetic vitamins. If food yeast is a success in Jamaica we may hear more of it at home.

THE HEALTH OF MANCHESTER

A feature of the report on the health of the city of Manchester for 1943 by the M.O.H., Dr. C. Metcalfe Brown, is a table of the vital statistics for Manchester since 1911. During these thirty-two years the birth rate has declined from 26 per thousand of population to 18.66, which is higher than for any year since 1926; the infant death rate has fallen from 156 per thousand births to 61, which is the lowest figure on record. There have been conspicuous falls in the death rate from all forms of tuberculosis (indeed, the rate has been halved since 1911), typhoid and paratyphoid fevers, scarlet fever, and all the common infectious diseases, while the death rate from bronchitis and influenza has gone up; that for cancer has doubled, and that for heart disease almost trebled. In tuberculosis the first years of the present war showed a progressive increase to 1.32 deaths per thousand of population in 1941, but the trend has been reversed in more recent years, and in 1943 was 1.07. There was a marked rise in tuberculosis also during the last war. The effect of the great influenza outbreak in 1918 is brought out in this table. The death rate for influenza, which had been about 0.16 per thousand population, rose in 1918 to 3.07, and returned to normal figures two years later.

The report also contains a statement on health centres, and this has been approved in principle by the city council. The city architect and the M.O.H. have planned a typical main health centre. The term must not be taken as meaning the kind of health centre which has figured in recent discussions as a centre for group practice; what is meant here is a centre where the various public health clinics, the maternity and school medical services, the health visiting, and so forth can be administered, though it is felt that if the group-practice centres are eventually set up they should be linked with these public health centres so as to ensure efficiency with economy. Manchester is regarded as conveniently divisible into fifteen units, each containing roughly 50,000 persons, and each having one main health centre and four subsidiary ones. The main health centres are first to be constructed, and the construction of the subsidiary health centres will depend upon the policy ultimately to be adopted for a comprehensive health service. From the drawings which accompany the report the centres appear to be spacious and conveniently planned.

THE PORTRAITS OF WILLIAM HARVEY

In 1913 the Oxford University Press published for the Historical Section of the Royal Society of Medicine a study of the portraits of Dr. William Harvey. The preface and the notes which accompanied the reproductions of the portraits were written by the late Sir D'Arcy Power, who believed his compilation proved "that the undoubted and contemporary portraits of Harvey are more numerous than was expected."

It seems that Sir D'Arcy Power must have approached his task with a somewhat uncritical spirit, for against his statement may be set the opinion expressed to me in 1937 by the present Director of the National Portrait Gallery, Mr. H. M. Wake, that there was only one well-authenticated portrait of Harvey in existence. Long experience of the problems of portraiture could not fail to engender an attitude of scepticism, but Mr. Wake's view may be unduly cautious. Nevertheless, it establishes a firm starting-point for the study of the numerous other claimants to the honour of representing the features of the great Dr. Harvey.

The portrait in question is the three-quarter-length seated figure, kept, until 1839, in the Large Library at the Royal College of Physicians. This is stated to have been one of three pictures saved from the old premises of the College at the Great Court of 1666, and if this be true it has an incontestable pedigree. Starting with the premiss that this portrait is the best-authenticated picture of Harvey's features to which all other supposed representations must be referred, it is easy to eliminate some of the pictures included in the compilation of 1913, which reproduces sixteen paintings, one engraving, and the bust in Hemstead Church. Of the paintings, two are obvious recent forgeries—namely, that hung in the Secretary's Room at the College of Physicians, and the one possessed in 1913 by Sir D'Arcy Power himself. I believe it is true to say that this fact was afterwards recognized by Sir D'Arcy. Of the remaining fourteen, five are early portraits of other persons at present unknown—namely, one in 1913 at University College, London, at Rolls Park, at University College, Cambridge, at the Erich Galleries, and in the

possession of Mr. J. P. Cobbold of Ipswich (a copy of this is at Caius College, Cambridge). This process of elimination leaves nine of Sir D'Arcy Power's list to be seriously considered. One of these, now hanging in the Bodleian Library, Oxford, is clearly derived from the R.C.P. portrait, though it was probably made long after Harvey's death. Three others—namely, those at Merton College, Oxford, in the dining room of the Royal College of Physicians, and at the Aberdeen Medico-Chirurgical Society—appear to belong to a different series of portraits which can now be partly elucidated. In 1936 Dr. Walter Radcliffe, of Wivenhoe, Essex, drew my attention to a portrait apparently representing Harvey which had been in the collection of Dr. Mead in the eighteenth century and now belonged to Sir Arthur Wilmot, Bart., of Alresford Grange.

The owner allowed the picture to be deposited at St. Bartholomew's Hospital for investigation, and it is still in the keeping of the Treasurer and Almoners. I soon afterwards learned that there was a related portrait in the Hunterian Collection at Glasgow. This picture, also unknown to Sir D'Arcy Power, represents a doctor with a striking resemblance to Harvey seated in a chair in more or less the same attitude as in the R.C.P. portrait. His right hand, however, rests on an open book, one page of which has drawings of two skulls, and beyond him is a landscape containing many buildings, the two most conspicuous of which can be identified as probably the dome of the old College of Physicians and Trajan's Column.

William Harvey, from the etching attributed to Hollar

Whether the Alresford Grange portrait was copied from this or vice versa it is difficult to determine, but comparison of both with the R.C.P. picture shows among various differences one which could scarcely have occurred if either of them were copied from it or taken from the life. In the R.C.P. portrait the forehead is high and rather narrow. In the Glasgow and Alresford Grange pictures it is wide and rather low. The associated book, or MS., with the skulls, and Trajan's Column seem to have no particular relevance to Harvey, and in Mr. Hake's opinion both pictures represent another, unknown, individual. If this supposition is correct, it eliminates the three last-mentioned pictures of Sir D'Arcy Power's list, as they are evidently derived from the same source.

Only four pictures remain for consideration. One of these is the very pleasing three-quarter-length standing figure in the

possession of the descendants of Dr. Richard Bright at Ditchingham, Norfolk. The face has some resemblance to that of the R.C.P. portrait, but it is not entirely convincing, and Mr. Hake is unable to accept it as undoubtedly representing Harvey. The fact that at one corner are the Harvey arms and William Harvey's *stemma* carries no weight as evidence, since these could have been added at a later date. I am inclined to think that this adverse opinion may be a little too cautious, and would like to accept this picture as a second authentic portrait of Harvey.

Two more of the list—namely, those at the Royal Society of London and at King's Weston, near Bristol—together with a third, unknown to Sir D'Arcy Power and now in the possession of Lord Cottesloe, are partly elucidated by another picture unknown to Sir D'Arcy Power, which has been at the Kent and Canterbury Hospital since 1807. This represents a subject closely resembling the Harvey of the R.C.P. portrait, but more haggard and worried in aspect. The style of the painting is stated to be much later than 1650, so that it is unlikely to have been painted from Harvey during his life. More probably it is a later interpretation of the R.C.P. portrait with variations according to the taste of the copyist, and clearly it is the source of the three other paintings mentioned above.

The sole remaining problem is the picture at the National Portrait Gallery, which was also rejected by Mr. Hake when making his survey. The picture is so badly painted that it would be no great loss to have it eliminated altogether. Recently, however (*Brit. J. Surg.*, 1943, 31, 39), I have drawn attention to the fact that a little-known etching of Harvey, certainly made in the seventeenth century, and attributed, perhaps erroneously, to Hollar, can be accepted at sight as almost, if not quite, the most vivid and life-like representation of Harvey that we possess. Furthermore, the National Portrait Gallery picture is recognizable as derived from the same source, and both have a good deal in common with the Canterbury portrait. I have tentatively suggested that the National Portrait Gallery picture may be the original of the etching spoilt by later, incompetent over-painting. This theory may perhaps be one day put to the test by scientific methods.

The well-known and somewhat idealized engraving by Faithorne, used as a frontispiece in some copies of the first English edition of *De Generatione Animalium*, 1653, seems to have been taken from the R.C.P. portrait. Harvey and Faithorne were acquainted, and the likeness is probably a good one, so that the engraving may provide important evidence for the authenticity of the painting.

The bust in Hemstead Church may have been made from a death-mask, but it is difficult to get from it much idea of Harvey's appearance during life.

To summarize, therefore, it can be stated:

- 1 That there is one well-authenticated portrait at the Royal College of Physicians, from which are derived Faithorne's contemporary engraving and the later Bodleian copy.
- 2 That there are the pictures of a somewhat different personality originating in the Canterbury portrait, which may in its turn have been derived from the R.C.P. portrait.
- 3 That there is the lost or spoiled original of the admirable etching attributed to Hollar.
- 4 That, lastly, there is the Ditchingham portrait, concerning which opinion is divided.

All other reputed portraits of Harvey so far known have had to be rejected.

GEOFFREY KYNPS.

Ninety years ago in October, 1851—Florence Nightingale sailed for Scutari, and on Nov. 4, 1911, U.S. Army nursing and medical officers accompanied by British colleagues, made a pilgrimage to her grave at East Wellow, near Romsey, Hants, to pay their tribute to the pioneer of military nursing. The United States have some special links with Florence Nightingale: her advice was asked and given during the American Civil War, and she inspired Longfellow's poem "Santa Filomena." U.S. Army authorities, in co-operation with the British Council, arranged for representatives of the nursing and medical staffs of U.S. hospitals in a wide area of Southern England to attend the ceremony. After short addresses at the graveside and the tying of a wreath, the gathering visited Embley Park, Miss Nightingale's home, and saw mementoes of her career, and then took tea with the Mayor at Romsey Town Hall.

INDUSTRIAL MEDICINE AND HEALTH

NUFFIELD FOUNDATION GRANTS TO UNIVERSITIES

One of the primary objects of the Nuffield Foundation is the advancement of health, particularly by the furtherance of teaching and research. In pursuance of this aim the Trustees have offered the Universities of Durham, Glasgow, and Manchester grants totalling £150,000 to assist them to carry out schemes which they have submitted for the development, as soon as suitable staffs can be appointed, of teaching and research in industrial health. These grants will be spread over a period of ten years. Manchester, where it is proposed to create a Chair of Industrial Health, will receive £70,000. Durham has been offered £40,000 for the establishment of a department under a University Reader. A similar amount is being allocated to Glasgow for a subdepartment of Industrial Health within the existing department of Social Medicine. The Minister of Labour and National Service (Mr. Ernest Bevin) has assured Sir William Goodenough (chairman of the Trustees) of his warm approval of the proposal, which he regards as an important contribution to further progress in industrial health.

The maintenance of a healthy industrial population involves the provision of greater facilities for education and research in problems of industrial health. Great Britain has no university department devoted to educational work in industrial health and no facilities for postgraduate training in industrial medicine. In January, 1943, the Select Committee of the House of Commons on National Expenditure on the Health and Welfare of Women Workers drew attention to this lack, stating: "Doctors who are new to industrial work have to learn slowly and painfully by experience many lessons that should and could be taught in courses of preliminary training if such were available." The three university departments which are to be formed should go a long way towards remedying this state of affairs by the direct promotion of teaching and research in industrial health, and should also prove of indirect assistance to the work of the Medical Research Council by creating further opportunities for the carrying out of medical research into specific problems connected with industrial medicine and health.

For the new departments to achieve their objective they will have to maintain close links within their universities with the science and engineering departments as well as with the organization for the teaching of social medicine, because the problems of industrial health are not limited to the field of medicine but relate also to engineering, chemical, and other sciences, and require for their solution the co-operation of both medical and non-medical people in various ways. The staffs of the departments will also have to work in the closest co-operation with such bodies and persons outside the universities as the Factory Department of the Ministry of Labour, the Industrial Health Research Board, local industries, employers, and trade union officials.

EMPIRE CANCER CAMPAIGN

At a recent meeting the British Empire Cancer Campaign allocated a sum of £39,000 for the continuation of cancer research during the year 1945. This sum compares with grants totalling nearly £36,000 for the present year.

The principal grants are as follows: £10,613 to the Royal Cancer Hospital (Free), including the Chester Beatty Research Institute; £8,000 to the Middlesex Hospital; £3,500 to St. Bartholomew's Hospital; £1,800 to the London Hospital; £2,743 to Mount Vernon Hospital and the Radium Institute; £850 to St. Mark's Hospital, City Road; £1,100 to the Marie Curie Hospital; £120 to the Bristol University Cancer Research Committee; £2,300 to the Cambridge University Cancer Research Centre; £1,740 to the Oxford University Cancer Research Centre; £1,125 to Westminster Hospital; and £5,165 for the expenses of cancer research at the Glasgow Royal Cancer Hospital, Glasgow University, Institute of Animal Genetics of the University of Edinburgh, University College, Nottingham, and St. Thomas's Hospital.

The present allocation for 1945 brings the total amount voted by the Campaign at headquarters during the war to approximately £207,000, and this does not include independent expenditure on cancer research by the autonomous branches of the British Empire Cancer Campaign in Birmingham, Yorkshire, Lancashire, Cheshire, North Wales, Northumberland, Cumberland, and Durham.

D. M. Gibson (*Tubercle*, 1944, 25, 35) records his observations on 283 cases of bone tuberculosis among women and children in Manchuria. The disease showed a predilection for the bones of the hands and feet, the long bones, the spine, and ribs in the order named. Single lesions preponderated, but multiple lesions were frequent. The diffuse spreading type of osteitis was by far the commonest. The great majority of cases occurred in the first three decades of life, with a preponderance in the second and third decades. Conservative treatment was disappointing, but the results of early and radical treatment of the focus were encouraging.

RADIOGRAPHY

of the urinary tract, veins, arteries, joints, and fistulae.

'Pyelosil' the Glaxo brand of Diodone injection is a pyelographic medium

giving dense and contrasting shadows. It has the advantage that, while the intravenous route is commonly used, it can where necessary be given intramuscularly. 'Pyelosil' is also used in the radiography of veins, arteries, joints and fistulae. Thrombosis and pain do not occur after intravenous injection and accidental perivenous extravasation is free from danger.

PYELECTAN Brand of Diodone is used for radiography of the urinary tract. It is a 3 cc ampoule.

PHENIODOL Brand of Diodone is used for radiography of the joints. It is a 3 cc ampoule.

PRODUCT OF THE
GLAXO LABORATORIES

PYELOSIL

BRAND OF DIODONE INJECTION

3 cc ampoules and 20 cc ampoules in boxes of 1 and 5

NEW 'EXAMEN' The concentration of activity of the new 'Examen' is increased per cc. to 3 or 4 times that of the original 'Examen' without loss of purity. This makes possible a new small standard dose of only 1 cc. and a considerable reduction in cost of treatment. Particulars on request.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX BYRON 3434

Cardophylin

A SPECIALLY PREPARED COMPOUND OF
THEOPHYLLINE ETHYLENEDIAMINE

3

MAIN INDICATIONS FOR ITS EXHIBITION

1 DISEASES OF THE CARDIOVASCULAR SYSTEM:

Angina Pectoris gives rapid relief from attacks and reduces their frequency.
Coronary Thrombosis promotes anastomosis and collateral circulation.
Congestive Heart Failure augments the blood supply and increases oxygenation of the myocardium.

In Tablets, Ampoules and Suppositories.

2 ASTHMA:

relieves, frequently with dramatic effect, attacks of Paroxysmal Nocturnal Dyspnoea,
Cardiac Asthma,
Bronchial Asthma,
Cheyne-Stokes Respiration.

3 OEDEMA:

Cardophylin is a powerful, yet harmless, diuretic with a smooth and efficient action. It has no irritant effect on the kidneys and is particularly useful in post-operative anuria.

Literature, with extracts from numerous clinical reports, and samples, sent on request.

WHIFFEN & SONS, LTD. • CARNWATH RD. • FULHAM • LONDON • S.W.6

ANAHÆMIN B.D.H.

According to the theory of Castle the hæmopoietic principle of liver results from the interaction of the extrinsic and the intrinsic factors; thus it follows that the liver principle must be effective in the treatment of all macrocytic anæmias whether they result from an intrinsic or an extrinsic factor deficiency. Confirmation of this is provided by clinical evidence that anahæmin, the liver principle in a highly-purified form, is effective not only in pernicious anæmia but also in nutritional macrocytic anæmia resulting from a deficiency of the extrinsic factor.

Further confirmatory evidence of this is contained in a recent paper (Ind. Med. Gaz., June 1944, p. 253) reporting a number of cases of nutritional macrocytic anæmia in which Anahæmin B.D.H. produced '*uniformly gratifying*' and '*remarkably quick*' results.

Thus the theoretical and scientific explanation of the outstanding efficacy of Anahæmin B.D.H. in pernicious and other macrocytic anæmias continues to be confirmed by clinical evidence.

Arsenic in Malaria

SIR—In his letter in the *Journal* on Oct. 28 Capt Good raises a question of considerable importance. He mentions his experience of the use of arsenic in cases of relapsed malaria (*Plasmodium vivax*). A single intravenous injection of neokharsivan (0.45 g) was invariably effective in terminating the attacks and no relapses occurred. He suggests that arsenical treatment might be tried in cases of malarial relapse acquired, which do not respond to quinine etc.

Some evidence of the effects of arsenicals in such cases of malaria was obtained during the last war. A long series of studies in the treatment of malaria was published, commencing in 1917, by a team of workers in this school. The cases we treated were suffering from long-standing infections which had relapsed frequently in spite of much treatment with quinine. In making our tests with any drugs we provided for an observation period of sixty days with daily examination of the blood, after the end of the treatment this period was not usually completed because most of the cases meantime relapsed. Among the drugs which we employed was arsenic—for example, novarsenobillon alone, liquor arsenicalis alone, and liquor arsenicalis in combination with strychnine or with quinine.

The novarsenobillon dosage employed intravenously was from 0.45 to 0.9 g. The immediate action of novarsenobillon on *Plasmodium vivax* was strikingly good. In this infection the drug was found to be even more rapid in its effect on the parasites than quinine: a single injection of 0.9 g caused the disappearance from the cutaneous blood of all stages of the parasites, usually in about twenty-four hours. The ultimate results, however, were most disappointing. Twenty cases of *P. vivax* were given a single injection of 0.45 g., of these 18 relapsed. Twenty-three cases were given a single injection of 0.6 g., of these 22 relapsed. Twenty-one cases were given a single injection of 0.9 g. of these 19 relapsed. It was noted, however, that a combination of novarsenobillon and quinine was more effective than either novarsenobillon or quinine alone. In *P. falciparum* infections novarsenobillon in the same dosage produced no good effects. Fourteen cases of *P. falciparum* malaria were given single injections of from 0.45 to 0.9 g., the parasites and temperature were practically unaffected. A similar result was obtained in the small number of quartan cases available for treatment. Two patients with *P. malariae* infection were each given 0.9 g. intravenously on two occasions with a week's interval between the doses, there was no evident effect on either the parasites or the temperature.

This evidence, so far as it goes, is against the probability of organic arsenic alone, in the form of neokharsivan, proving curative of natural malaria infections which have relapsed after quinine treatment. On the other hand, the use of inorganic arsenic in the form of liquor arsenicalis combined with treatment by quinine gave a very interesting result, as shown in one of our series. The object of this series of observations was to determine whether or not (the disappearance of parasites from the cutaneous blood and the control of symptoms having been ensured by two initial intramuscular injections of quinine bihydrochloride 15 grains) the daily administration of liquor arsenicalis minimis 30 would suffice to prevent relapses (parasitic and febrile). The arsenic was given according to the following plan: two weeks on treatment, one week off, two weeks on, one week off, two weeks on; all cases were able to tolerate this. Continuous administration of 30 minimis daily for longer periods than about two weeks had been found to produce signs and symptoms of arsenical poisoning. In all cases parasites disappeared from the cutaneous blood in from one to four days. Of 31 cases which completed the course of treatment and were then observed for sixty days, only three relapsed during this observation period. Adding and counting

as a relapse one case which became positive during the treatment period, the total failures were 4 (12.5%). In a control series of 30 cases which were treated by two intramuscular injections of 15 grains of quinine bihydrochloride without the arsenic 70% relapsed—I am, etc.,

School of Tropical Medicine, Liverpool

D B BLACKLOCK

Time of Ovulation

SIR—I beg to offer the following comments on your annotation on ovulation and fertilization (Oct. 21, p. 537). You state that "ovulation in woman usually occurs about 14 ± 1 days before the onset of the ensuing menstrual period," but you add that "its timing is probably subject to considerable variations." This latter caution should be particularly emphasized, since the generalization that ovulation usually occurs at a specified time before the onset of the next menses has led and will continue to lead, to serious errors when applied indiscriminately to individual cases. The frequency of variation in ovulation time was clearly revealed in the excellent review of the literature on this subject by Stein and Cohen (*J. Amer. med. Ass.* 1938, 110, 257). Owing to this variation, postulation that ovulation in a given case occurred 14 ± 1 days before the anticipated onset of the next menstruation is not a reliable method for estimating the age of a young human embryo. For example, Hamilton, Barnes, and Dodds (*J. Obstet. Gynaec. Brit. Emp.* 1943, 50, 241), whom you quote, estimated the age of the pre-villous human embryo described by them to be 10 to 11 days largely on the strength of this postulation. I have submitted detailed evidence elsewhere (*Trans. roy. Soc. Edin.*—in the press) for believing that this embryo is probably 12 days old. This age is consistent with the coital history, and would indicate that ovulation in this case occurred earlier than postulated by the authors.

The earliest pre-villous intra uterine human embryo so far discovered in this country is that described recently by Harding and myself (*J. Obstet. Gynaec. Brit. Emp.* 1944, 51, 225), which was estimated from its histological structure and comparison with other human and with macaque monkey embryos to be 9 to 10 days old. This age, taken in conjunction with the precise menstrual and coital history, provides positive evidence that ovulation in this case occurred on the 9th or 10th day of the cycle, and the patient, an intelligent woman, was insistent that her previous periods for as far back as she could remember occurred every 4 weeks ("every fourth Sunday")—a statement which was accepted with the full knowledge of the variability in the duration of the menstrual cycle which may occur even in the same individual. The specimen and history also suggest that in this case ovulation may have been precipitated by the first copulation during the cycle (on the 10th day). If ovulation time had been postulated as suggested by your article, the embryo would have been calculated to be 5 to 7 days old—an age which is absurdly young in view of the developmental stage reached by the various embryonic elements.

The evidence which you bring to bear on this problem since your previous article (*B.M.J.*, 1938, 1, 344) comprises mainly the discovery of tubal ova, and you state that ten tubal ova have so far been described and that every one of these has confirmed the accepted view as to the time of ovulation. Presumably the ten ova to which you refer are those quoted by Hamilton and his colleagues (above ref.), including the two described by these authors themselves. I would draw your attention to the fact that five other unfertilized tubal ova have been discovered (Miller, Engel, and Reimann, *Growth*, 1938, 2, 381; Reimann and Miller, *Arch. Pathol.*, 1939, 27, 412), to which no reference is made either in your article or by Hamilton. All five of these ova indicated that ovulation occurred 15 to 17 days before the onset of the next menses in these 28-day cycle cases, and, incidentally, it is interesting that one of these ova is claimed by its discoverers (Reimann and Miller) to have exhibited parthenogenetic activities after mechanical stimulation. Further, advice on a "safe period" in a given case, based on the generalization that "ovulation usually occurs etc." is likely to lead to failure in many instances, as is clearly shown in the literature revealed by Stein and Cohen (quoted above).

Finally, you mention a gap in our knowledge of human development in that "no one has yet seen a fertilized human

ovum undergoing early segmentation or during the morula and free blastocyst stages, when it is still in the tube." I would mention, however, that J. Krafka jun. (*Anat. Rec.*, 1942, 82, 426) described a tubal ovum made up of a solid mass of small cells, 200 to 300 in number, with zona pellucida intact, which he estimated to be 6 to 7 days old.

I hope, Sir, you will bring these facts, which are of both scientific and practical importance, to the attention of your readers so that they may take them into consideration alongside your annotation.—I am, etc.,

FRANCIS DAVIES.

Industrial Dermatitis

SIR,—Dr. G. P. B. Whitwell in his letter (Nov. 4, p. 607) writes that it seems to him "strange that some dermatologists, instead of collecting rare and relatively unimportant skin diseases for exhibition at learned society meetings, have not long before [sic] taken more interest in workaday medicine and gone into the factories to learn something useful." And more in the same strain. Now, although the Section of Dermatology of the Royal Society of Medicine, of which he is a member, is not specifically named by Dr. Whitwell and his shafts are possibly not aimed at it, yet as it holds more frequent meetings for the exhibition of dermatological cases than probably any other society, it must be considered to come within his "target area." As president of the Section for the time being I should like to point out that we had a discussion on industrial dermatitis on May 21, 1942, opened by Dr. Sibyl Horner and Dr. Silcock, thirteen other speakers taking part. Another discussion on diseases liable to be mistaken for industrial dermatitis took place on June 24, 1943, with Dr. H. MacCormac in the chair. This discussion was introduced by Dr. Sibyl Horner, and the present writer showed 84 photographs illustrating about 30 common skin diseases which are liable to be mistaken for industrial dermatitis. One of the referees for industrial dermatitis subsequently told him that he had seen every one of those diseases certified as industrial dermatitis not once but many times. At this meeting Dr. Swanston described the effect on the skin of T.N.T. and tetryl, etc. During the presidency of Dr. Semon three visits to factories for members of the Section were kindly arranged by Dr. Sibyl Horner and were attended by about the maximum numbers that could be accommodated. These included a screw-and-bolt factory, a shell-filling factory, and Woolwich Arsenal, in June, 1942, July, 1943, and September, 1943, respectively. During my own presidency there has been a visit to Woolwich Arsenal in October, 1943, and cases illustrating various industrial skin hazards have been shown at meetings, and discussions on them have taken place as follows:

1943 Nov. 18, "Occupational Melanoderma" (Dr. G. B. Dowling).

1944 Jan. 20, "Chlorine Acne from Chlorinated Naphthalenes" (Dr. J. E. M. Wigley).

Feb. 17, "Cheese Itch and Itchy Cargoes," a paper by Prof. J. A. Nixon discussed by seven members.

May 18, "Occupational Argyria" (Drs. Wigley and Deville).

Dermatologists in this country know that industrial dermatitis forms only a part, though admittedly an important part, of the whole field of dermatology, and it is important that they should keep their perspective and should not neglect the other equally important and much more numerous skin diseases which occur outside the industrial field.

With the very large number of hospital clinics that the educated numbers of dermatologists remaining in this country now to deal with, the time available for visits to factories is limited, especially as such expeditions always have to be arranged some weeks in advance.

Dr. Whitwell is a member of the Dermatological Section of the Royal Society of Medicine, so these facts should be known to him, but I think they ought to be set down here in case his letter should mislead others. I hope I have made it clear that at all events some dermatologists do not deserve the criticisms of Dr. Whitwell.—I am, etc.,

A. C. ROXBURGH,
President, Section of Dermatology, R.S.M.

Artificial Insemination

SIR.—Some of your correspondents have recently raised questions concerning the legal position of doctors, donors, or donees who are parties to the procedure of artificial insemination. Not all of these questions permit of direct and definitive answers, in view of the fact that the subject is relatively new to the lawyers and the issues that emerge have not been examined by the courts or discussed exhaustively in the legal press. While recognizing these difficulties, together with the need to provide guidance and assistance to medical practitioners, the council of the Medical Defence Union has devoted much time and thought to exploring the subject, and has considered the advice of its experienced solicitors. A document dealing with artificial insemination in its several aspects has been prepared and is available for members of the Union who communicate with the secretary requesting a copy.

It must be patent to most of your readers, however, that there are serious hazards lying about the path of any practitioner who undertakes to make available to a patient the procedure of artificial insemination. These hazards may be diminished to some extent by the adoption of certain legal precautions directed towards the protection of the professional interests of the practitioner involved, the observance of professional confidence, and the elimination, so far as is practicable, of prospective litigation.—I am, etc.,

ROBERT FORBES,
Secretary, Medical Defence Union.

The Hazard of Anaesthesia

SIR,—I am glad to see that someone with the long experience of Dr. G. Dunderdale in his letter (Oct. 28, p. 578) supports mine of May 6. Both he and I plead for open ether, a good airway, simple armamentarium, and a complete disregard of an impatient surgeon.

I quite agree with his letter, in which he says that only experience can make a good anaesthetist. The present market price of a good resident anaesthetist seems to be about £350 a year: not much attraction for a man of experience! In some hospitals newly qualified men are expected to deal with any emergency; in one I know a man who has never given any anaesthetics has been appointed. In some hospitals the patients are aged and infirm, and if surgical treatment be needed great care is essential when one is dealing with a worn-out heart and chest.

I quite agree with Dr. Dunderdale that tonsil and adenoid operations present great difficulties. In the first place we have to face respiratory obstruction owing to the adenoids, and, secondly, anaesthesia must be induced quickly to avoid nervous shock. After rapid induction, deep anaesthesia must be maintained for a few minutes to enable the surgeon to complete his work.

Whatever agent is used the patient must leave the table with his cough reflexes back, otherwise there is a danger of respiration pneumonia. I get over this problem by using two masks, one soaked in ethyl chloride, the other in ether. The child is under in about two breaths, and deep anaesthesia can be obtained by the ether in a few minutes with the aid of Gamgee tissue over the ether mask. The pupils should be carefully watched, and when two-thirds dilated the child can be left to the surgeon. If one is experienced the child should leave the table coughing. All these and other tricks can be learned only by experience.

Better salaries and full-time experienced anaesthetists is the only answer to this problem.—I am, etc.,

Birkenhead Municipal Hospital, Cheshire.

JOHN H. HANNAN.

Drugs and the Doctor

SIR,—The letter from the National Pharmaceutical Union under the above title in your issue of Nov. 4 suggests to the casual reader that when the *Pharmacy and Medicines Act*, 1941, was in Parliament the Union was fighting a lone battle against the manufacturers of proprietary medicines, who were supported by the Pharmaceutical Society and defended by the Minister of Health. It further suggests that the Society's opposition to control of proprietary medicines was withdrawn

because it wanted to see certain other sections of the Act become law. Had the late Dr. G. C. Anderson been still with us he would have been able to testify to the laborious work of the Society, together with the B.M.A., in a committee under the chairmanship of Sir G. Elliston, in preparing a scheme of control of proprietary medicines. The proposals of that committee went further than the provisions of the 1941 Act controlling those medicines but the draftsman lifted into the Act many sections from the draft prepared by the committee which met at the Society's house during 1935 and 1936.

In the House of Commons the National Pharmaceutical Union sought at the last moment to secure an amendment which would have confined the sale of new proprietary medicines to chemists. The Society might have desired to support them, but the Bill was an agreed measure between the Government and a number of organizations, and for this reason the Society's hands were tied. The Minister of Health may have "castigated" the Union, but he did so because, rightly or wrongly, he regarded their action as a breach of an agreement. Of the Society he said (*Hansard* July 16, 1941, col. 688): "When people talk about the National Pharmaceutical Union it might be assumed that they speak for the whole of the chemists. That is not so. There are two bodies, one of them a great professional body, the Pharmaceutical Society, who were a party to all the discussions. There has been no last-minute going back on their agreement on their part. I wish to make that clear."

I am sorry to import the ashes of old controversies into your columns, but the Pharmaceutical Society really cannot allow this imputation upon the part it played in this matter to go unchallenged, and it must invite your readers to compare what the Union now says with what the Minister had to say at the time.—I am, etc.,

The Pharmaceutical Society of Great
Britain, London W.C.1

HUGH N. LINSTED,
Secretary

Rate of Artificial Respiration in Cyanosis

SIR,—As Dr. Eve's letter (Oct. 14, p. 510) would appear on casual reading to cast discredit on my article (Sept. 16, p. 366) it is necessary for me to point out that no such views are justifiable, for his letter is not only unclear and ambiguous in vital parts but is also fallacious in its main arguments.

Dr. Eve is unwise to have presumed that I had embarked upon the precarious course of attempting to improve one small aspect of the long-established teaching of artificial respiration without having fully acquainted myself with all aspects of the subject. My whole article deals only with cases of asphyxia or cyanosis and not at all with cases without cyanosis, except to exclude them. Thus my statement "that an increased rate can do no harm in any case and must in many cases do much good" refers clearly to cases of cyanosis only and not to cases without cyanosis. An increased rate may, of course, produce acapnia in those cases whose respiratory failure is not due to cyanosis, but will not produce it in cyanosed cases (discussed later), hence this irrelevant condition "acapnia" was not mentioned in my article.

Dr. Eve states that my arguments are unanswerable "if one falls into the old error of assuming that the state of a drowned person and his needs are similar to those of a conscious subject. They are quite different." This statement is unclear and ambiguous, and in its present form means nothing definite at all. Does Dr. Eve mean a "conscious normal subject" or a "conscious cyanosed subject"? There is a vast difference between the two, and the statement cannot apply to both. If he means a conscious "normal" subject, such as the subjects of his own investigations in 1933, this assumption is indeed an old error still shared by many. I have, however, dissociated myself from this error, for the whole argument of my article is dependent upon the great difference between "cyanosed" and "normal" subjects. If, on the other hand, he means a conscious "cyanosed" subject (as would appear from the context), he has made a grave error. It is quite incorrect to speak of the subjects of my experiments as "normal subjects." These subjects reproduce almost exactly the state and needs which the drowned person has passed through before losing consciousness, and there is no error in assuming that the state of a drowned person and his needs are similar to those of a conscious

cyanosed subject and that they vary only in degree; the difference being that in the drowned subject the O_2 is fast decreased and the CO_2 correspondingly increased, so that body cells are further affected thereby, and unconsciousness and respiratory failure have resulted. In both cases respiratory exchanges are required to improve the condition and only respiratory exchanges can do so—a further proof of similarity. That Dr. Eve still adheres to the old error is shown by the statement later in his letter that "increasing the rate up to 20-22 per minute increased the ventilation but reduced the CO_2 too much." Naturally it would reduce the CO_2 too much in the "normal" subject, but it would not have done so in the "cyanosed" subject to whom the statement is now freely applied.

Writing of the subjects of my experiments Dr. Eve states: "Combustion is active . . . and CO_2 is accumulating in the blood . . . Respiration has then to be violent to make up for arrears." This increased respiration is necessary because of the cyanosis present. Continuing the quotation: "But in the cold and toneless drowned combustion is in abeyance, the consumption of O_2 is minimal, and very little CO_2 is being formed." Quite true, so far as it goes, but it is here that Dr. Eve makes another serious mistake. He claims that because little CO_2 is now being formed there is little present in the blood, and that increased respiration is no longer required. This is most certainly not the case, and the enormity of such an error is astounding. Has not this cold and toneless subject passed through all the earlier stages of cyanosis leading up to his present condition? What of his "arrears" which required increased respiration (and did not get it) before losing consciousness? Are they not still present, and have they not, in fact, been considerably further increased? Therefore is not increased respiration even more required? And if CO_2 is toxic to nerve cells in extremis (as stated in Dr. Eve's letter) is this not a further need for increased respiration? Thus Dr. Eve admits that increased respiration is required in the earlier cyanosis but claims that it is not required later in the deeper cyanosis, which is absurd.

Continuing the quotation: "Hence when cyanosis and errors of CO_2 and O_2 have been adjusted by the first few minutes of artificial respiration, overventilation may then easily wash out too much CO_2 and produce a deficiency of it in the blood (acapnia)." This short sentence covers the whole field of physiological changes which take place in the blood and body cells from deep asphyxia until "presumably" acapnia is produced. It is here that Dr. Eve has made yet another grave error, for somewhere in this gradual scale of improving blood conditions (increasing O_2 and decreasing CO_2) is the region in which the subject naturally recovers normal respiratory control and consciousness. Indeed, "when cyanosis and errors of CO_2 and O_2 have been adjusted," be it in few or many minutes, the object of artificial respiration has been achieved, and its performance is discontinued. It is obvious that this stage must be passed through sometime before overventilation could possibly go on to cause acapnia. That there is little danger of the subject being rushed through this stage of fairly normal CO_2 - O_2 blood levels into acapnia without regaining respiratory control and consciousness is amply supported by Dr. Eve's statement, on excellent authority, that ". . . in some operations apnoea is maintained by hyperpnoea for 20 or 30 minutes without apparent injury from acapnia."

There would appear to be no danger in the cyanosed subject of the increased rate washing out CO_2 in amounts disproportionate to the amount of O_2 that can be absorbed—as does happen in the normal subject—for in the cyanosed subject the O_2 level is very low and the need is very great, so that the blood would take up O_2 as readily as it would part with its CO_2 . In my experiments it is seen that eight times the normal respiratory exchanges cause no disproportion between the diminishing CO_2 and increasing O_2 ; and as no artificial means can provide more than about four times the normal exchanges there would appear to be no danger whatever in such usage for cases of asphyxia or cyanosis. Indeed "Nature's method" cannot be wrong.

Space does not permit me to comment on minor matters raised in Dr. Eve's letter; but I have, I think, clearly nullified his main criticisms. I therefore maintain that there is no practical danger of acapnia supervening as the result of my

suggested increased rate in cyanosis, and that the result of any such rate would be the earlier resuscitation of the subject.—

I am, etc.,

Manchester.

P. R. TINGLEY.

Atmospheric Conditions and Group Recurrences

SIR,—The interesting note of Dr. G. C. Pether (Nov. 4, p. 608) on three migraine patients having attacks at times of barometric instability opens up a subject dealt with in detail by W. F. Petersen clinically and biochemically (*The Patient and the Weather*, 1934, 2, 53).

Group recurrences are perhaps best seen in neuralgias, fibrositis, and arthritis in relation to moving cyclonic disturbances (S. Weir Mitchell, *Amer. J. med. Sci.*, 1877, 73, 305). But study for some years of about 30 cases of leukaemia suggests that some of those frequently recurring do so in groups, simultaneously or nearly so; also there are indications that some cancer patients recur in groups about the same times. This suggests that external cyclic influences (? atmospheric) raise and lower the patient's resistance. This resistance side of cancer has been much neglected, as was suggested lately by Dr. Thomas Lumsden (*Lancet*, 1944, July 15, p. 91), and if there are indeed group recurrences associated with meteorological factors, this might facilitate the attempts to prevent recurrences, in some cases at least (Webster, *Practitioner*, 1942, 148, 226). The subject is one worthy of further studies.—

I am, etc.,

London, W.1.

J. H. DOUGLAS WEBSTER.

Mistaken Diagnoses in Infectious Fevers

SIR,—Dr. D. F. Johnstone's article (Oct. 28, p. 555) should be very helpful. May I emphasize, even amplify, a few points from fevers hospital and G.P. experience?

1. *Diphtheria*.—Every acute throat seen early should be swabbed before the conventional and useful mist. ferri perchlor. and pot. chlorate is given. To use the antiseptic first is to burn your boats, both clinical and bacteriological. Swabs should be carried in the bag, and the swabbing should be done after all clinical examination is completed, especially in a child. The time spent is negligible, the gain immense. I have never found bacteriologists complain that I send them too many swabs. A negative swab is not necessarily final: if you are asked to repeat, stop local antiseptics for one day before.

2. *Scarlet Fever*.—The most useful clincher in all cases of doubt is a pulse rapid in proportion to temperature. Remember a fevered pulse does not accelerate much from psychic causes, even in a child. A really fast pulse, whether after childbirth or in a child with a rash, should suggest the streptococcus.

3. *Rubella*.—It is amazing how often a fit of sneezing occurs early in the onset. Small hard glands behind the ear, in a child with a clean scalp, are another clincher.

4. *Measles*.—A sick child should not be fussed about, but an examination of the throat should be made at each visit in this disease to exclude intercurrent diphtheria.

5. *Acute Pneumonia*.—The surgeons could supply the obverse of Dr. Johnstone's medallion. Abdominal pain and rigidity often usher in pneumonia, especially if it is a double. It is a worse mistake to operate than not to operate in cases of doubt, whatever the disease.—I am, etc.,

Edinburgh.

A. GUTHRIE BADENOCII.

Débridement

SIR.—If further proof were needed, your correspondence columns show that the meaning of "débridement" is not clear to English surgeons. The term first appears in French surgical literature at the time of Paré and was regularly employed by Baron Larrey in his case reports from the Napoleonic campaigns. It signified incision of the superficial and deep tissues to release tension, and is still so understood by the French. The use of "épluchage" in a surgical sense was introduced during the last war. As you say, it means to clean out, and it is descriptive of what we call "wound excision." The word does not come easily to the English tongue, and perhaps on that account has not been generally accepted here.

In view of these facts I would suggest that in the interests of precise statement and corresponding action it would be well

if the use of these foreign terms were abandoned. The procedures in question can be perfectly well described in English, and writer and reader will thereby no longer be left in doubt.—

I am, etc.,

Oxford.

C. MAX PAGE.

"Skiagram"

SIR,—Mr. McAdam Eccles, in appealing for a universally accepted name for the negative image produced by the action of x rays, raises a point which is not without some importance. Those older members of the profession whose youth was, as mine, spent at school, and perhaps also university, entirely in the study of the dead languages, and who retain some reverence for them, will wish to see that the term we use is at least derivatively correct. Mr. Eccles gives a list of 19 names which he says are applied to the product of our labours, and I should have no quarrel with him were it not that in describing what he means by these 19 he adds a twentieth, which is one of the least correct of all—i.e., "a photogram produced by x rays." Now, a photogram means "a thing inscribed by the agency of light," and x-radiation is as far removed from light as is the radiation of "wireless." What frightens the nervous patient when he enters an x-ray room is the belief that a brilliant light is going to flash about him. I would therefore plead for the rigid exclusion of any reference to light which might be implied by the use of such words as "photogram" or the ever less correct "photograph."

About half the terms in Mr. Eccles's list can be deleted at once since they end in "graph" as distinct from "gram." The word "graphe" (I do not expect the *Journal* to produce the Greek script) means writing or drawing in the abstract; the word "gramma" means writing in the concrete—i.e., a thing inscribed. Telegraphy means the art of writing from afar; a telegram is a thing written from afar. The word, then, which we choose should end in "gram" and not in "graph"; and here we are at once at a disadvantage. A radiologist should by radiography produce a radiogram, but a radiogram has by a corruption of two wrongly applied words come to mean the commercially produced noise-box of the drawing-room. There it is firmly implanted, and any attempt to rescue it would result inevitably in confusion. I suggest we leave it alone. What then? Roentgenogram? God forbid. It's German; it's grossly ugly; few of us, probably, can pronounce it correctly; and I, at any rate, after 23 years as a radiologist, am never quite sure about its spelling. Surely we need never use so hideous a word because a German once stumbled on a discovery by accidentally fogging a plate? Any Englishman can fog a plate. No, we can do better than that. There remain, then, in Mr. Eccles's list, for practical purposes, only "shadowgram," "actinogram," and "skiagram." The first goes out at once. It is a childish combination of English and Greek—worse than some of the Latin-Greek combinations of medical nomenclature. Actinogram is incorrect because "aktis" means a ray of the sun, which we do not use. There remains, then, only "skiagram," which is etymologically correct: "skia," a shadow, and "gramma," a thing inscribed. And, what is more, the Greeks themselves combined the two words. Skiagraphéo means "I etch out in light and shade." Personally I do not shudder if I am asked for "an x-ray," though there are no rays about it and x is an unknown quantity. I have got used to it. But if we must have a rather ugly word of classical origins I do not think many radiologists will quarrel with Mr. Eccles and those other distinguished gentlemen who instruct our students if they teach them to ask for a skiagram. But skiagram, please, not the sciagram or skiogram of Mr. Eccles's list. No Greek word ever began "sci"—and our love is feminine, not masculine.—I am, etc.,

Bedford.

H. B. PADWICK.

* According to Liddell and Scott (6th edition) γραμμα means "that which is drawn"; and γραφή, "properly a representing by means of lines." γραμμα, incidentally, also means "a small weight"; hence the French, gramme. The *Shorter Oxford* says of -graph: "The bulk of the words in -graph are of very recent invention, and have the general sense of 'that which writes, portrays, or records.' . . ." For the "shadow which is recorded" we join with Mr. McAdam Eccles and Dr. Padwick in preferring "skiagram."—ED., B.M.J.

Mr. Shaw on Doctors

SIR.—Greatly as I enjoyed reading Prof Greenwood's criticism of Mr. Bernard Shaw's new book, *Everybody's Political What's What* (Oct. 28, p. 570), I cannot help thinking that both you and the writer of the criticism take Mr. Shaw too seriously. I have read, and greatly enjoyed in parts, all Mr. Shaw's plays, not to mention the lengthy prefaces, and have seen them acted. There is no doubt that the world of drama and literature would be much poorer without them, but to take them seriously would be a poor compliment to this author, who always writes with his tongue in his cheek. In his old age Mr. Shaw has confirmed that his Socialism is no more than a façade, notably in his pathetic letter recently in the *Times* wherein he complains of the preposterous tax he has to pay on his income of £20,000 a year.

M. Colbourne, in *The Real Bernard Shaw* a book worth reading, deals at length with the attack of pernicious anaemia which Mr. Shaw contracted and for the cure of which he made no bones about taking liver extract. This is a curious renunciation to have had to make for an antivaccinationist, antivaccinationist, and anti everything which science has proved to be of value in the practice of medicine. The words "filth" and "poisons" quoted by Prof Greenwood mean nothing to Mr. Shaw when necessity compels him to employ such a remedy for his recovery—I am etc

Norwich

H J STARLING

SIR.—If one may be allowed to criticize is not Prof Greenwood's apology for his profession too ponderous and erudite for most laymen, whereas, in so far as it is designed for his professional brethren, is he not preaching to the already converted? Bernard Shaw has always relied for his effects upon verbal fireworks, paradox, and the denial of the obvious and long-established, and those of us to whom, in our youth, he was a literary idol have, in our middle age, been alienated by those qualities in him which formerly excited our admiration.

The facts of medical science are already, as it were, on the statute book, and need no defence against Bernard Shaw or any other layman.

Does anyone ever take Shaw seriously about anything? Nearly everything he writes has a profoundly irritant effect for the reasons stated above. Need we therefore as doctors be disturbed by his ignorant incursions into medical science?—I am etc,

Here.

G L DAVIES

Psychology of the 'Presser'

SIR.—In the answer in "Any Questions?" (Oct. 21) on the psychology of the man who "presses" at golf your contributor says that this is the result of a longing to do superlatively well, and a parallel is drawn with the "pressers" in everyday life, who are always aiming too high. The remedy suggested is simple persuasion or "more intensive psychotherapy."

On the face of it, this sounds the height of common sense, but I wonder in practice how many "pressers" have ever been influenced to change their ways by such methods. As a supporter of the teaching of Matthias Alexander, I agree with him that in practice the solution is never as easy as is suggested, and that it is not enough to rely on persuasion. Alexander, in his rather bizarre terminology, describes what is here called "pressing" as "end-gaining"—i.e., devoting the entire attention to the end result to be attained, at the expense of what he calls the "means-whereby." He has devised a delightfully subtle technique for teaching people to turn their attention from the "end" to the "means," and, by reducing activity down to its basic components, he builds up reaction again with the components in the right order.

A satisfactory explanation of "pressing" can be obtained by referring to the hypothesis of the "total pattern of reaction" and the "partial pattern of reaction," as described by the late G E Coghill in his *Anatomy and the Problem of Behaviour* (Cambridge, 1929). Briefly, Coghill describes how in the developing amblystoma, the wave of neuromuscular excitation arising in response to peripheral stimulation travels cephalo-caudal from segment to segment, so that in the early stages of neuromuscular maturation the excitation which reaches the limb segments is preceded by excitation in the body segments. The response to a stimulus to a limb, early in the life cycle, will produce a "total reaction" in which the trunk

is involved before the limb. However, later on in the life cycle stimulation of the limb segment will produce a separate "partial pattern of reaction," and the limb moves on its own, during its reaction the "total pattern of reaction" in the trunk is maintained undisturbed, but its maintenance is the essential prerequisite of adequate limb reaction. It is Alexander's contention that a condition of mal-coordination such as is manifested in "pressing" is due to the "partial pattern of reaction" in the limb coming to dominate the underlying basic "total pattern," which should be maintained constant throughout activity energy which should be devoted to keeping the "total pattern" constant is misdirected into the "partial pattern." In the well-coordinated organism the wave of neuromuscular activity arising from a stimulus is directed first into the total pattern and then on into the partial pattern, and the problem of "pressing" can never arise, because any increased effort is directed first into maintaining the "constant" of the total pattern, and only secondarily into the partial pattern by means of which the end is to be attained.

I trust that this explanation does not make Alexander's work sound more obscure than ever, but I myself have found it helpful in explaining his method of restoring a constant element to neuromuscular reaction. It also explains why people will persist in a given type of activity long after they have decided that it is valueless, and in spite of their efforts to change. Any increase in effort in these people means that more and more energy is poured into the partial pattern, increasingly at the expense of the total pattern. It is only by teaching such people to cease distorting the total pattern and to work in conformity with it that they can make their efforts to succeed effectual, and can effectively translate good advice into practice—I am, etc

London NW 1

WILFRED BARLOW.

Association of Municipal Specialists

SIR.—At a meeting held at the Royal College of Physicians on Oct. 26, 1944, it was decided to form an Association of Municipal Specialists, and that the qualification for membership should be "Registered medical practitioners who are specialists principally engaged in clinical work, pathology, or radiology and who are employed whole time by a local authority." It was also decided that the term "specialists" should be defined as those medical men who are looked upon by their professional colleagues as specialists.

I am anxious to get into touch with those who are qualified to become members, and I should be much obliged if medical officers of health would send me, or ask one of their specialists to send me a list of such persons employed by their local authority. We have no other means of getting in touch with them—I am, etc,

12 Manchester Square London W 1

GEORGE F STEBBING,
Hon Secretary

Registration of Specialists

SIR.—The proposals for the registration of specialists which have been accepted by the General Medical Council (Aug. 5, p. 188) have a direct bearing on the future development of the salaried and private medical services of the tropical Empire, and through them on its whole development.

If a register of specialists is prepared solely as a part of the internal administrative machinery of a National Health Service applicable to the United Kingdom alone, it is right and proper that it should be limited to persons domiciled in the United Kingdom, or normally so but temporarily absent on war service. A statutory entry in the Medical Register has, however, a significance much wider than this, as the Register is used in courts of law and medical services for the assessment of the qualifications and status of medical people in many parts of the Empire other than Great Britain. The absence of an entry showing classification as a specialist against a practitioner's name will ultimately inevitably be taken to imply his lack of qualification to practise or be recognized as a specialist. I therefore notice with concern that the sole provision for the registration of specialists living abroad refers to those people temporarily absent on war service.

Medical specialties are practised and the necessary experience can be gained in many parts of the Empire. If the Far East is to return soon after the war to its previous state of development, and if the entire tropical world is to rise to a properly developed condition, it is imperative that the hygiene and

medical services should be of the highest standard, because the biggest impediment is still disease. Statutory registration of specialists in the United Kingdom and failure to register those abroad will have serious detrimental effects on these services. It will discourage young men from going to parts of the Empire where they could not secure the recognition of their abilities that they could at home; those living abroad will have a reduced incentive to advance themselves because the unregistered specialist cannot hope for the financial reward in any salaried service that would go to a registered one; as a result, people who have in fact qualified themselves abroad may be expected to return to Great Britain to secure recognition and all the material advantages it will imply. Lastly, it is of interest that it is doubtful whether, on their return to England, either Dr. Patrick Manson or Major Ronald Ross, as they were then, or many other distinguished medical men subsequently returning from the Tropics, would have been entitled to practise as specialists.

It may be answered that the position will adjust itself by newly qualified practitioners staying in Great Britain until they have secured specialist status, and then proceeding abroad. Though this would occur to some extent, as a full solution it would be most unsatisfactory. The best specialists are those with previous experience of general practice, but these men could certainly not have had previous tropical experience. Also such a system would divide the medical profession abroad into two classes—the acknowledged specialists, many of them young, and those without hope of acknowledgment, whatever their experience and qualities.

For these reasons a statutory entry in the *Register* should not require any domiciliary condition. It should be obtainable by all registered practitioners, whose sole qualifications should be experience, postgraduate qualifications, and practice of the specialty concerned. These can be acquired in the normal course of a medical career in the Tropics by progressive men, who would not need or ask any relaxation of standard for their recognition.—I am, etc.,

C.M.F.

GEORGE MACDONALD.

Mental Health Service

SIR,—In reply to the letter under the heading "Asylum Doctors' Pay" it may be stated that the question of salaries and conditions of service of the medical staff in the mental health service is by no means being overlooked. Some useful preliminary work has been done in conjunction with the Medical Superintendents Society, and it is hoped that at the forthcoming annual meeting of the Royal Medico-Psychological Association (Nov. 29) a small but representative committee may be appointed to draw up recommendations. The matter, looked at with regard to the future, is not devoid of complications—e.g., employment of house officers, grading of specialists, tramural duties, etc.—but it is well recognized that an equitable scale of salaries is overdue.—I am, etc.,

W. GORDON MASEFIELD,

Honorary General Secretary, Royal Medico-Psychological Association.
11 Chardon Street, Cavendish Square, W.

The Services

Surg. Lieut. J. M. Couchman, R.N., has been awarded the D.S.C., and Temp. Surg. Lieuts. A. C. Smith and T. A. M. Johns, R.N.V.R., have been mentioned in dispatches for distinguished services in operations, carried out in the face of determined opposition from the enemy, which led to the capture of the Island of Elba.

Temp. Surg. Lieut.-Cmdr. J. W. Buchanan has been mentioned in dispatches for good services to the wounded.

Capt. (Acting Major) S. H. A. Gardezi, M.C., I.M.S., has been mentioned in dispatches in recognition of gallant and distinguished services in Sicily.

CASUALTIES IN THE MEDICAL SERVICES

Wounded.—Capt. P. N. Swift, I.M.S.

Missing at Arnhem.—Capt. C. E. C. Wells, R.A.M.C.

Missing, presumed killed.—Surg. Lieut. Robert Frederick Barlow, R.N.

Reported missing, now reported prisoner of war.—Capt. J. Rutherford, M.C., R.A.M.C.

Obituary

RAYMOND JOHNSON, O.B.E., F.R.C.S.

Raymond Johnson, consulting surgeon to University College Hospital, died in his sleep in his 83rd year. Entering University College in 1881 as an Exhibitioner he very soon showed his mettle, and by the time he had completed his clinical studies at University College Hospital he was the holder of three gold and six silver medals. In 1886 he added to these by winning two gold medals in the London M.B. He then started seriously on his surgical career by becoming a demonstrator of anatomy before taking the Fellowship of the Royal College of Surgeons in 1888. Four years later he was appointed to the staff of University College Hospital, where he remained for 31 years, retiring before his time in 1923 because he feared that he was standing in the way of his colleagues, who at that time were committed to retirement at the age of 60. He retained his active connexion with the Royal College of Surgeons until 1926, when he finally gave up his professional interests after serving on the Council of the College for eight years and as a member of the Court of Examiners for nine years. At various times he also acted as examiner for the Universities of Birmingham, Cambridge, London, and Leeds.

Raymond Johnson had no doubts as to his place in the profession he had chosen. He had no desire to pose as a research worker or even to lay claim to a great deal of original work. He was content, as well he might have been, with the reputation which he attained as an eminently sound consultant, a skilful surgeon, a lucid teacher, and an ideal colleague. Yet it would have surprised him to know how vividly he is remembered to-day by those who knew him well. His character was in fact a rare one, for he combined with a gentle and rather retiring disposition a surprisingly wide knowledge of human nature and a comprehensive tolerance for its failings. His standards of conduct were very high, but they were for himself, and if others did not live up to them Raymond Johnson would always be their friend but never their judge. His apparent meekness could disappear in a flash when defending the rights of others, and he could be positively disingenuous when occasion arose to cover the faults of his colleagues or his juniors.

Two wars interrupted his career, for he served as surgeon to the Imperial Yeomanry Hospital in the South African War, and again in 1914-18, first as a surgeon rear-admiral, and later, when his naval appointment promised to provide more honours than work, as a captain in the R.A.M.C. Then, as always, he considered first and last his own standards. It would not be true to say that honours meant nothing to him, but they would not have been sweet unless by his own standards they were deserved.

It is good to think that Raymond Johnson, who always preferred gentleness, had twenty years of great happiness after his retirement, enjoying his country home, which he shared with his wife and two daughters.

A. J. G.

GREVILLE MACDONALD, M.D.

Dr. Greville MacDonald, consulting physician for diseases of the throat, King's College Hospital, emeritus professor of King's College, London, and formerly physician to the Throat Hospital, Golden Square, died at Haslemere on Nov. 3.

Greville Matheson MacDonald was born in Manchester on Jan. 20, 1856, eldest son of George MacDonald, LL.D., poet and novelist. Brought up in a literary and musical home he met as a child many leading writers of the day, and after

leaving King's College School, London, he went with his father to the United States in 1872 and there was introduced to Whittier, Longfellow, Oliver Wendell Holmes, and Emerson. He entered King's College as a medical student and won scholarships there, and graduated M.B. Lond. in 1877, with honours in materia medica and pharmaceutical chemistry. During his clinical course at the hospital he became one of Lord Lister's clerks. Greville MacDonald's career in laryngology began as R.M.O. to the Hospital for Diseases of the Throat in 1886, and he was appointed physician soon afterwards. At King's College Hospital he served as throat physician and lecturer on diseases of the throat and nose from 1893 to 1906, when he retired from the active staff and was elected consulting physician. Between qualification and launching out as a specialist he had earned a living in turn as a ship surgeon, as medical officer to a private asylum, and as a doctor in private practice in Florence. His appointment to the Golden Square Hospital was due in the main to an introduction by Sir Morell Mackenzie, whose private work in London he looked after when Morell was in attendance on the Emperor Frederick at San Remo and Charlottenburg.

Greville MacDonald acquired a large practice and ranked high as a lecturer in his specialty. He was vice president of the Section of Laryngology at the Annual Meeting of the B.M.A. in 1895 and president at the Montreal Meeting two years later. His foreign honours included corresponding membership of the Société Française d'Otologie et de Rhinologie, et de Laryngologie, and corresponding Fellowship of the American Laryngological Association. Among his medical publications were *A Treatise on Diseases of the Nose and its Accessory Cavities* (2nd edition 1892) and *Hay Fever and Asthma* (1893). From boyhood he had had many interests outside medicine and he wrote a number of philosophical essays and romances and studies in human personality. He wrote a life of his father and mother in 1924, and *Reminiscences of a Specialist* in 1932.

Dr FREDERICK WALKER formerly chairman of the Holland Division of the British Medical Association, died at Holbeach Lincs, on Oct. 23. He was born at Wakefield on July 27 1871, and studied medicine at Leeds, taking the English Conjoint diplomas in 1894. A year later he became senior house-physician and anaesthetist at the Infirmary at Leeds and then practised at Wakefield, where he was assistant honorary surgeon to the Clayton Hospital. He moved later to Holbeach and was appointed medical officer to the Holbeach Institution, the Lincolnshire Joint Board for Mental Defectives and the Isolation Hospital at Fleet. He was also deputy coroner for the Spalding district. Dr Walker joined the B.M.A. in 1896, and in recent years was chairman of the Local War Emergency Committee.

We regret to announce the death of Dr JAMES ALEXANDER DAVIDSON of Montpellier Avenue Ealing, W.5, on Oct. 27, at the age of 61. He was born in Aberdeen, and graduated M.B., Ch.B. at Aberdeen University in 1907 and M.D. in 1909. He was assistant casualty medical officer at Great Ormond Street Children's Hospital. In 1909 he started his practice in Hanwell, and in 1929 he moved to Ealing, and had practised in Hanwell and Ealing for the past thirty-five years. He became medical officer to the L.C.C. residential schools (which work he enjoyed more than any other) and medical officer to the Hanwell Cottage Hospital. In the last war he was a captain in the R.A.M.C. and medical officer to a British auxiliary hospital in Belgrade. After the war he was appointed medical referee for the Mental Treatments Act, 1920, and more recently medical officer to the Associated Equipment Company. During this war Dr Davidson served as medical officer to the Middlesex Battalion Home Guard and physician and chairman of the Medical Recruiting Board. He had been a member of the B.M.A. since 1911, was secretary of the Ealing Division in 1922 and chairman of the West Middlesex Division in 1933-4, representing the latter at three Annual Meetings. He was also a member of the Harveian Society. The following appreciation comes from a former partner. Dr J. A. Davidson was a conscientious and painstaking physician, thorough, calm, and possessing that power which inspires patients with both confidence and assurance. Constantly keeping in touch with current medical literature he was always familiar with the latest methods of treatment. He was a sound diagnostician, dogmatic but willing to see both sides of a question. Dr Davidson was a dearly loved friend to both young and old, and his passing leaves a gap which cannot be filled.

Universities and Colleges

UNIVERSITY OF LONDON

Sir Ernest Graham Little, M.P., has been elected chairman of the Council for External Students of London University for the year 1944-5.

LONDON HOSPITAL MEDICAL COLLEGE

The subject for the next award of the Hutchinson Triennial Prize is "The Value of Local Chemotherapy in the Treatment of Wounds." Every candidate must be a full student of the London Hospital, but not necessarily of the Medical College. He may be qualified, and he is eligible to compete until the expiration of ten years from the date of registration as a student of the hospital. Dissertations must be delivered by Oct. 31, 1947. A printed copy of the conditions may be had from the Secretary of the London Hospital Medical Council, Whitechapel, E.

UNIVERSITY OF GLASGOW

Four illustrated lectures on the evolution of social medicine will be given by Dr Douglas Guthrie in the Zoology Lecture Room of the University on Mondays and Thursdays, Nov. 27 and 30, and December 4 and 7. The lectures are open to members of the University staff, students, and medical practitioners.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following candidates were successful in the recent Primary Fellowship Examination:

W. P. Cleland T. H. Cullen J. S. Davidson E. W. Graham J. D. Green
J. W. P. Gummer J. D. Halliday H. O. Jones P. F. Milne M. R. Milne
M. R. Rifaat J. M. Sanderson D. W. Thomas Jean K. M. C. Wilson,
W. K. Yates

Medical Notes in Parliament

Penicillin Supplies

Mr KENDALL on Nov. 2 raised the question of penicillin. He said Britain, regrettably, had not started producing this drug until recently. A factory costing £1,000,000 had begun operations that day.

Mr PEAT (Joint Parliamentary Secretary to the Ministry of Supply) intervened to say that was a Press mis-statement.

Mr KENDALL said all information on the manufacture of penicillin and of treatment by it had been given to the United States of America which had done a wonderful job producing it. This production to-day was some 1,200,000,000,000 Oxford units per annum. The supplies they had sent over here represented about 200,000,000,000 Oxford units. Many of our Service men were treated with the drug, which was obtained under Lend-Lease from America. He understood that Germany had been given all the information regarding production of penicillin. Proceeding, Mr. Kendall said bacterial endocarditis was a disease which hitherto had been fatal. Without this drug there was no hope at all. With it lives had been saved here and in the United States. Young people had already been helped in Middlesbrough and Manchester by penicillin. He asked the Ministry of Health to take regionally the few similar cases that would come along. There had not been more than 30 letters asking M.P.s for help. This, Mr. Kendall said, would relieve him from having to try to get penicillin. He neither manufactured nor purchased, but had been allowed to have 4,000,000 or 5,000,000 Oxford units. By regional control the Minister could get doctors trained, through his experts, in the use of penicillin.

Mr WILLINK said the matter was of great importance. He was anxious to relieve the anxiety of those who believed there had been undue rigidity or inhumanity in the administration of the supplies. In 1941, 1942, and 1943 the resources of America in penicillin had been hardly less strained than our own. From the beginning of this year, owing to the American supplies provided under Lend-Lease for the armed Forces and civilian air-raid casualties—those were the terms—the Ministry had been able to do a lot for those two classes or people. In the early part of 1944 it became clear that during that vital summer the total supplies, home-produced and imported, would probably be more than sufficient for the needs of the armed Forces. The first allocation for clinical trials under the control of the Clinical Trials Committee of the Medical Research Council had been in January, 1944. By August, 1944, the Ministry was able to provide a general supply on a very restricted basis for the use of civilians. In the three subsequent

At a meeting of the Colour Group of the Physical Society on Wednesday, Nov. 22, at 3.30 p.m. in the Physics Department of the Imperial College, Imperial Institute Road, S.W.7, Mr E. Willmer of the Cambridge Physiological Laboratory will read a paper on "Retinal Structure and Colour Vision". The spectral sensitivities of the rods and the cones in the human eye, their neural connexions, their phylogenetic and ontogenetic development, their behaviour, and their varieties will be discussed in relation to a hypothesis that human colour vision is primarily due to the relative performance of these photo-receptors and not to the performance of the cones only. The peculiar properties of the so-called red free area of the fovea centralis will be examined and the general hypothesis will be considered in relation to the essentially trichromatic basis for colour vision. An informal discussion will follow the paper.

The 103rd annual meeting of the Royal Medical Psychological Association will be held on Wednesday, Nov. 29 at 11, Chandos Street, Cavendish Square, W., under the presidency of Lieut-Col. A. A. W. Petrie, M.D., F.R.C.P. On the previous day the council and committees will meet at the same address.

Durham University has decided to open the vacant whole-time professorship of surgery at King's College, Newcastle-upon-Tyne, to candidates serving in H M Forces. This enlightened decision was made after consultation with the Director General, Army Medical Services. The salary of the chair is £2,000 a year, and Dec 31, 1944, has been given as the preliminary date by which applications should be received. The University will not, however, fill the appointment until it is satisfied that persons serving overseas have had full opportunity to apply. If the successful applicant is on national service, he will not be required to take up his duties until his release from such service. Applications should be made to the Acting Registrar, University Office, 46, North Bailey, Durham.

Dr. George Walker Hinchliff of Dover has been commended for brave conduct when attending to wounded under shell fire.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales the incidence of measles, scarlet fever, and whooping-cough continued to rise there being reported respectively 663, 112, and 91 more cases than last week. Returns for acute pneumonia fell by 102, for dysentery by 29, and for diphtheria by 26.

Yorks. West Riding reported 40 more cases of scarlet fever than last week. The greatest increase in measles was in the north, especially in Lancashire, where returns rose by 267 in Yorks West Riding they went up by 66, in Staffordshire by 63, in Durham by 53, in Northumberland by 44, and in Glam. organshire by 41. In contrast to the general trend, Devonshire had 72 fewer cases than last week, and Cheshire 39

The notifications of dysentery, 362, fell by 29. The largest returns were Lancashire 53, Glamorganshire 41, London 38, Essex 31, Suffolk 29, Yorks East Riding 29, Hertfordshire 19, Surrey 16, Gloucestershire 15.

In Scotland there were 56 more cases of measles than last week, and 29 more of diphtheria. During the recent outbreak of gastro-enteritis among infants in Glasgow there were 296 deaths during the eleven weeks from mid-August to mid-October. No specific factor causing the epidemic has been found.

In *Eire* notifications of diphtheria fell by 25, but were still high—128 cases.

In Northern Ireland scarlet fever rose by 23 cases after the large fall of 46 in the preceding week.

Diphtheria

According to returns received from all but a few local authorities in England and Wales the number of notifications of diphtheria in 1943 among immunized children was approximately 5,050. According to the same returns, of 1,079 children who died from diphtheria in 1943 42 had been immunized at some time. In the two years 1942-3 the annual rate of incidence of diphtheria among immunized children, based on the estimated time of exposure to risk, was rather more than a quarter of that among those not immunized, and the corresponding mortality ratio was about 1 to 23.

The returns received from medical officers of health in Scotland show that the number of immunized children under age 15 who developed diphtheria during the first six months of 1944 was 827. The information at present available shows that 2 immunized children died during the period.

Week Ending November 4

The notifications of infectious diseases in England and Wales during the week included scarlet fever 2,149, whooping-cough 1,135, diphtheria 633, measles 4,827 acute pneumonia 520, cerebrospinal fever 42, dysentery 256 paratyphoid 3, typhoid 5, poliomyelitis 14.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 28:-

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland

London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for

(a) The 126 great towns in England and Wales (including London)
 (b) London (administrative county) (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available

Disease	1944					1943 (Corresponding Week)

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELGRAMS: *Atitology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.) TELEPHONE: EUSTON 2111. TELGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELGRAMS: *Medisecra Westcent London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh

ANY QUESTIONS?

Water Testing

Q.—Can you kindly explain how the same water can give such different results as the following?

E.P.H.L.S.	Probable Number of Coliform Bacilli
15/12/43	0
15/8/44	8
15/8/44	70
15/9/44	350
18/10/44	110 (A)
18/10/44	250 (B)
Dr. A. 15/9/44	0
Dr. B. 2/10/44	0

What am I to infer? I have advised it to be boiled. (All samples were collected by the water engineer in sterile (?) bottles supplied by the laboratories.)

A.—The bald inference from the data submitted is that the water supply is unsafe and the questioner's action in advising boiling is justified. This, however, can be only a temporary measure, and the conditions require close investigation. In this connexion it should be made clear (1) whether the samples are of water at the tap or at some other stage before delivery; (2) whether samples from E.P.H.L.S. 15/9/44 and Dr. A. of the same date were taken by the same person and at the same place; (3) whether the sampling officer's procedure is such as to preclude contamination after the sterile bottle leaves the laboratory; and (4) as to the weather conditions at the several dates, especially as regards flooding. The discrepancy between the reports on samples A and B collected 18/10/44 is not of great significance. Before advising his authority on this problem the M.O.H. should discuss these results in detail with the bacteriologist (preferably at the waterworks), who may suggest further experiments to determine what defects exist in the system.

Insulin to Increase Weight

Q.—Injections of insulin 10 units t.i.d. a.c. over a period of four or five weeks are said to increase the weight of persistently thin individuals (healthy, non-diabetic). Is there any foundation for this belief, and if so, how does insulin bring about such an increase in weight?

A.—Insulin is sometimes useful in increasing the weight in patients whose appetite is very bad. It does this by producing hypoglycaemia, and it is useless unless pressed to this point. Many patients rendered hypoglycaemic become ravenously hungry and therefore eat more. Unfortunately the method often fails, sometimes because the patient still lacks appetite despite hypoglycaemia and sometimes because the increased intake of food does not cause a gain in weight.

Tests for Liver Function

Q.—What are the best tests of liver function? How are they applied and the results interpreted?

A.—The choice of suitable tests depends upon the clinical material and the facilities available. The serum bilirubin estimation, urinary tests for urobilinogen, and the hippuric acid test are the easiest to perform and will often give useful results, particularly in non-jaundiced patients. They will rarely distinguish between obstructive and non-obstructive jaundice, for which purpose more help may be obtained from the flocculation tests—e.g., the serum-colloidal-gold reaction and the cephalin-cholesterol test—the serum alkaline phosphatase, modern versions of the galactose-tolerance test using load-galactose estimation, or the serum-protein determination. It is impossible to deal here with technical details, which are described in current articles and textbooks. Two recent numbers of this journal contain accounts of most of the tests mentioned. (Feb. 12, 1944, p. 211, and Sept. 16, 1944, p. 363.)

The interpretation of results needs care because of the possibility of secondary liver involvement in various diseases such as heart disease, acute and chronic infections, anaemias, and hyperthyroidism.

In general it may be said that a suitable combination of tests will materially assist the clinician in the diagnosis of liver disease and in the differentiation of the various types of jaundice. Thus in jaundice due to hepatitis or cirrhosis the flocculation tests are usually positive, the phosphatase moderately raised, galactose tolerance impaired, and the serum globulin may be raised. In obstructive jaundice the flocculation tests are usually negative, the phosphatase much higher, and galactose tolerance and serum globulin may be normal. In subacute and chronic hepatitis the serum albumin has prognostic significance, very low values indicating a poor outlook.

Bacterial Enteritis

Q.—We recognize infections of the air passages and call them by the names of the parts affected—e.g., bronchitis. Is there any fundamental reason why parts of the gut—e.g., the colon—should not be similarly the seat of infection? Yet physicians generally doubt such a diagnosis as streptococcal colitis. I know a doctor who developed acute diarrhoea during an epidemic of what G.P.s called gastric flu. But his diarrhoea continued for thirteen months, then stopped. His weight fell, and after a few weeks he sought advice—? neoplasm or other serious cause. Radiological investigation showed an exceptionally hyperactive stomach and long spasmodic contractions in the colon, which was lacking in normal haustrations. A barium meal was voided in less than five hours' time. Examinations of the stools showed large numbers of bacteria, mostly *Strep. viridans*. The percentage of these varied from 80 to 10 and roughly corresponded with the severity of the diarrhoea. Sulphaguanidine was helpful but not curative. One physician's diagnosis of streptococcal colitis was negated by another's of anxiety neurosis. But the latter seemed to be secondary to the bowel upset and the uncertainty of its cause.

A.—Of course enteritis occurs from bacterial infection—as, for example, tuberculosis, typhoid, and cholera—and pathologists recognize a type due to the streptococcus. To diagnose such a lesion one would require not merely the presence of bacteria in the stools but also signs of inflammation—red blood cells, white cells, a positive test for occult blood, and albuminoid secretion in the stools, together with general phenomena such as fever, leucocytosis, and a raised erythrocyte sedimentation rate. The difficulty about the findings in the present case is that *Strep. viridans* is only feebly pathogenic and is generally supposed to be a mere transient which has been swallowed from foci in the mouth and nasopharynx. The numbers surviving depend largely on the pabulum provided and the rate of passage through the alimentary tract. The number of streptococci in cultures from stools may therefore vary directly with the severity of a diarrhoea, without their having any aetiological connexion with it, and this is probably what is happening in the present case. In the absence of the other signs of infection a diagnosis of enteritis is not justified, and the condition should be treated as a disturbance of motility. Such disturbances are often severe and intractable. Is there any fundamental reason, in fact, why disturbances of intestinal motility should be any less serious than disturbances of cardiac motility?

Intravenous Anaesthetics

Q.—I notice that all references to intravenous anaesthesia for a considerable time have specified pentothal. I have always used soluble hexobarbitone under various proprietary names, and have found it quite satisfactory. Will you please say if you consider that pentothal has any definite advantage over soluble hexobarbitone.

A.—Safe general anaesthesia is largely a matter of muscular relaxation achieved at the expense of little respiratory depression. Many consider that pentothal is better than hexobarbitone because it gives a given degree of muscular relaxation with less respiratory depression. Weight for weight pentothal is the more powerful drug. Anyone accustomed to use hexobarbitone will find that he gets approximately equal effect by giving only a little more than half the amount of pentothal.

Local Authorities and Dance Halls

Q.—Are there any regulations relating to ventilation of dance halls and to the number of people allowed in a room of a given size?

A.—The control of dance halls is a function of the licensing authority, which, in England and Wales, may or may not be a health authority. For instance, in London and the Home Counties it is usually the county council, but elsewhere the justices of the peace are the authority, unless the power has been otherwise allotted by local Act of Parliament. Licences may be granted subject to terms and conditions, which might include reference to ventilation and other sanitary matters. In practice the licensing authority is primarily concerned to ensure that proper order is kept and precautions are taken for the safety of the public, especially as regards fire. Due regard to health questions is more likely to be taken in those places where the chief constable and the medical officer of health have close liaison in preparing reports for the authority. Regulations have been made by the London County Council and could no doubt be obtained by application to the County Clerk, County Hall, London, S.E.1.

Rheumatoid Arthritis and B.S.R.

Q.—Is it correct that in the presence of a normal blood sedimentation rate treatment of rheumatoid arthritis by gold injection will be of no value?

A.—A normal sedimentation rate is so unusual in true rheumatoid arthritis that it raises a doubt whether the case may not be of different pathology. It is also possible that the disease is no longer active. In either case a careful review of the clinical features must be the guide as to whether gold treatment is indicated, and in view of the possible risks it should be avoided unless there is strong evidence for its use. On the whole it would seem unlikely that gold would be of any service in the case in question, possibly before arriving at a final decision it would be wise to have the test repeated, as many circumstances affect it which may not always operate.

Pre-menstrual Psychology

Q.—What, if any, is the nature of the endocrine imbalance which produces the change in personality of so many women during the seven days preceding menstruation? Many of these patients complain, not of dysmenorrhoea or of any physical discomfort but of sheer loss of self-control, wickedness, hatefulness and excessive drive which render life almost intolerable for themselves and for their families. I have tried progesterone during this period and in some cases have followed it for a few days after menstruation, by oestrogens, but judging by results I may simply be adding fuel to the fire. Is there any means of determining if the anterior lobe of the pituitary is overactive, and if it is so how can one inhibit its influence? Most alienists insist that the change is purely psychological, but in women whose menstrual type is irregular this week of anxiety definitely begins earlier or later to correspond with the alteration in the time of onset of each period. This would appear to rule out conditioned reflex as a cause.

A.—Mental and physical changes in the pre-menstrual phase have been studied by a number of workers. There is some evidence that disturbances of water balance due to the water-retaining properties of steroid hormones operate unfavourably in individuals of susceptible constitution (Thorn, G. W., Nielson, K. R., Thorn, D. *Endocrinol.* 1938, 22, 155). It has been claimed by J. P. Greenhill and S. C. Freed (*J. Amer. med. Ass.* 1939 112, 1573) that relief of pre-menstrual discomfort may be obtained by administration of ammonium chloride to discharge sodium tension and effect an output of water. Both Israel and Schmidt have reported cases in which insufficient production of corpus luteum hormone appears to be associated with severe mental swings in the pre-menstrual phase, and have suggested progesterone as a possible cure (Israel, S. L., *J. Amer. med. Ass.* 1938, 110, 1721; Schmidt, H. J., *ibid.* 1943, 121, 190). There are certainly several factors involved, and it would be fair to say that an unalterable basic mental constitution is the most important. The extent to which endocrine changes can influence the psychological state is subject to great individual variation. The methods suggested above can be tried, and should prove to be successful where the physical element is the relatively strongest factor. There is obviously no one specific endocrine cure, and no simple functional disturbance of the anterior lobe of the pituitary can be held responsible.

Treatment of an Epileptic

Q.—I should be glad of advice on the treatment of an epileptic girl aged 15 years. She has had fits all her life. They are not very severe; she usually remains unconscious for two or three minutes and has up to three fits a day. She is an intelligent girl and is anxious to become independent of her parents and to earn her own living. For several years she has been on sod. bromid gr 15, tinct. bellad in 5 t.d.s., together with sod. phenobarbitone gr 1 b.d., but the fits have never been reduced to below one a day. Phenitoin gr. 3 b.d. and sodium diphenyl hydantoinat have also been tried with no better result.

A.—There are some epileptics whose attacks can never be completely controlled by anticonvulsants in any combination, and the dose of bromide and phenobarbitone that this patient is having is approaching the maximum possible. If sodium diphenyl hydantoinat has not been of benefit alone, it would be well to add it to the dose of bromide and phenobarbitone that the patient is having, and after a few days to drop the bromide, because in some cases luminal and epanutin together are of more benefit than a large dose of each alone.

Combining Vitamins

Q.—What are the limits of compatibility of vitamins? Can vitamins A and D be combined in the same mixture with vitamin C or B using glycerin as a base? By the mixing of the oil- and water-soluble vitamins, is the value lost?

A.—There is very little evidence to suggest that fat-soluble vitamins, which are sometimes rather sensitive to acid conditions, and water-soluble vitamins, some of which are easily decomposed by alkalis, cannot exist together when properly combined at round about neutral pH. It is difficult, however, to understand what is

meant by "combining" fat-soluble and water-soluble vitamins, "using glycerin as a base." Pure glycerol is a substance in which the fat-soluble vitamins will certainly not dissolve at all, and it seems unlikely, although there is little experimental evidence on the subject, that it would be a particularly good solvent for water-soluble substances. Thus, an attempt to present fat-soluble and water-soluble vitamins in a glycerin base is most likely to lead to a suspension, of more or less fineness, in which both fat-soluble and water-soluble substances are liable to oxidation, and therefore to destruction. This is, however, not incompatibility in the pharmaceutical sense as usually understood. If the question refers to physiological compatibility it is hardly sufficient to refer to the fact that all the vitamins occurring in food appear to be effective in the presence of one another. Mixtures of synthetic vitamins might quite well behave differently. Evidence that they do is non-existent or at best inconclusive. There are good grounds for accepting the fact that the importance of vitamin E in human nutrition is at least in part due to its anti-oxidant protective action on the β -carotene in the diet, there are also curious reactions between the water-soluble vitamins, probably associated with the fact that we depend to some extent for some of these substances on our gastro-intestinal flora, the nature of which is, in turn, determined by the nutrients in our, the host's, diet. These are causes of compatibility, rather than the opposite. In general, much the best procedure, if it is desired to prepare some multi-vitamin product, is to study the survival therein of the individual constituents by recognized and approved methods, under various conditions of storage, and not to use (or market) such a product until satisfactory proof has been obtained for the stability of all those constituents. Indeed, the recent Pharmacy Act and food-labelling regulations now make it necessary to proceed in this way, whether for medicinal or food products.

Sodium Morrhuate for Ganglion

Q.—Is the treatment of a ganglion with sodium morrhuate or other solution a reliable cure? What is the exact method of using these solutions in this condition?

A.—There is no absolutely reliable cure for a ganglion. Rupture by pressure evacuation after puncture by a tenotome, injection of a solution of sodium morrhuate, and excision are all recognized methods of treatment. Any of these methods may cure; none can be guaranteed to cure. Excision gives the best chance. The technique for injection of sodium morrhuate is as follows. The skin over the ganglion is sterilized and anaesthetized by local injection of 1% novocain. A large bore needle is inserted into the ganglion, the contents expressed, and then half a cubic centimetre of a 5% solution of sodium morrhuate injected, the needle is then withdrawn and a sterile dressing applied. The reaction is sometimes unpleasant, but cure has been known to follow.

Penicillin and Poliomyelitis

Q.—I have had an inquiry regarding the possible use of vivillin in late infantile paralysis, and the assertion was made that there was a recorded case of cure and recovery of function. Can you corroborate or refute this, and is there any evidence to show that vivillin or penicillin is of any avail in the treatment of the sequelae of infantile paralysis?

A.—It is inconceivable that any chemotherapeutic agent could be of benefit in "late" infantile paralysis—i.e. after the infection has done its damage. It is improbable that penicillin would have any effect even in the acute stage. Virus diseases in general are unsusceptible to penicillin, the only evidence to the contrary of which we know being experiments by Heilmann and Herrell (*vide B.M.J.* July 15, 1944, p. 85) showing an effect on ornithosis. We are at a loss to understand how the suggestion that vivillin is of any use for this purpose can have gained currency. The only report on this material which has appeared in a regular medical journal (T. Crawford, R. S. Handley, and W. H. Hargreaves, *Lancet* June 3, 1944, p. 738) was to the effect that it failed to cure any of 12 cases treated, although they were suffering from conditions due to penicillin-sensitive organisms.

Pethidine

Q.—Pethidine is a drug new to most medical men. What are its uses and abuses? What are the appropriate doses? Is it habit-forming or are people said to have become addicted to it, probably of the type who would abuse almost anything—e.g. alcohol, tea, tobacco, etc.? Would it be indicated for spasmodic contractions of the stomach and colon (as shown by screening and x-ray pictures)?

A.—Pethidine is used for relief of pain and the dose is 25 to 50 mg (about 1/2 to 1 grain) three times daily. Ampoules are available for intravenous or subcutaneous injection, and when given slowly into a vein it is said to produce prompt relief. It is not as effective as morphine but it is more effective than aspirin. Its chief value is that it does not cause nausea or vomiting as morphine does in many people, and so can be used for these patients. It was recently used successfully

in a patient of this kind who was suffering from inoperable carcinoma with secondaries in the spinal column. It seems to be less effective for traumatic than for neuritic pain. It is advocated for spasm of the intestinal tract and urogenital system, and is described as a spasmolytic as well as an analgesic. It is probably a habit-forming drug, though to a less extent than morphine or even codeine.

Effects of Stilboestrol

Q.—Does the administration of stilboestrol stimulate the adrenals and the hypophysis cerebri, causing increased blood pressure, vertigo, and other disturbances resembling the symptoms of arteriosclerosis?

A.—In small animals stilboestrol administered in large doses may produce hypertrophy of the adrenal cortex. It appears to inhibit the hypophysis, and large chromophobe adenomas have been produced by continued administration, together with cessation of skeletal growth. In man no evidence of adrenal effect has been clearly indicated, but inhibition of pituitary activity is shown by the diminution or disappearance of gonadotrophins from the urine in menopausal women treated with stilboestrol. Clinically, this results in disappearance of unpleasant vasomotor symptoms, and even a reduction in the increased blood pressure which sometimes occurs at the climacteric. I know of no clinical evidence, and certainly have not observed any, which suggests that "increased blood pressure, vertigo, and other disturbances resembling the symptoms of arteriosclerosis" are ever produced by stilboestrol or other oestrogens as usually administered in woman.

Iron and Constipation

Q.—Is ferri et ammon. cit. constipating? I have a number of anaemic women who complain they cannot take iron as it makes them feel constipated. What is the remedy?

A.—The large doses of iron and ammonium citrate which are prescribed nowadays more often produce diarrhoea than constipation, but if constipation does occur it is well to substitute mistura ferri aperientis, N.I.V.F., which contains ferrous sulphate and sodium sulphate. Freshly prepared Bland's pill is often well tolerated, and if this also fails, colloidal iron may be given in the form of liquor ferri dialysatus, B.P.C., or one of several similar proprietary preparations.

Xerodermia

Q.—A young woman who has always suffered from xerodermia has one child of about 2 years of age. During pregnancy the skin became almost normal, but now is as bad as ever, and in addition she now gets severe chilblains, deep, painful cracks on the plantar surface of her heels, and swelling of her ankles and legs, especially if she walks any distance. No cardiac, renal, or other cause can be found for the swelling. Calcium treatment has proved of no value. In view of the improvement during pregnancy, do you consider hormone treatment is indicated and, if so, in what form and dosage? Is any other treatment likely to be of any value, and is friar's balsam the most satisfactory local treatment for these cracks as for cracked fingers?

A.—It has for long been known that a number of conditions of the skin appear and persist during pregnancy, and that others temporarily clear up, but in our present state of knowledge there are no guiding principles indicating the kind of hormonal treatment suitable for such conditions. Treatment for xerodermia aims at supplying something to counteract the abnormal dryness, such as liquid paraffin, to which a little starch may be added. The painful cracks on the feet call for protection by elastoplast and boric ointment, or possibly friar's balsam. The swelling of the legs and ankles is probably an independent phenomenon arising from other causes.

LETTERS, NOTES, ETC.

Demobilization of Medical Students

Dr. H. STRATFORD COLLINS writes: As you have opened the subject of medical demobilization in your columns, may I raise the question of demobilization of medical students. There must be an appreciable number of them in all branches of the Services at present, and many of them have served for some years. They include students who from high motives have abandoned their studies to serve but who may, after Germany is beaten, be ready and anxious to take them up again. There are also students who had their exemptions withdrawn as their tutors did not consider that they were making satisfactory progress. No standard was laid down for this, and it appears to have varied considerably in different schools and even under different tutors in the same school. Some students, having lost their exemption for failure in an examination, passed it while waiting for their call-up, but were not allowed to continue. These men may be the most high-spirited and least studious of their years, but are not necessarily the worst doctors when qualified. Discipline, service, and experience have probably produced a more serious out-

look by now. If they are retained in the Services and sent to the Japanese theatre of war, and the break in their studies is lengthened by two or probably three years, they may well be lost to medicine for good. On qualification, should the war be over, they will be immediately available to help to fill the vacancies in the profession, as they will have completed their compulsory military service. The welfare of these students appears to be nobody's business. They do not seem to be under the jurisdiction of the Central War Board, and are left entirely to the tender mercy of the Ministry of Labour.

Diagnosis of Minimal Hyperthyroidism

Dr. E. C. H. HUDDY (Truro, Cornwall) writes: The reply to the first question in "Any Questions?" in the *Journal* of Nov. 4 raises a point which is continually giving rise to difficulty—namely, the diagnosis of mild cases of hyperthyroidism. In this connexion the work of J. D. Robertson does not seem to have attracted the attention that it deserves. Quite apart from his demonstration of the fact that the estimation of basal metabolism in ambulant patients is, subject to certain conditions, a perfectly satisfactory procedure (*Journal*, May 6, 1944, p. 617; and see also the impressive letter from I. M. Rabinowitch of Montreal in the *Journal* of July 29 last), he points out that the response of the basal metabolic rate to the administration of iodine constitutes a specific test of very great value in the diagnosis of cases of minimal hyperthyroidism. Robertson refers to one patient with hyperthyroidism who had a B.M.R. of minus 8 falling to minus 27, after administration of iodine, and another such patient in whom these figures were respectively minus 2 and minus 15. He points out also (*Practitioner*, Dec., 1935) that the B.M.R. (subject to certain conditions) is remarkably constant for a given normal individual; the "error" of the B.M.R. is often referred to, but this should apply to the differences between the rates of normal individuals, not the differences between rates given by the same normal person at different times. Admittedly, a high proportion of cases of hyperthyroidism can be diagnosed on clinical grounds alone, but it would appear that the response of the B.M.R. to iodine should be used far more widely than it now is in cases of minimal hyperthyroidism, particularly in those worrying diagnostic problems which are presented by such minimal hypersecretion in women of middle age whose symptoms are cardiac.

In regard to technique, the papers referred to repay close study. The answer to your "question" states that "we have no test for thyroid function." I would suggest that the response of the B.M.R. to iodine may fairly claim to be such a test, for, as Robertson states, the "normal" rate shows no change after iodine, but in hyperthyroidism iodine produces almost invariably a significant fall (rarely a rise) in metabolic rate, and Plummer's demonstration of the value of iodine as pre-operative preparation for subtotal thyroidectomy incorporates this essential fact. Of course, the patient with hyperthyroidism generally responds to iodine with a fall in pulse rate, but this test is not infrequently vitiated by the existence of auricular fibrillation. Consideration of the result of a given test necessarily entails inquiry as to whether the patient has recently received iodine, and it would seem that there may be scope in many cases for carrying out the test and the pre-operative preparation over largely the same period of time.

Tobacco Smoking and Nicotine Dosage

Dr. LENNOX JOHNSTON (Wallasey) writes: The answer given to questions on the injured man's "fag" (Oct. 28, p. 585) concluded "... there is no reason to withhold a cigarette from an injured man. Nicotine is a central stimulant, but in small quantities is unlikely to have either a beneficial or deleterious effect in traumatic shock." This answer supports the popular view that the dose of nicotine administered by smoking tobacco is infinitesimal or at all events immaterial. Experimental injections of nicotine, however, given to 35 volunteers and to myself indicated that "the cumulative psychic effect of a cigarette inhaled (approximately 12 inhalations) closely resembled that of nicotine gr. 1/50 hypodermically" ("Tobacco Smoking and Nicotine," Johnston, L. M., *Lancet*, 1942, 2, 742). It was also found that nicotine gr. 1/40 and sometimes gr. 1/50 induced toxic symptoms, which included nausea, vomiting, and faintness, in non-smokers. These experiments point the conclusion that the dose of nicotine administered when a cigarette is inhaled to average depth is in the vicinity of 80% of the toxic dose—hardly a "small quantity." The faintness induced by minimal toxic doses of nicotine in healthy subjects suggests that when cardiac action is depressed, as in traumatic shock, cigarettes should be forbidden. Smokers develop a considerable degree of tolerance to nicotine. How far tolerance protects an addict against the toxic effect of his drug is, however, unknown, while it is certain that the withholding of a dose of nicotine, although causing discomfort, will do no harm. Although nicotine is a central stimulant, my experience of over 150 personal doses suggests that stimulation, which usually lasts 15 to 20 minutes following the administration of 1/50 gr. hypodermically, is followed by a similar or even longer period of depression evidenced by psychic depression and lassitude.

GENERAL ANAESTHESIA IN SHOCK

BY

A. C. CROOKE, M.D.*
Assistant to Medical Unit

C. J. O. R. MORRIS, Ph.D.
Freedom Research Fellow

AND

R. G. BOWLER, B.Sc.
Technical Assistant.

(From the London Hospital)

Operations on seriously shocked patients are associated with a notoriously high mortality. This may be due to further loss of blood entailed during the operation, to the stimulus of the operative manipulations, or to the anaesthetic. In the present investigation an attempt has been made to evaluate the relative importance of these factors and to determine if any modifications of the methods in common use can lessen the mortality rate. It has become apparent that the most important single factor has been the anaesthetic, and an examination has therefore been made of the effect of different anaesthetics on the cardiovascular systems of patients with normal plasma volumes who have undergone various operations. These observations have enabled a clearer interpretation to be placed on the effect of these anaesthetics on shocked patients whose plasma volumes were below normal.

A series of 26 patients with normal plasma volumes were examined, of whom 19 underwent various major operations—the majority a partial gastrectomy—and 7 underwent minor operations. In all cases the pulse and respiration rates and the blood pressure were recorded at about three-minute intervals. Determinations of plasma volume (Crooke and Morris, 1942; Morris, 1944) were made and the dye-concentration curves followed at about 30-minute intervals until the end of the operation. The haemoglobin (Rimington, 1942) was also determined at the same intervals. Electrocardiographic records were made in nine cases which underwent major operations.

Changes in the blood pressure were not found to be related to any particular operative manipulation by the surgeon in any of these cases, but they could be produced by alterations in the depth or type of anaesthesia. The effect of increasing depth of different anaesthetics on blood pressure is summarized in the following table.

Anaesthetic	Blood Pressure				
	Rise	Rise, then Fall	Fall, then Rise	Fall	Constant
Nitrous oxide, oxygen, and ether	5	2	2	2	3
Cyclopropane	7	0	0	1	0
Spinal	0	0	0	4	0
Sodium pentothal ..	0	0	0	2	0

Fourteen patients who were given nitrous oxide, oxygen, and ether underwent major operations. At some period of the operation a large amount of ether was given in order to obtain very deep anaesthesia, but the effect on the blood pressure was very variable. Two examples are shown in Figs 1 and 2. Eight patients were given cyclopropane, but two have already been included in the group who were given nitrous oxide, oxygen, and ether. In these two the anaesthetic was changed to cyclopropane towards the end of the operation. The blood pressure rose in proportion to the depth of the anaesthesia

(Figs. 2 and 3), except in one of three patients who had only minor operations. In this case the blood pressure fell from an initial level of 195/100 mm. Hg to 145/90 mm Hg. Two of the four patients who had spinal analgesics under-

FIG. 2.—Effect of nitrous oxide, oxygen, and ether, followed by cyclopropane and oxygen, on blood pressure, haemoglobin, and dye concentration

went major operations. The blood pressure fell in all of them, and in one the fall was very marked (Fig. 4). Two patients who had minor operations were given sodium pentothal, and the blood pressure fell in both.

* Member of the Mobile Team of the Shock Committee of the Medical Research Council under Sir James Walton.

These changes in the blood pressure did not appear to be effected through any changes in the plasma volume, since the dye-concentration curves and the haemoglobin level showed no significant alterations during the operation, as would have occurred if water had been lost from the blood stream into the surrounding tissues. The plasma volume was determined a second time at the end of all major operations in order to measure the haemorrhage. Anomalous dye-concentration curves were obtained in 10 patients, due to the previous injection of morphine or hyoscine (Bowler, Crooke, and Morris, 1944), but 9 patients had good second dye-concentration curves. Two of these showed an increase of plasma volume, three no change, and four a fall, but the changes were probably within the error of the method. In all these cases very great attention had been paid to haemostasis in order to eliminate haemorrhage

FIG. 3.—Effect of cyclopropane and oxygen on blood pressure, haemoglobin, and dye concentration.

FIG. 4.—Effect of spinal analgesia on blood pressure, haemoglobin, and dye concentration.

as a factor affecting blood pressure, but haemorrhage occurring during an operation can be readily measured, as demonstrated by three other patients who underwent radical operations for carcinoma of the breast. Good dye-concentration curves were obtained, and the plasma volume fell from 3.31 to 2.47 l. in the first, from 2.47 to 2.0 l. in the second, and from 2.87 to 2.73 l. in the third.

The changes in the blood pressure were not effected through the heart, as judged by serial electrocardiograms which were taken in nine cases. Nitrous oxide, oxygen, and ether was given to five of the cases, nitrous oxide, oxygen, and ether followed by cyclopropane to two, cyclopropane and oxygen to two, and a spinal analgesic to one. The three limb leads were recorded in all cases before the operation, and Lead II was then

taken at about 15-minute intervals during the operation, and at other times when marked changes in the blood pressure occurred. Although cardiographic irregularities did take place they were never constant. When present they appeared to be related in no way to the changes in the blood pressure, when these were as marked as those shown in Fig. 4.

When these anaesthetics were given to patients with traumatic shock whose plasma volume was significantly reduced, there was a greater tendency for the blood pressure to fall. Cyclopropane and oxygen generally caused an increase in the blood pressure except in very severe cases, but even here the effect was less pronounced than with the other anaesthetics except Nitrous oxide and oxygen with a minimal amount of ether was the next most satisfactory, but an adequate amount of oxygen was essential. Deep ether or ether-and-oxygen anaesthesia caused a marked fall of blood pressure. In this series there are no records of shocked patients being given spinal analgesics, but several had sodium pentothal. Two of these had extensive burns, and the blood pressure fell from 145/80 mm. Hg to an unreadable figure in one and from 145/80 mm. Hg to 80/60 mm. Hg in the other. Induction was given to both patients by an expert anaesthetist, yet the former died on the operating table and the latter caused some anaemia. Examinations of plasma volume were attempted, but the concentration curves were anomalous because the patients received morphine shortly before injection of the dye.

Illustrative Cases

A number of examples are recorded to show the effects of various anaesthetics on shocked patients whose plasma volume had been determined.

Case 1.—A man aged 49 was injured by bomb splinters at 10.15 a.m., and was admitted to a small hospital together with a large number of casualties. He was probably not severely shocked on admission, because the surgeon had left him in order to deal with what he considered to be more serious cases. He had a compound fracture of the lower third of the right radius and ulna with much laceration of the tissues, a compound fracture of the left ankle involving mainly the astragalus with a metal foreign body retained subcutaneously, and a small deep puncture wound of the right forearm. He was given morphine gr. 1/4 at 11 a.m. At 4.15 p.m. he was conscious, quiet, and listless. His skin was ashen grey, cold, and moist. His pulse was 90 and blood pressure 50/45 mm. Hg. An electric blanket was placed over him. A rapid determination of plasma volume was begun at 4.32 p.m. Only two readings were taken, but they agreed closely, and gave a value of 2.54 l., or about 3.1% of body weight (about 13 st.). His haemoglobin was 10.5 g./100 c.cm. At 4.50 p.m. his condition appeared to be unchanged, but the blood pressure was unreadable. An attempt was made to start a transfusion; but there was considerable delay in getting this working, and it was 5.30 p.m. before it began to run freely. At 6.5 p.m. he had already received 686 c.cm. of plasma, and blood was transfused instead. He was now warm, more restless, and in some pain. At 6.15 p.m. his pulse was 70 and blood pressure 65/40 mm. Hg. At 6.45 p.m. he was definitely better and more co-operative, even smiling at the doctors; his blood pressure was 60/40 mm. Hg. At 6.50 p.m. the transfusion was stopped and he was moved to the theatre. He had now received 924 c.cm. of blood, and at 6.56 p.m. his haemoglobin was 9.6 g./100 c.cm. A further reading of plasma volume based on the initial injection of dye gave a figure of 2.9 l., or about 4.7% of body weight. This showed an increase of 1,360 c.cm. in the plasma volume, and agrees fairly well with the estimated water content of the transfusion, which was 1,300 c.cm., for he had obviously been losing some blood from his injuries during this period. At the same time a second injection of dye was given, and induction with a mixture of ether and chloroform was begun by a practitioner. At 6.58 p.m. the blood pressure was 70/50 mm. Hg. It then fell rapidly, being 65/40 mm. Hg at 7 p.m. 60/40 mm. Hg at 7.3 p.m., and then unreadable. The puncture wound of the left forearm was cleaned and sutured, and the wound of the left ankle was cleaned and sutured and the ankle put in plaster. The right forearm was not touched, for the patient died at 7.10 p.m. A sample of blood taken at this time showed a haemoglobin of 9.6 g./100 c.cm. and a plasma volume of 3.9 l. based on the second injection of dye. This is identical with the reading taken at 6.56 p.m. based on the first injection of dye, and confirms the observation that his plasma volume was now within the lower limit of normal. A post-mortem examination made by Dr. Joan Ross on the following day revealed no other injuries than those already described.

Case 2.—A man aged 29 was injured by bomb splinters at 12.30 a.m. and was admitted to hospital at 1.45 a.m., when his condition was described as "pretty serious." He was conscious but

drowsy and ashen-coloured. His systolic blood pressure was 60 mm Hg and pulse rate 130. He was immediately given morphine gr. 1/4, followed by gr. 1/6 soon after. There was no obvious haemorrhage, so he was left quiet till 4 a.m., when a fuller examination was made. His systolic pressure had now risen to 80 mm Hg. He had a compound fracture of the middle third of the right radius and ulna, total destruction of the ulnar side of the right carpus, and amputation of the right index and middle fingers. There was a laceration on the dorsum of the left ring-finger, with removal of the nail and exposure of the terminal phalanx. There were superficial abrasions of the abdomen. A two-inch-long penetrating wound was present on the outer aspect of the lower third of the right thigh and several small wounds above it. There was a large T-shaped lacerating wound on the anterior surface of the upper third of the right leg, with several small perforating wounds below it. The arterial supply to the lower two-thirds of the right leg had failed. A blood transfusion was started at 6 a.m., when his systolic blood pressure had risen to 105 mm Hg and the pulse rate had fallen to 100. At 8 a.m. two bottles of blood had been given. At 10 a.m. the systolic pressure had again fallen to 85 mm Hg, and the pulse rate was 120. There was little change until 11 a.m., when a plasma transfusion was started, and at 11.20 a.m. morphine gr. 1/4 was given. At 12.45 p.m. an attempt was made to determine the plasma volume. Two readings of 2.58 and 2.63 l. or about 2.8% of body weight (about 12 st.), were obtained. These figures are not very reliable, because morphine had been given only 80 minutes before injection of the dye and a slow transfusion was being carried out at the time. The haemoglobin was 11.8 g/100 c.c.m. At this time his blood pressure was 105/65 mm Hg. Two bottles of plasma were then given, and at 4 p.m. his general condition had improved considerably, and the systolic pressure was 130 mm Hg. At 8 p.m. the systolic pressure was 120 mm Hg, and at 8.40 p.m. a second determination of plasma volume was begun. No more morphine was given until 8.45 p.m., when a reliable curve was obtained, giving a value of 3.6 l., or about 3.8% of body weight. The haemoglobin was 11.4 g/100 c.c.m. Induction with nitrous oxide oxygen and a little ether was begun at 9.31 p.m. The blood pressure was 100/55 mm Hg immediately before anaesthesia was started. It rose to 110/65 mm Hg at 9.35 p.m., and then fell gradually to 80/50 mm Hg at 9.59 p.m. Subsequently it was maintained at 85/50 mm Hg until the operation ended at 10.20 p.m. No ether was given after 9.38 p.m. and no nitrous oxide after 9.52 p.m., but oxygen was continued until the end of the operation. During this time the wounds were cleaned, and dead tissue and a few small fragments of loose bone were removed. The affected limbs were covered with vaseline packs, the right arm up to the hand encased in plaster, and the right leg bandaged. At 10.55 p.m. the systolic blood pressure had risen to 100 mm Hg, and it continued to rise gradually to 140 mm Hg at 8 a.m. on the next day. He was too ill, however, to have his gangrenous leg amputated, and he died at 4.30 p.m.

Case 3—A man aged 56 was admitted to hospital at 11.52 a.m. shortly after being injured by a falling chimneystack. He was alert and in considerable pain. His skin was warm, moist, and of fairly good colour. He had a compound fracture of the lower third of the left tibia and fibula, a hematoma of the scalp above the left eye, and pain in the chest, especially on antero-posterior compression. His pulse rate was 47 and his blood pressure 110/60 mm Hg at 12.30 p.m., when he was given morphine gr. 1/4. At 1.50 p.m. a determination of plasma volume was begun. In spite of having had morphine recently, a flat curve was obtained over the next five hours. It showed a value of 3.3 l., or 4.3% of body weight (12 st.) and his haemoglobin was 12.2 g/100 c.c.m. His general condition remained unchanged during the afternoon, and at 5 p.m. his pulse rate was 48 and his blood pressure 130/70 mm Hg. At 5.10 p.m. anaesthesia with nitrous oxide, oxygen, and a minimum amount of ether was begun. His pulse rate increased to 96 and blood pressure to 170/75 mm Hg at 5.20 p.m. The pressure then gradually fell to 140/75 mm Hg at 5.45 p.m. and remained at about this level until the anaesthesia ended at 6.35 p.m. During this time the wound in his leg was cleaned and excised, pins put through the two fragments of the tibia, the fracture reduced, a dressing applied, and the leg and foot put in plaster-of-Paris. Subsequently he made a good recovery.

Case 4—A woman aged 38 was admitted to hospital at 11 p.m. semiconscious and smelling strongly of beer, having been picked up in the street. No further history was obtainable, but she was found to have multiple lacerations of the scalp, and a laceration of the left ankle, with an oblique fracture of the left tibia just above the malleolus and involving the articular surface. She was drowsy but abusive if roused. Her skin was moderately pale and sweating, her pulse rate was 80 and her blood pressure 100/60 mm Hg. A determination of plasma volume was begun at 11.31 p.m., and gave a figure of 2.1 l., or about 3.8% of body weight (about 8½ st.). The haemoglobin was 14 g/100 c.c.m. She was given morphine gr. 1/4 at 11.52 p.m. and anaesthesia was begun at 2.3 a.m. Cyclopropane was given first, and the blood pressure, which was 100/65 mm Hg when anaesthesia started, was maintained at about 110/80 mm Hg

until 2.23 a.m. Ether was then gradually substituted and the blood pressure became erratic, eventually falling to 80/60 mm Hg at 2.38 a.m. Ether was then withdrawn, and the blood pressure returned to 100/80 mm Hg at 2.41 a.m. The patient was beginning to come round, and cyclopropane was given again from 2.42 to 2.47 a.m., the blood pressure being maintained at about 100/70 mm Hg. During this time the wounds were cleaned and sutured, the fracture reduced, and the ankle put in plaster. Subsequently she made an uninterrupted recovery.

Case 5—A man aged 67 was knocked down in the street by a lorry at 6.30 a.m. and sustained a comminuted fracture of the left femur and a right Colles fracture. On admission to hospital at 7 a.m. he was conscious and in considerable pain. His pulse rate was 45, with many extrasystoles, and his blood pressure 170/80 mm Hg. At 9.20 a.m. his pulse rate had increased to 82 and his blood pressure had fallen to 110/60 mm Hg. His skin was very pale, but warm and not sweating. A determination of plasma volume was begun at 9.30 a.m., and gave a figure of 3.05 l., or about 4.8% of body weight (about 10 st.). The haemoglobin was 8.8 g/100 c.c.m. There was no appreciable change in his condition throughout the day. He was given morphine gr. 1/4 at 11.15 a.m. and omopon gr. 1/3 and scopolamine gr. 1/150 at 4.28 p.m. A second determination of plasma volume was begun at 4.32 p.m., but gave an anomalous curve. He was taken to the operating theatre at 5 p.m. and intravenous pentothal was given at 5.22 p.m. There was a rapid fall in blood pressure from 110/70 mm Hg, taken immediately before anaesthesia started, to 85/55 mm Hg six minutes later. Thereafter the blood pressure was maintained at about 90/55 mm Hg until the operation ended at 5.48 p.m. Altogether 0.5 g of pentothal was used. A Kirschner wire was inserted through the upper end of the tibia and extension applied to the femur. The Colles fracture was reduced and a plaster applied. Subsequently he improved steadily, the blood pressure returning to the original level of 110/70 mm Hg at 7 p.m. Unfortunately, he had to undergo a further operation four days later for malposition of his fractured femur, and afterwards he developed pneumonia and died.

Discussion

The effect of various anaesthetics on plasma volume and the cardiovascular system has been extensively studied. It has been claimed that some anaesthetics—notably ether—cause a reduction of plasma volume in the human subject (Bonycastle, 1942). No significant changes were found, however, in the present series of cases even with prolonged anaesthesia for major abdominal operations unless there was appreciable haemorrhage such as occurred with radical operations for carcinoma of the breast.

That the anaesthetics affected cardiac action seems unlikely, because no significant changes were found in the electrocardiograms of patients showing such profound alterations of blood pressure as that revealed in Fig. 4.

It seems likely, therefore, that the main effect of anaesthetics on blood pressure is by the vasomotor system. Most anaesthetics lower the blood pressure, but nitrous oxide, oxygen, and ether may elevate it, and cyclopropane and oxygen nearly always elevate it. In shocked patients all anaesthetics tend to be more depressing, and in patients whose plasma volume is much reduced the effect of depressing anaesthetics may be disastrous. This may apply to severe cases even after the plasma volume has been restored to normal, because the vasomotor system is apparently unstable for some time afterwards. Case 1 is an example of this. A man was wounded in the peripheral parts of his limbs and the bleeding was not checked. His plasma volume fell in the next 6½ hours to 3.1% of body weight, his haemoglobin to 10.5 g/100 c.c.m., and his blood pressure became unreadable. A transfusion during the next 2½ hours restored his plasma volume to 4.7%, which is within the lower limit of normal; his haemoglobin was then 9.6 g/100 c.c.m. There was considerable improvement in his general condition, but the blood pressure was still only 70/50 mm Hg. An operation was undertaken 8½ hours after the injury to clean the wounds and arrest further bleeding. So little was done surgically that it can have had only slight effect on the general condition, but the anaesthetic, a mixture of ether and chloroform, caused a rapid progressive fall in blood pressure and death in nine minutes.

The use of nitrous oxide and oxygen with a minimal amount of ether has a much less depressing effect, as demonstrated by a somewhat comparable patient (Case 2) who sustained severe wounds, chiefly to the peripheral parts of his limbs. Two bottles of blood were given between 5½ and 7½ hours after

the injury, and the plasma volume 12½ hours after was about 2.8% of body weight. The haemoglobin was 11.8 g./100 c.cm. There was a temporary improvement after the first transfusion, but the blood pressure subsequently fell to 85/50 mm. Hg, and two bottles of plasma were given, therefore, between 10½ and 15½ hours after the injury. A second determination of plasma volume 19½ hours after the injury gave a figure of about 3.8% of body weight; the haemoglobin was 11.4 g./100 c.cm. Anaesthesia was begun 21 hours after the injury, and the blood pressure rose from 100/55 to 110/65 mm. Hg in the first 4 minutes and then fell steadily to 80/50 mm. Hg in the next 15 minutes. Ether was stopped after the first 7 minutes. The blood pressure was then maintained at 85/50 mm. Hg until the operation ended 49 minutes after the anaesthetic began. During the next 12 hours the systolic pressure rose to 140 mm. Hg, although eventually the patient died with a gangrenous leg.

In less severe cases nitrous oxide and oxygen with a minimal amount of ether may cause the blood pressure to rise, as demonstrated by Case 3. This patient sustained a compound fracture of the left tibia and fibula. His blood pressure was 110/60 mm. Hg 40 minutes after the accident, and his plasma volume was 4.3% of body weight and haemoglobin 12.2 g./100 c.cm. two hours after. No transfusion was given. When anaesthesia was begun 5½ hours after the accident his blood pressure was 130/70 mm. Hg. It rose to 170/75 mm. Hg in the first ten minutes and then fell gradually to 140/75 mm. Hg in the next 25 minutes, remaining there till the operation ended 50 minutes later.

The best anaesthetic used in our shocked patients was cyclopropane and oxygen. It was employed in Case 4. This patient, who had a crushed foot and lacerated scalp, had a plasma volume of 3.8% of body weight and haemoglobin of 14 g./100 c.cm. 30 minutes after the accident. The blood pressure was then 100/60 mm. Hg. Anaesthesia was begun three hours after the accident, and the blood pressure rose slightly to 110/80 mm. Hg, where it remained for the next 20 minutes. At this time the cyclopropane was gradually changed to ether for the purpose of comparison, and the blood pressure fell during the next 15 minutes to 80/60 mm. Hg. After withdrawal of ether the blood pressure recovered, and it was maintained at 100/70 mm. Hg during the last five minutes, when cyclopropane was given again.

In attempting to assess the depressing effects of anaesthetics on the cardiovascular systems of shocked patients, it is necessary to emphasize that quite severe injuries can occur with little reduction of plasma volume. This may explain why the lowering of blood pressure by an anaesthetic is sometimes less than might be expected. It occurred in Case 5, a man who sustained a compound fracture of the left femur and a right Colles fracture. His plasma volume was within the lower limit of normal—about 4.8% of body weight—his haemoglobin was 8.8 g./100 c.cm., and his blood pressure was 110/60 mm. Hg three hours after the accident. During the next 11 hours his general condition remained about the same and his blood pressure was 110/70 mm. Hg when intravenous anaesthesia with sodium pentothal was begun. It then fell steadily to 85/55 mm. Hg in the next six minutes, and remained at about this level until the anaesthesia ended 25 minutes later.

The chief factors in anaesthetizing shocked patients seem, therefore, to be, first, the use of a minimal amount of anaesthetic—and it is often surprising how little these patients require; secondly, the choice of an anaesthetic which stimulates rather than depresses the cardiovascular system; and, thirdly, an adequate amount of oxygen. It is unfortunate that the two most satisfactory anaesthetics—cyclopropane and oxygen, and nitrous oxide, oxygen, and ether—both require somewhat elaborate apparatus. Fortunately, however, in modern war it is possible for the great majority of patients to be brought back for operations to base hospitals where such apparatus is available.

Summary

Plasma volume and haemoglobin concentration were measured repeatedly in 26 patients undergoing various operations under nitrous oxide, oxygen, and ether, cyclopropane and oxygen, sodium pentothal, and spinal analgesics. No significant changes were found, although marked alterations in blood pressure occurred.

Serial electrocardiograms examined in nine patients showed no constant changes even though a marked alteration in blood pressure had taken place.

It is concluded that anaesthetics affect blood pressure mainly through the vasomotor system.

Cyclopropane and oxygen tended to raise the blood pressure; nitrous oxide, oxygen, and ether had variable effects on it; sodium pentothal and spinal analgesics depressed it.

In patients whose plasma volume was reduced by trauma there was a greater tendency for these anaesthetics to depress blood pressure.

Cyclopropane and oxygen was the best and nitrous oxide with adequate oxygen and a minimal amount of ether was the next best anaesthetic for these cases.

We are indebted to Dr. Miles for access to clinical material and to Mr. Whittingham and Dr. Murdoch for their co-operation in the cases undergoing major operations at Oldchurch Hospital Romford. Dr. William Evans kindly examined the electrocardiograms for us.

THE USE OF PENICILLIN PASTILLES IN ORAL INFECTIONS

A PRELIMINARY REPORT

BY

ALEXANDER B. MacGREGOR, M.A., M.D.

M. and L.D.S., R.C.S.
Squad. Ldr., R.A.F.V.R.

AND

DAVID A. LONG, M.B., B.S.

Demonstrator of Pathology, St. Bartholomew's Hospital;
Pathologist, E.M.S.

In July of this year it was decided to attempt to treat various types of oral infection with local penicillin. Previous experience had shown that the use of a spray was unsatisfactory in the treatment of acute tonsillitis, presumably owing to the transient action so exerted, and it was felt in consequence that if any success were to be obtained, a means of maintaining an adequate concentration of penicillin in the mouth would be required.

It was therefore decided to try the effect of penicillin contained in a pastille. For this purpose a slow-melting medium unlikely to cause excessive salivation, approximately neutral in reaction and not containing any penicillin inhibitor, was required. This was found in gelatin. To the gelatin base 0.1% nipagin was added in order to preserve the pastille, though whether this was necessary is doubtful, as pastilles kept over a period of three months do not appear to have deteriorated, apart from a slight hardening of the medium. In the preparation of the pastilles care was taken that the penicillin was not subjected to excessive heat; it was added to the gelatin base at 42°C and stirred in just before the latter was about to set. Pastille were cut to a standard size of approximately 3/8 in. square and 1/8 in. thick to facilitate insertion and retention in the buccal sulcus, and for trial purposes they were made in varying strengths from 1,000 units of penicillin to 100 units in each pastille.

With these pastilles experimental work was then carried out in order to determine: (1) that the penicillin derived from the pastille was present in effective concentration in the mouth, and that this concentration could be maintained; (2) that the incorporation of the penicillin in the pastille base would not interfere with its action, and that the pastille would keep and would remain active after its manufacture; (3) the effect of the pastille on the mouth and throat and their bacterial flora; (4) the required dose of penicillin in each pastille.

The results of these investigations were as follows:

1. A pastille containing 500 units of penicillin was allowed to melt in the buccal sulcus. After 15 minutes the pastille was removed and the penicillin content of the saliva was estimated by the standard technique. Further estimations at 15 and 30 minutes after removal

the presence of haemolytic streptococci after treatment with pastilles had been initiated, and it was possible to show that they were present only by what would be ordinary standards be considered gross over-inoculation. As previously stated, plates in which penicillinase was used were identical with those in which it was not used.

3. Chronic Streptococcal Throat Carriers

Twelve patients, all asymptomatic but proved by culture to be chronic carriers, were treated with pastilles given over a period of five days. Since they did not show any symptoms or noteworthy signs, the bacteriological results only will be discussed.

Bacteriological.—Of the 12 patients, seven gave negative cultures within 24, three within 48, and two within 72 hours. Two still show no haemolytic streptococci a month and six weeks respectively after cessation of treatment; one who became negative after 48 hours has not been seen again, and the remaining nine became positive within 1 to 15 days after stopping treatment, the average being 6 days. It was evident from these results that carriers could be kept clear while having pastilles, but that in the great majority of patients the organisms returned soon after cessation of treatment.

That the pastilles might be of some value even in carriers was shown by the case of a medical student who was known to be a carrier but who was unwilling to part with his tonsils. The presence of Group A haemolytic streptococci was not compatible with midwifery, and an attempt was therefore made to eliminate the organisms with a course of pastilles. Cultures became negative within 24 hours, but were positive again a few days after cessation of treatment. This result was repeated with a second course of pastilles, and it was decided, in consequence, that although his throat was a potential menace without pastilles, with them it was safe, and he was allowed to finish his course by taking them before and during deliveries.

4. Operations in the Mouth and Lesions of the Oral Cavity involving Loss of Surface

Three cases of fracture of the mandible compound into the mouth, two of difficult dental extraction involving considerable trauma, three of ulceration of the mucous membrane unassociated with Vincent's organisms, and three post-tonsillectomy cases have been treated. While these are too few in number for any definite conclusions to be drawn, certain facts are suggestive.

Fractures of the Mandible Compound into the Mouth.—All three patients with fracture of the mandible showed fractures at the region of the junction of the ramus and body of the mandible, and in one the fracture was bilateral. They were first seen 2, 5, and 15 days respectively after the original injury, had received no treatment at all, and all showed fractures compound into the mouth with displacement of the posterior fragment, and gross sepsis in the region of the fractures. All had marked external swelling over the fracture area and intense oral fetor, while one seen for the first time 15 days after injury showed a marked ulcerative gingivostomatitis associated with Vincent's organisms dating from the injury. Smears and cultures taken from the fracture line revealed many extremely penicillin-sensitive anaerobes. Within 24 hours of starting treatment the intense fetor had gone and patients stated that the mouth felt "cleaner." Cultures taken from the fracture line at this point were sterile in two cases, and in the third case yielded a small growth of *Haemophilus influenzae* only. Forty-eight hours after starting treatment cultures were negative in two patients and showed coliforms only in the third. The spirochaetes and fusiform bacilli present in the patient with associated ulcerative gingivostomatitis were entirely absent after 48 hours. Fixation and splintage of the mandible was carried out 24 hours after admission. In all patients the external swelling and oedema subsided at the end of a week. Two fractures have united firmly without incident, and the third appears to be uniting, though as only a fortnight has elapsed since the patient's admission the final result is not yet assured. In no case did local abscess formation occur.

Difficult Dental Extraction with Associated Trauma.—In two patients in whom lower molar teeth were extracted under regional novocain analgesia carious crowns broke off and

elevators were used for extraction of the roots, causing damage to the bone and tearing of the gum. After the extractions the patients were given pastilles and were forbidden to use mouth washes. In both cases the blood clot remained *in situ* as in an uncomplicated extraction and the gum healed rapidly without sloughing.

Ulceration of the Oral Mucous Membrane unassociated with Vincent's Organisms.—Three patients have so far been treated. Two showed large single painful ulcers inside the lip, and one had large multiple ulcers over the area of the uvula, lip, tongue, and cheeks. In the latter the ulcers had recurred over a period of 14 years, the Wassermann and Kahn reactions were negative, and the blood count was normal. Of the first two patients, one had a pure growth of pneumococci from the ulcer and the other a mixed growth of pneumococci and haemolytic streptococci, with the former predominating. In the first two patients cultures were sterile 24 hours after the beginning of treatment. The ulcers were healed in six and eight days respectively. In the third patient haemolytic streptococci and pneumococci were present in large numbers in the ulcerated areas of the uvula, lips, and tongue. No organisms could be demonstrated in any of these areas 24 hours after treatment had begun. During the next 10 days coliforms only were present. With the exception of one small area on the tongue, the ulcers were healed at the end of a fortnight, and coliforms also were found in the cultures of the remaining area for one week after cessation of treatment. The patient was then sent on three weeks' leave. On return, three more ulcerated areas were present, and these proceeded to increase in size until the condition was very much as it was when first seen. Haemolytic streptococci and pneumococci were again present in large numbers.

Post-tonsillectomy.—Three patients have been treated. Two the tonsillar beds were sterile after 24 hours' treatment; they then started to show coliforms, *N. catarrhalis*, and *H. influenzae* in the cultures on the third and fifth days respectively. Both healed rapidly, with a reduction in the usual slough. The third yielded a profuse growth of haemolytic streptococci from the tonsillar beds after operation. The streptococci were greatly reduced in numbers after treatment for 24 hours and were absent after 72 hours.

Conclusions

Penicillin included in a pastille under suitable conditions of manufacture is liberated in the mouth in an active form. Its concentration in the mouth can be maintained and the pastille kept for a period of at least three months without appreciable deterioration or loss of efficiency of the penicillin. It is simple to use and is well tolerated even by children. (The youngest patient receiving pastilles was aged 5.)

Acute ulcerative gingivostomatitis (Vincent's type) can be treated more simply and more quickly with the use of penicillin pastilles than by any other method. In addition, the loss of tissue caused by the more usual treatments with caustics or escharotics can be avoided. It is not suggested that gingivectomy or other procedures to eliminate the gum pockets or stagnation areas will not be necessary at a later date, since while these pockets and areas remain, the possibility of recurrent infection is always present. The treatment described advocated in the acute stages, and the fact that no recurrence have been seen over a period of three and a half months suggests that immediate recurrence is unlikely. In view of the fact that intravenous arsenicals are still widely employed in the treatment of the disease in spite of much evidence to show that it is ineffective, we consider that it is worth drawing attention to the fact that three of our most severe cases have been undergoing treatment for syphilis with injections of bismuth and intravenous arsenicals.

Patients with acute haemolytic streptococcal tonsillitis, including four with scarlet fever, seemed to respond clinically to treatment with pastilles. The effect on the throat flora appeared to be rapid, but, even so, a larger series of cases is necessary before any final conclusions can be drawn. The early disappearance or reduction in numbers of haemolytic streptococci in the throat after treatment had started suggests that the risk of droplet infection is greatly reduced, and we regard this point as of importance epidemiologically.

The treatment of throat carriers of haemolytic streptococci proved disappointing, as was anticipated. Nevertheless it is of interest that they became negative while undergoing treatment, and, in the case of the medical student described, this fact proved of practical value.

In the small series of patients so far treated it appeared that surgical conditions of the mouth and throat could be kept free from pathogenic organisms during administration of the pastilles, with marked symptomatic relief.

On bacteriological grounds faucial diphtheria should be an indication for treatment with penicillin pastilles. Unfortunately we have as yet been unable to obtain suitable cases but it is hoped to publish these results later in a fuller report.

We would like to express our gratitude to the Penicillin Clinical Trials Committee of the Medical Research Council and Prof. L. P. Parrot for providing the penicillin which made the investigation possible, and to the latter for his encouragement and helpful criticism. We are indebted to Miss G. E. Root for grouping the streptococci and cheerfully accepting other onerous duties. We could also like to thank Dr. Paton, the matron and staff of the Sisters' Hospital for Infectious Diseases, St. Albans, for their kind co-operation; Lieut.-Col. O'Connor, and Captains Batten, Fairhurst, and Patterson of the Army Dental Corps for their help in referring cases of ulcerative gingivostomatitis to us, and many members of St. Bartholomew's Hospital Staff at Hill End E.M.S. Hospital, St. Albans, for kindly allowing us to treat their cases. We are greatly indebted to Mr. L. T. Martin, of the dispensary Hill End Hospital, for making the pastilles.

AN ANALYSIS OF 259 OF THE RECENT FLYING-BOMB CASUALTIES

BY

R. C. BELL, M.B., M.R.C.S.

Resident Surgical Officer to an E.M.S. Hospital

THIS is an attempt to present a picture of the recent flying-bomb raids as seen in a small E.M.S. hospital. For those interested in figures I have included tables. We admitted anyone requiring treatment that the rest centres could not provide. The selection was quite varied: by no means all our patients needed dramatic surgery to staunch a sea of blood, and some of our bizarre cases presented interesting problems. At the least was a poor soul who had been blown into the tank of dirty industrial oil and appeared in the midst of a rush of casualties: we used our gas-decontamination centre for the first—and we hope the last—time.

In order to keep on admitting every day, every night—sometimes several times in the same night—we conveyed our patients soon as they were fit to travel. Conveying has its own advantages and disadvantages. The former are obvious in the high turnover possible; the latter only appear later. We came the first cog of a large wheel. We admitted; we provided immediate treatment; we darned and patched and then transferred our patients at the first possible moment, accompanied by only brief notes. Continuity of treatment is hard to suffer, and it is very difficult to estimate the success or failure of one's efforts. This is the great weakness of our service. Some of our cases went as far afield as Wales: their progress we knew nothing until discharge notes—like as brief as ours had been—came trickling in. Later still a few of the patients themselves began to arrive as out-patients for review, but many have fallen by the wayside. There are great gaps in the story—inevitably so; some so big that I wondered if it were possible to hold the interest in our jumbled facts and many loose ends; but I felt that each link in the chain were pieced together—the casualty hospital, the base hospital, the ambulance trains, the distant evacuation centres—the story would be worth while.

In all we dealt with 222 out-patients and 259 in-patients, with 18 deaths. Our story began in June, 1944, when the first large incident occurred near by. Twenty-six casualties were admitted and 12 required theatre treatment. This proportion remained fairly constant throughout the series. Altogether we had 83 theatre cases out of 259 admissions, and had to deal with 35 cases on untreated, most of whom required the theatre. In this first incident no fewer than 16 of the casualties were

due to flying glass. It was noticeable how the proportion of glass injuries dropped as the importance of taking adequate cover was realized while the percentage of crush injuries increased from people being trapped by falling masonry.

In July we admitted 32 patients from a neighbouring hospital which had been hit, only to send them on in a few hours, to the great grief of the nursing staff, who had just succeeded in disentangling prostatic tubes from false teeth and restoring order out of chaos.

A night in July began our peak period. We admitted 24 cases, 6 requiring theatre treatment. Next morning, at 10 o'clock, a flying bomb dropped in a near-by market-place. The incident caused the highest number of casualties of the whole London attack. We admitted 74 to the wards and dealt with over 90 in the casualty department. At one time we had ambulances evacuating the night's casualties, waiting their turn with ambulances bringing fresh wounded. In 24 hours over 100 patients were wards. This is the brighter side of the convoy system. As we could not deal with all the cases in our single theatre in reasonable time we re-evacuated 35 patients after rest, cleaning, and first-aid attention, and 15 more who had had minor operations. The most gravely injured we retained. In the tables T refers to the transferred cases, and any remarks about them are more liable to error since only a clinical diagnosis was made at the bedside and was unsupported by further investigations.

So much for the conditions. It was impossible to obtain complete accuracy when the cause of every death could not be proved by necropsy and some of the cases were whisked away with only a partial diagnosis.

Air-raid casualties may be divided into two great groups: (1) those who require surgical treatment, and (2) those who do not.

GROUP 1: REQUIRING SURGERY

These cases are best described in reference to the agent which caused the injury. Any patient may fall into more than one such category.

A. Flying Glass

This was the most frequent cause of injury, totalling over 100 casualties in all. Many included severe damage to the eyes. It is noticeable that most of the injuries were above the nipple line, chiefly of the face and neck: a large proportion were received when looking out of windows—a modern version of curiosity killing the cat. We had five cases of perforating wounds of both eyes and ten perforating wounds of one eye. The globe was usually completely destroyed. Many of these injuries were avoidable, and therein lay their great sadness.

The penetrating power of flying glass is, in the main, low. It is unusual for it to pierce the deep fascia. Usually it lies just under the skin in the fat, but when present in hundreds of pieces it presents a problem which has not yet acquired a satisfactory solution; nor has the condition made its way into the textbooks of war surgery. Often the gashes are also begrimed with earth, wood, and stones. Orthodox surgical toilet is an impossibility, or at least ill advised. We had two outstanding examples of this condition, which may stimulate interest and which are quite comparable in that the wounds were of roughly the same intensity and situation and both patients were very bad surgical risks—fat, heavy, and chronic bronchitics.

Case I (Miss X., aged 58)

This patient was admitted on June 23 suffering from compound fracture of the medial epicondyle of the left humerus, with surrounding destruction of skin and subcutaneous fat for an area of three-quarters of a square foot on the posterior surface of the arm. There was a similar wound on the posterior surface of the right arm, except that it was without bony injury. Her back was lacerated by flying glass—there were probably 100 cuts in all. On admission she was barely conscious, with a blood pressure of 90/70, and her pulse was scarcely perceptible. She was treated for shock by morphine, rest, hot-water bottles, and hot sweet tea. She was given A.T.S. 3,000 units and A.G.G.S. 4,000 units. An attempt to administer intravenous fluids by the legs failed owing to previous extensive ligation and injections for varicose veins, and her arms were unsuitable for intravenous therapy because of the many cuts. Some six hours after admission her condition had considerably improved; blood pressure had risen to 110/80, and she was quite rational and complaining of pain. She was taken to the theatre.

C. Masonry

At the beginning of the series these injuries were uncommon. Later they became more frequent as adequate cover was taken, and instead of being killed the victims were buried with varying degrees of trauma. We did not have a single case of crush syndrome with oedema of the injured part, anuria, and uraemia. This is probably due in great measure to the increased speed of the A.R.P. rescue service, and possibly to a lessening in the enthusiasm for intravenous plasma therapy. The injuries tended to be severe, and there was a proportionately high death rate—9 out of 52.

TABLE III.—Masonry (52 Cases)

Description	No. and Remarks	Deaths
Fractures of limbs and pelvis	23 (16 severe; 7 minor) 1 T	3
Fractures of skull	7	6
Dislocations:		
Hips	1	
Tarsus	1	
Shoulder	2 2 T	
Lung injury	1 (with surgical emphysema and haemoptysis)	
Bruising	17 3 T	

D. Blast

(a) *Affecting the Lungs.*—It was difficult to estimate the number of patients whose lungs were affected by blast and to assess the relative damage caused by blast in contradistinction to the other agents. Three patients, however, presented a clear syndrome not confused by other lesions. They had severe pain in the chest, breathlessness, and traces of blood in the sputum, without any visible lesion of the bony cage in the radiograph. One of these died, and he provides the one certainty.

This man had been repairing a cinema roof when a bomb fell about 100 yards away. He lay down on the tiles, but the left side of his body caught the full force of the blast. On admission he was concussed and irrational; he appeared to be drunk. Later he was taken to the theatre for repair of a facial gash made by flying slate. His confusion increased after the operation, and he died two days later with signs of consolidation of the left lung. At necropsy he was discovered to have: (i) a gross contusion of the left side of the brain; (ii) a gross contusion of the left lung; (iii) a small split in the capsule of the spleen, with a little free blood in the abdomen; (iv) a haematoma over the lateral side of the left femur. Microscopy showed blood cells among the brain tissue and blood cells in most of the alveoli of the left lung. Many of the alveolar walls were torn.

(b) *Affecting the Eyes.*—Again it is difficult to decide on the exact part played by blast in eye injuries. From personal experience of a flying bomb at 400 yards in the open, when lying down, there were a few seconds of smarting and a feeling of pressure on the eyes, comparable to that of the impact when diving 10 ft. into water. There were four hyphaemias, which were not explicable except as the result of blast; in other cases the cause was obscured by the presence of dirt, debris, or perforating wounds of the globe.

(c) *Affecting the Brain.*—Once more there was great difficulty in deciding whether blast had been the sole agent, but the cases recorded in Table IV almost certainly were due to blast alone.

TABLE IV.—Blast Injuries (26 Cases)

Description	No.	Remarks	Deaths
Eyes:			
Hyphaemia	4		
Injured iris	3		
Subconjunctival haemorrhage	2		
Contusions	6		
Lungs	1 T		
Cerebral concussion	2	Two cases had blood in C.S.F. One had free blood cells in brain tissue (see above) One had sudden paralysis of left arm	2
Cerebral contusion	3		
Severe bruising	2		

E. Burns

The number of burns (9) in the series was low (Table V). All these burns appeared to be of partial skin thickness, but it is impossible to tell accurately until they are five days

TABLE V.—Burns (9 Cases)

Description	No.	Deaths
Extensive partial-skin-thickness burns of body	6	1 died a few minutes after admission
Burns of hands and arms	2	
Burns of face	1	

old, owing to tissue coagulation due to heat. Of the three with more than half the body involved, one died shortly after admission and the other two were conveyed a few days later. They were treated initially for shock by fluids, plasma, morphine, etc., and then subjected to a quick clean in the theatre with cetab or half-strength dettol (depending upon the surgeon), taking care not to spend at the outside more than 10 minutes over the toilet. The areas were then dressed with sulphamilamide powder and tulle gras or vaselined gauze roll. The use of any agent which obscures the future view of the wound is unsound. When the dressings required changing the patient was put in a normal-saline bath and the dressings soaked off. The final results, so far as we have been able to determine, have been quite satisfactory.

GROUP 2: NON-SURGICAL CASES

These fell into five categories:

A.—Cases transferred from other hospitals and requiring food, clothes, and a wash.

B.—These were cases of the crippled and infirm who could not be dealt with by a rest centre. We had several paraplegics, diabetics, etc. In all there were 15 in this category.

C. *Hysteria, Fear, and Other Psychological States.*—Some of these cases were interesting. A man was admitted who had been about 100 yards away from a bomb. For some hours afterwards he continued his work (heavy rescue) and then collapsed and began to count "one, two, three, four, five, six" over and over again. He was quite rational, and complained bitterly of the compulsion to count. He was given a sedative, and next morning appeared to be normal. Another man was admitted in an extreme state of acute fear, with grossly dilated pupils which did not respond to light. We had a second case of paralysis of the pupillary constrictor mechanism through chronic fear.

An intelligent woman (aged 24) was admitted with widely dilated pupils; the right was quite irresponsive to light, and the left contracted only very slightly. There was also marked sweating. In a few days the left eye had improved a little. She was sent away from the bombing to the country, but even then took about six weeks to make a full recovery.

One woman in an acute anxiety state required heavy doses of paraldehyde to keep her at all manageable.

In Table VI it will be seen that I have used the terms "psychological" and "surgical" shock. Psychological shock was a term we coined to cover hysteria, fright, and mental upset requiring only rest and reassurance. Surgical shock was used for patients who had had some physical injury and whose pulse or blood pressure had been affected but who did not need theatre treatment.

D. *Dust.*—Two organs were affected by this agent. Corneal abrasions were very common—so common that they were reported in the notes only if they were severe. The 17 cases in Table VII therefore represent only the more serious lesions. As a routine, any affected eye was irrigated with boric acid. and sulphacetamide drops, 30%, were instilled. Some received atropine drops, 1%, in addition. The respiratory system also suffered from the effects of dust. At operation the anaesthetist remarked time and time again on the dirt in the pharynx and trachea. Unfortunately no record was kept of these cases, but standing out in my memory are two in which the inside of the trachea was quite black and dry with caked dust. Both patients died a few hours later; one almost certainly through the respiratory condition. Of the cases in which the dust lesion was the main injury, in one a severe cough developed in a young healthy male, and he was too ill to convey for several days. In another the dust inhalation precipitated a severe asthmatic attack. I happened to mention these two cases to an

air-raid warden, who told me that several of the dead found by his rescue party had been suffocated by dust—the mouth, nose, and throat being completely blocked, while no other injuries were visible.

E. Oil.—The last physical agent we encountered was oil, and the only problem was to clean the victim up in the midst of a heavy rush of casualties. The gas-decontamination chamber provided a satisfactory answer.

TABLE VI.—Non-surgical (132 Cases)

Description	No.	Remarks	Deaths
Chronic sick transferred from other hospitals	32	4 T	
Crippled and infirm	15		
Psychological shock	39		
Surgical shock	28		
Dust:		Eyes affected as well	1
Corneal abrasions	17		
Respiratory tract	4		
Oil	1		

Conclusion

An attempt is made to review 259 air-raid casualties admitted to an E.M.S. hospital in the recent flying-bomb attacks and to analyse the types of injuries and the agents which caused them. I include three further tables to aid the analysis.

TABLE VII.—Eye Injuries (52 Cases)

Agent	No. and Description	Deaths
Glass	20 eyes with perforating wounds 1 conjunctival abrasion. (2 T)	1
Dust*	17 corneal abrasions and conjunctivitis	
Blast	1 traumatic iritis 1 ruptured iris 2 contusions 3 subconjunctival haemorrhage 4 hyphaemia	
Bomb splinter	1 perforating wound of globe	
Fear	2 cases of acute dilatation of the pupils, which did not contract to light	

* It is probable that many of these lesions were due to blast and that the presence of dust was coincidental. In several cases the corneal and scleral epithelium had been wiped off, leaving a denuded circular area of varying diameter, the largest about half an inch.

TABLE VIII.—Fractures (39 Cases)

Agent	No. and Description	Deaths
Masonry	23 (mostly severe fractures), 1 T	3
Glass	4 minor fractures	
Bomb fragments	5 severe 3 minor	1
Cause unknown	4	

TABLE IX.—Head Injuries (23 Cases)

Agent	No. and Description	Deaths
Masonry	7 cranial fractures 1 cerebral irritation (blood in C.S.F.) 1 unconscious	6
Blast	1 paralysis of left arm 1 partial paralysis of left arm 1 mental confusion 3 contusions 4 concussions	
Cause unknown	1 unconscious 1 contusion 1 concussed (4 hours' retrograde amnesia)	1
Bomb splinter	1 lodged in frontal lobe (now convalescent)	

Guidance to local authorities in England and Wales as to the lines on which proposals to provide temporary housing should be framed is given in a memorandum entitled *Temporary Accommodation* by the Ministry of Health and the Ministry of Works (H.M. Stationery Office; 6d.). This matter, it says, should not be considered in isolation but in relation to the whole housing programme of the authority. The use of temporary accommodation will, the Government believes, make it possible approximately to double the number of dwellings which could otherwise be provided with the limited amount of skilled labour available in the first year after building can be resumed. The temporary scheme must not be allowed to stand in the way of the permanent scheme, and it will be for each authority to whom temporary houses are allotted to ensure that both sections of its programme can proceed side by side without stultifying one another. Temporary houses will be provided and owned by the Government; they will be erected on sites acquired and developed by the local authority.

MASSIVE SURGICAL EMPHYSEMA DURING THE COURSE OF GENERAL ANAESTHESIA

BY

N. R. BARRETT, M.Chir., F.R.C.S.

Surgeon to Out-patients, St. Thomas's Hospital

AND

DILLWYN THOMAS, M.R.C.S., L.R.C.P.

Surgical Assistant, Sully Hospital, Glam.

Surgical emphysema occurring during the course of endotracheal anaesthesia has been the subject of several reports in the literature, and much experimental work has been carried out to ascertain the cause of the phenomenon. The first mention of the subject was made in 1912 by Woolsey, who reported one case of surgical emphysema. Luke in 1913 recorded a case of gross emphysema due to obstruction of the return airway, and Georg in 1917 suggested that surgical emphysema was likely to occur if the tracheal mucosa had been traumatized during intubation. He also demonstrated the occurrence of emphysema in dogs after the use of insufflation pressures of 25 to 33 mm. Hg. Marcotte *et al.* (1940) found that an intrabronchial pressure of 24 mm. Hg usually produced mediastinal emphysema in dogs, and had seen it occur after 18 mm. In cats, lower pressures of 16 to 20 mm. Hg were sufficient to produce emphysema. Macklin (1937), by the use of very high intrabronchial pressures in experimental animals, has demonstrated exactly how such emphysema could occur in the lungs and mediastinum. He showed that air could break through in small bubbles from overdistended alveoli to the perivascular connective tissue and could track along the course of the arterioles to the great vessels.

We would like to submit the histories of two cases of massive surgical emphysema that have occurred during endotracheal anaesthesia.

Case I

A girl aged 9½ years was admitted to hospital with a diagnosis of acute appendicitis. The illness had started with generalized abdominal pain about 52 hours previously, and for the last 12 hours this had been localized to the right iliac fossa. The child had vomited on several occasions in the early stage of the illness, when a mild gastro-intestinal upset was considered probable: a dose of castor oil had been administered by the doctor in charge of the case, and the pain subsequently became localized to the right iliac fossa. When she was brought to hospital the signs and symptoms all pointed to a diagnosis of acute appendicitis, with some evidence of local peritonitis. The tongue was dry and dirty; the temperature was 101.4° F., and the pulse varied from 140 to 160 a minute. The only other abnormal physical sign was a loud systolic murmur, which was conducted well into the axilla. The heart was not enlarged. An immediate operation was advised.

Operation.—A preliminary injection of atropine sulphate gr. 1/150 was given and anaesthesia induced with gas, oxygen, and ether by means of a Clover's apparatus. The abdomen was opened by a modified Battle's incision and a large gangrenous appendix was removed without difficulty. The inflammation appeared to be well localized to the right iliac fossa. As the abdomen was being closed convulsive twitchings developed which rapidly became generalized. In an effort to deal with the situation the Clover's apparatus was discarded, and an intratracheal tube was passed with a laryngoscope, and through this tube oxygen containing a small amount of CO₂ was liberally administered. Almost immediately the anaesthetist noticed surgical emphysema of the eyelids. The condition spread with great rapidity over the face, neck, arms, chest, and abdomen. The oxygen was shut off at once and artificial respiration started, as the condition of the patient was now desperate. The convulsions continued, and death occurred within about five minutes of the first seizure. At the time of death the patient was quite unrecognizable as a human being. The features were so completely changed by massive emphysema that the eyes could scarcely be distinguished from the nose and mouth; the neck merged directly into the chin. The appearance was reminiscent of a toy balloon made to represent some animal which had been overdistended. The emphysema extended from the head to the legs. In order to improve these unpleasant appearances an attempt, after death, was made, on the operating table, to deflate the tissues by means of multiple small incisions down to the deep fascia, but no air could be expelled.

At the necropsy a tiny abrasion of the pharyngeal mucosa was discovered. The emphysema involved the glottis as well as the whole pharynx, the mediastinum, and the subcutaneous tissues. It was

evident that, apart from the convulsions, which in this case were probably the actual cause of death, the patient had suffered from acute laryngeal obstruction.

The striking features of this case, which occurred in 1934, were the speed with which the emphysema developed and the fact that by the time it was first noticed it was already too late to do much about it, and that the emphysema appeared after the introduction of an endotracheal tube. The whole operation was completed in less than 20 minutes, and the anaesthetic was administered by an experienced anaesthetist.

Case II

A coloured boy aged 11 years was admitted to hospital with a diagnosis of "bronchiectasis—for investigation," with a view to surgical treatment of the condition. He had suffered from a cough with foul sputum for some years as well as frequent colds of long duration, and two febrile attacks of more severity which were thought to be bronchopneumonia. On admission he was of average size for his age, with early clubbing of the fingers. Clinical examination of the chest revealed showers of rales over the right lung and occasional rhonchi. He expectorated daily 4 oz of foul smelling sputum. The plain radiograph suggested a cystic bronchiectasis in three lobes of the right lung.

In view of the foul sputum, postural drainage was carried out for several weeks, before attempting bronchography, in an endeavour to clear the bronchial tree. When it was finally decided to carry out the examination the sputum had been reduced to 1 oz daily. His age and temperament were considered to be unsuitable for successful bronchography under local analgesia and so a general anaesthetic was given.

On Feb. 22, 1944, he was given morphine gr. 1/12 and atropine sulphate gr. 1/100 as premedication. The child was then anaesthetized with CHCl₃ and oxygen. The induction was not uneventful—sputum proving troublesome and cyanosis difficult to eliminate. A Magill endotracheal tube was therefore passed under direct vision and the anaesthetic continued. Cyanosis was still prominent, and on one occasion the pulse faded, oxygen was liberally administered in an attempt to combat this. About 15 minutes after the induction the anaesthetist considered the patient to be more or less settled, and as the cyanosis had improved he felt that the bronchogram could now be made. It was, however, plain that the condition of the patient was not altogether satisfactory. It had been our recent custom in small children receiving a general anaesthetic for bronchography to inject the lipiodol through a fine Monaldi catheter inserted into the lumen of the endotracheal tube. This catheter was so small that, while allowing a flow of lipiodol, it encroached but little upon the airway. This method has not caused us any anxiety. At the moment when the oil was about to be instilled it was noticed that the child's neck was grossly deformed, there being complete loss of the angle between the chin and the neck, and that the neck was alarmingly ballooned right down to the clavicles. Palpation suggested deep emphysema, little or no subcutaneous emphysema being observed. The child was again cyanotic, the CHCl₃ was discontinued at once and the oxygen flow increased. A serum needle, which was fortunately lying on the bronchography trolley, was inserted into the left side of the neck, about two fingerbreadths above the clavicle. No diminution in the size of the neck occurred, and the child's condition appeared to be critical. A 20-cm. Record syringe was then applied to the needle, but the absolute resistance of the plunger to withdrawal suggested that the needle-point had not reached an air-containing fascial space. The needle was then inserted more deeply until the plunger could be withdrawn with ease. Aspiration was started, the thumb being placed over the hilt on disconnecting the syringe. During the first minute or so there did not seem to be an appreciable reduction in size, but as the plunger's easy withdrawal suggested the continual aspiration of air, the process was continued and the swelling began to recede. At this point a two-way adapter had been procured, the reduction was then more rapid and the aspiration on a better basis. When the contour of the neck seemed almost normal and the condition of the patient much improved, the syringe was disconnected, but the needle was left *in situ*. Within a few seconds the neck ballooned up once again. The process of aspiration was repeated, and the neck returned to reasonable dimensions once more. On disconnecting the syringe a further ballooning occurred. Again aspiration was performed for a period of about 15 minutes, and on this occasion on disconnecting the syringe ballooning did not recur. The oxygen administered in this last 15 minute period was appreciably reduced in amount. It has been estimated that, in all, aspiration was carried out for a full half-hour. While waiting to ensure that no further gross emphysema occurred a radiograph was taken, as the child had been anaesthetized in the x-ray room. The radiograph shows the needle *in situ* and emphysema to be present in the neck—although the neck appeared normal to palpation.

The child made an uneventful recovery from this operation with no further treatment; but a full course of sulphathiazole was given

as a precaution against infection of the fascial planes in view of the foul expectoration.

On examination of the anaesthetic apparatus it was apparent that the expiratory valve was not working at the maximum of efficiency and that the pressure of gases in the pharynx must have been unduly high. The anaesthetic was administered by an anaesthetist of skill and experience in the procedure.

Summary and Conclusions

Two cases of massive surgical emphysema which occurred during the administration of general anaesthesia are recorded. The common features are the rapid onset of the condition, the alarming rate of spread and that in both cases oxygen was liberally administered to combat an emergency—convulsions in one and cyanosis in the other. It is suggested that incision or the mere insertion of needles into the superficial tissues is not sufficient to control the emphysema, and that aspiration is necessary, that if the cause remains the emphysema returns with alarming rapidity when aspiration of air is discontinued. Finally, if aspiration is attempted the needle may have to be passed through the deep fascia of the neck.

In both these cases it is probable that the condition was caused by a minute perforation of the pharyngeal mucosa, through which gas, under pressure was forced into the fascial planes of the neck and mediastinum. It is therefore conceivable that, once such a process has been started, it might continue, even after the primary cause has been removed, if the patient develops an obstruction to the airway and struggles for breath.

AN UNUSUAL CASE OF GENERALIZED TUBERCULOSIS

BY

W. H. MYLECHREEST, M.B., B.Ch.

Major, R.A.M.C.

AND

I. M. SCOTT, M.B., Ch.B.

Capt. R.A.M.C.

The following case of generalized tuberculosis seems to us to be well worth recording.

Case History

An American seaman aged 26 was suddenly taken ill on Nov. 22, 1943, complaining of headache and chills. He ran a continuous fever from the onset to his death in March, 1944. During the course of the illness, which was difficult to diagnose, he developed erythema nodosum. The interest of the case is in the x-ray and post-mortem findings, which are as follows.

Summary of X-Ray Reports—23/12/43—Marked increase in left hilar shadow, continuous with a fan-shaped opacity spreading into left mid-lung zone, consistent with a localized area of consolidation and associated glandular enlargement. 30/12/43—No appreciable change. 14/1/44—Increase in size of opacity in left hilum and mid-lung zone, consistent with tuberculous infiltration and glandular enlargement of the type usually seen in children. 20/1/44—Increase in the spread. 9/2/44—Increase in size and density, associated with widening of the mediastinum. The possibility of lymphadenoma or neoplasm, with secondary lung involvement, cannot be excluded. 21/2/44—Slight increase of the glandular enlargement to the right of the midline.

Post-mortem Examination—Lungs.—There was approximately half a pint of deep-yellow fluid in the left pleural cavity. There were adhesions at the base on the left side, and a large breaking-down caseous peribronchial lymph gland in the left side of the mediastinum approximately the size of a tangerine. The lower lobe of the left lung was solid, very little caseation being apparent. There were some scattered tubercles throughout the rest of the left lung and also the right lung. The condition in the left lower lobe seemed to be a direct spread from the affected peribronchial gland. Trachea and bronchi were not involved in the disease process. **Heart.**—There was a large amount of fibrous pericarditis. Numerous tubercles (up to 1/4 in in diameter) were present in the pericardium; these did not extend into the myocardium. However, a solitary tubercle (approximately 1/2 in in diameter) was found in the myocardium of the right ventricle. There was healthy myocardium between this tubercle and the pericardium. The valves were normal.

in appearance, as were the aorta and coronary arteries. The liver was enlarged, and was the seat of many tubercles. These varied in size from 1/4 in. to 1/2 in., and showed a surprising lack of caseation. They were in several cases surrounded by necrotic liver tissue and there was little or no fibrosis around the tubercles. The spleen was enlarged to about four times the normal size and was congested. Here again were seen many tubercles similar in size and appearance to those in the liver. There was a fibrinous perisplenitis. The kidneys showed several small tubercles scattered through the organs. The pancreas appeared normal, though there was an enlarged semicaseous lymph gland near the head. The suprarenals were normal. The oesophagus, stomach, and intestines were also normal in appearance. There was little free fluid in the abdominal cavity, and only an occasional small tubercle was present in the peritoneum.

Microscopical Examination.—Smears taken from the peribronchial lymph gland and from a tubercle in the liver showed acid alcohol-fast bacilli. Sections of the tubercle in the myocardium revealed a central area of early caseation, surrounded by endothelioid cells, histiocytes, and small round cells. Scanty giant cells of the Langhans type were present. Acid alcohol-fast bacilli were also found.

Comments

The heart and pericardium are seldom involved in military tuberculosis, and although solitary tubercles in the myocardium have been described, they are quite exceptional. Tuberculosis of the pericardium is not uncommon, and is due in most cases to a backward infection by the lymphatics from a tuberculous gland. To quote *Muir's Pathology* (4th edition, 1940): "At an early stage tubercles are formed, but these soon lead to inflammatory reaction and become covered with fibrin. The disease may thus appear like an ordinary fibrinous pericarditis, and its real nature may be discovered only on microscopical examination." In this case, however, there were, as already described, many large and very obvious tubercles. The lesion in the myocardium (1/2 in. in diameter) was discrete and presumably blood-borne, as no connexion between it and the pericardium could be traced either macroscopically or microscopically. The condition in the liver, too, is very rare. To quote the above author again: "The presence of large almost tumour-like tuberculous masses in the liver has been recorded in a few cases, but the occurrence is very rare."

The disease in this case would appear to have been a bloodstream infection with a ? primary focus in the peribronchial lymph gland. The size of the tubercles and the absence of macroscopic caseation in the tubercles in the various affected organs argue a comparatively high resistance on the part of patient, and in some way account for the lack of clinical which, until within a few weeks of his death, consisted of a persistent pyrexia and the early erythema nodosum.

We wish to thank Col. W. D. Arthur, M.B.E., and Lieut.-Col. W. L. Ackerman for their help and permission to forward this paper.

Medical Memoranda

Local Analgesia for Adult Circumcision

No claims for originality are made when a technique of local block for adult circumcision is described; but at the same time the textbooks do not stress this method as being a technique of choice for this operation. Under certain conditions it is definitely the most satisfactory anaesthesia. If a general anaesthetic is employed circumcision in the adult demands a much deeper level of anaesthesia than is often realized. For instance, a "shot of pentothal" will not do; a large dose of this barbiturate is not sufficient in most cases. The advantages claimed for local block are speed for the surgeon in the organization of a clinic, a high degree of haemostasis, and the use of a very small quantity of an inexpensive fluid. And the patient is not subjected to the risks of a general anaesthetic, small though these are.

Recently, local block for adult circumcision was carried out in 41 cases at a military hospital in India, on British and Indian troops. The cases were largely drawn from the venereal disease department, but there were cases of non-venereal balanitis and phimosis also. During this series, admittedly small, no other technique was used, although there were slight variations in the method. Sepsis was not considered to be a contraindication, and a few of the cases were in such a condition that the operation was confined to a "dorsal slit."

Of course the soldier is the ideal subject for all forms of block analgesia, provided that they are successful. Reports

of incomplete anaesthesia and the consequent suffering very quickly spread round a ward. Patients then arrive at the theatre in the worst possible state of anxiety for a local. Therefore as soon as any pain is felt it is essential for something to be done, and the best is a very light inhalation, open ether being satisfactory. One case in this series was so treated, and the confidence of the wards was not upset.

The patients were sent to the theatre at the same time, and were anaesthetized in a batch if the number on the list did not exceed four. One patient was circumcised after a lapse of an hour, and there was no falling off in the standard of analgesia. The question of premedication is simple in these cases. From this series it was decided that, whether morphine was given or not, the results were the same as regards the analgesia, but a greater tranquillity of mind was present in the premedicated. But we were dealing with trained soldiers, and it is suggested that in the case of a civil clinic all cases be premedicated. In order to cut down the number of stretch-bearers which would be required—since the ward which provided these cases was a long distance from the theatre—the patients walked to the anaesthetic room. At the beginning of the series all cases were given morphine gr. 1/3 intravenously on arrival. Then the local analgesic was injected, novutox being the agent, and the dose within the limits of 6 to 8 c.cm. A 10-c.cm. syringe fitted with a hypodermic needle was used. The first injection was made into the base of the penis on the dorsal surface in the midline, and the area on each side of this puncture was infiltrated as far as the lateral border of the organ. Approximately 4 c.cm. of agent would be used over this area. A second puncture was then made into the ventral surface in the midline, and this area was similarly infiltrated to meet the lateral boundaries of the first injection. Less solution would be required here, since the previous infiltration had included the lateral borders. But before the needle was removed at least 1.5 c.cm. was inserted into the midline of the ventral surface. This was most important, as in any case of imperfect anaesthesia the frenum is the sensitive structure. After the infiltration was completed a period of at least ten minutes was allowed to elapse before the operation was started. When premedication was abandoned, about half-way through the series, the patients were allowed to walk back to the ward, accompanied by an orderly, and every one arrived there none the worse for the experience.

It has been suggested that the efficient haemostasis provided by the local block might lead to post-operative haemorrhage: this did not happen. No doubt the haemostasis is produced by the mechanical compression of the vessels by the ring of swelling resulting from the infiltration. There were no ill effects.

I am indebted to Major J. D. Wilson, R.A.M.C., surgical specialist to the hospital where these cases were treated, for his interest and co-operation in the anaesthesia.

A Case of Sensitiveness to Strychnine

The following record seems worthy of publication not only for its rarity but for the moral lesson it affords.

CASE REPORT

A married woman aged 42 came under my care in a busy panel practice recently, already certified as unfit for work on account of rheumatism, of which there was no objective evidence. Thinking that aperient treatment might be of value, I prescribed a bottle of mist. casc. co. Next day I was summoned urgently, to find that after one dose of the new medicine the patient had collapsed, and was pale and pulseless. No definite diagnosis occurred to me, although I toyed with the idea of belladonna poisoning in an aberrant form, since, as some may know, the mist. casc. co. of the 1943 *Formulary* contains the astonishing amount of 12½ minims of the tincture to the dose, whereas the 1939 mist. casc. co. contains only 3 minims, as I found on looking it up.

After some weeks of treatment with iron the patient asked for a tonic, intending to return to work. I prescribed the mist. phosph. & strych., of which the patient warily took only a teaspoonful, and within a few minutes suffered a similar though not so severe attack. On my arrival in haste I had to defend myself against accusations of poisoning. Since the only item common to the two mixtures is strychnine, I was forced to the conclusion that this must be the cause of the attacks, and at the request of the patient obtained another opinion. My colleague rather sceptically injected intradermally 0.05 c.cm. of liq. strych., which caused an immediate wheal followed in a minute or two by a typical anaphylactic attack, which required the injection of adrenaline.

I have now equipped the patient with a written note to be shown to any future doctor. Inquiry among friends and chemists of wide experience has not brought to light a similar case.

D. R. C. SHEPHERD, M.R.C.P.

Reviews

A STUDY OF NATIONAL HEALTH INSURANCE

National Health Insurance: A Critical Study. National Institute of Economic and Social Research. Economic and Social Studies IV. By Hermann Levy. (Pp. 366. 1s.). Cambridge University Press, 1944.

This is a searching examination of our National Health Insurance system by a staunch believer in the principle of health insurance who has a remarkable acquaintance with the working of similar systems in other countries. It is fully documented. Prof. Hermann Levy characterizes our system as "costly, wasteful, and overlapping," and ascribes these defects chiefly to the admission of the approved societies to such a prominent place in its administration. The price paid for their support, which apparently for political reasons could not be avoided, was that it entailed a flat rate of contribution. If an adequate range of medical benefit had been made available, a flat rate would have been actuarially impossible. Its effect was 'levelling down the statutory benefits to cover only the average basic incidence of sickness—the lowest common factor.' Continental systems which adopted the method of aggregation of contributors into regional and occupational groups, with elasticity in contributions and in benefits in accordance with the risks involved, have been able to give a much wider range of medical benefit. Our 'Additional Benefits' he considers to have failed lamentably to fill the serious gaps left in normal medical benefit, and as a consequence "medical benefit is bolstered up by charity and voluntary effort." Medical benefit, in his opinion, plays the vital part in any health insurance scheme. "The more effective the scheme is medically, in physical terms, the less costly it would be financially in terms of cash. He condemns the inequalities imposed upon contributors, for 'it is contrary to conditions of purchase and sale that for the same contribution one purchaser may receive less than another.' By eliminating the approved societies and grouping contributors in regional and occupational groups, he claims, and gives good reasons for his belief, that we should save (a) in administrative expenses, (b) by shortening the duration of sickness through more efficient treatment, (c) by the change from the piling up of actuarial reserves to a yearly assessment of probable liabilities with any consequential alteration of contribution, and (d) by making the Workmen's Compensation responsible for the cost of treatment for injured workmen.

Prof. Levy quotes freely the B.M.A. and other critics of our system, but is of the opinion that they have missed the fundamental defects to which he calls attention. He thinks that the doctors are underpaid and that the method of payment is unsatisfactory. He favours a system of payment by attendance, but on this point he is far from definite. He mentions with approval the abandoned Manchester and Salford system of payment, but either does not know, or does not give sufficient weight to, the reasons which led to its abandonment. He has no use for the salaried doctor, and says, "There is no reason to suppose that a State doctor practising for a number of insured persons would be the ideal solution."

In his last chapter the author says the book was written before the Beveridge report (to which he pays generous tribute) was published, but in spite of the glowing prospects held out by that report he does not favour any system which depends on a flat rate of contribution. He ends by saying that the Government will have to decide between (a) a centralized plan with fundamental assumptions and financial implications which are difficult to foreshadow, and (b) one working on clearly assessable risks to be met by integrated local and occupational funds and with variable contributions. He thinks it would be better to organize our system "not from the roof but from the ground." Whatever may happen to the proposed comprehensive health service, the author can congratulate himself on a sound piece of constructive criticism and on having drawn attention to many defects in our present system which ought to have great weight in contemplating a new one.

MAN, SOCIETY, AND RELIGION

Man, Society and Religion: An Essay in Bridge-building. By W. Russell Brain. D.M. F.R.C.P. The Swarthmore Lecture 1944. (Pp. 177. 7s. 6d. cloth covers, 2s. 6d. paper covers.) Published for the Woodbrooke Extension Committee by George Allen and Unwin.

This is a Swarthmore Lecture and so is necessarily concerned with the Quaker attitude. All may not share this point of view, too many do not understand it, but few can withhold admiration for the steadfastness and high motives of the Society of Friends. The text for the lecture is, 'We are members one of another' and here members are not the loose associates of a club but limbs of a body without each of which and without the contribution of each the body cannot function properly. We are each responsible to all. Like the cells of a multicellular organism the individual is essential to the group. It is the business of psychology to guide the interactions of the individual and to define how they may best contribute to the group mind. All too little is known about this, but increased knowledge is essential for the progress of mankind. Altruism does seem to be a natural function of man, but it requires direction. The Quakers have done much as pioneers to direct this altruism, and the story of social progress in the last century has shown how it is gradually leavening the masses, but the possibility and the realities of war show that the bounds of altruism are still far too narrow. Suttie has pointed out that the infant requires to give as well as to take, and so does every adult. Individual independence so much lauded by the generation responsible for the consequences of the industrial revolution, is really quite impossible, and social security must ultimately be based on the recognition of the essential interdependence of all individuals and all classes of society.

So with international security. Force cannot ultimately succeed unless all nations agree to be subject to discipline, as the majority of the citizens of this country agree to be subject to the discipline of the law and the police. Aggression will not be curbed until peoples no longer want to be aggressive. Thus, as most people know, is the Quaker ideal. After a discussion of the Quaker form of worship Dr. Russell Brain points out the need for revaluing and revitalizing the inner subjective world which science has done so much to discredit and repress. We must recognize the importance of the inner light in the modern world, and no profession can turn its mind to this conception with greater advantage than can the medical profession, apparently so engaged with the practical scientific aspects of life yet drawing its inspiration from that inner force of altruism and love. We as doctors cannot, therefore, but be grateful for this charmingly written study, so provocative of thought, by a distinguished member of our own profession.

ELEMENTS OF ANATOMY AND PHYSIOLOGY

Elementary Anatomy and Physiology. By James Whillis, M.D., M.S., F.R.C.S. Foreword by T. B. Johnston, M.D. Second edition. (Pp. 250, illustrated. 15s.) London: J. and A. Churchill, 1944.

Anatomy and Physiology for Students of Physiotherapy, Occupational Therapy and Gymnastics. By C. F. V. Smout, M.D. and R. J. S. McDowall, M.D. (Pp. 418, illustrated. 6s.) London: Edward Arnold and Co.

Elementary Anatomy and Physiology by James Whillis, first published in 1938, has now reached a second edition. This, which follows the lines of the first edition, aims at presenting the facts of anatomy and physiology in "broad outline," and is published within the compass of a single volume of 280 pages. The succinctness of the first edition has been maintained in the second, notwithstanding additions, such as examples, with special illustrations, of the action of certain groups of muscles in co-operation with controlling groups of opposing muscles which regulate the action of the primary group—e.g., walking, or standing on one foot. Some sections have been revised and some rewritten, more particularly those dealing with digestion, metabolism, and vitamins. Owing to the limited size of the book the description of some organs and physiological processes may seem to have been curtailed too drastically. By reason of the lack of illustrations showing the histological structure of such organs as the internal secretory glands, and the omission of many of the chemical formulae which form the basis of the organic chemistry concerned in digestion and metabolism, beginners may find difficulty in fully understanding and picturing for themselves the objects and the processes described in the text. The illustrations on the whole

are good, but some are apt to give a false impression because there is no delineation of structural texture. Thus some give no indication of muscle fibres, the muscular tissue being left white while the glistening white tendons are represented black. Considered as a whole the author has succeeded in packing a large amount of essential information into a small space, and the book contains much that the type of student for which it is written should know.

Anatomy and Physiology for Students of Physiotherapy, Occupational Therapy and Gymnastics has been written by Dr. C. F. V. Smout, University of Birmingham, and Prof. R. J. S. McDowall, University of London, King's College, to supply a textbook of moderate size, the scope of which will correspond to the syllabus drawn up by the Chartered Society of Massage and Medical Gymnastics—now called the Chartered Society of Physiotherapy. The anatomical section occupies about three-quarters of the book, while the physiological section is comprised in an excellent epitome of this subject occupying rather less than 100 pages. The text is clearly written, and the illustrations, many of which are coloured, are well adapted for the use of students who in general have no opportunity of dissecting for themselves the regions depicted. In a book specially designed for people who will be engaged in treating muscular defects, and deformities such as wry-neck, scoliosis, and kyphosis, one would expect the relations of the muscular attachments to the movements that take place at the joints concerned to be considered in greater detail; one finds, however, that with few exceptions the actions of muscles with respect to leverage, fixation points, axes of rotation, angular movements, and the planes in which gliding movements can occur receive scant attention. This is particularly the case in the description of the action of the sternomastoid muscle and the muscles at the back of the neck, the action of which, in co-operation with the muscles of the suboccipital region, is not mentioned. Nor are the occipito-atlantal and atlanto-axoidean joints specially described. There are also too many mistakes belonging to the categories of incorrect labelling, misprints, omissions, and errors arising from too diagrammatic illustrations. These defects can, however, be corrected in reprints or later editions, and the book may be recommended as giving a good elementary knowledge of anatomy and physiology such as is required by the above-mentioned syllabus.

Notes on Books

to Theatre Technique is a member of the Aids Series written for the nurse in training (Baillière, Tindall and Cox; 4s.). By covering the syllabus of the General Nursing Council this series constitutes a textbook of nursing, but the present book, by MARJORIE HOUGHTON and MARGARET HARDING, is complete in itself and should be a valuable guide to anyone called on to undertake the work of a theatre sister. It is a product of University College Hospital, and it is pleasing to note the reference to the names of past distinguished members of its surgical staff such as Victor Horsley and Wilfred Trotter. The text is clear and concise and the illustrations are good, the many and excellent photographs constituting one of its most attractive features. A few errors are noticeable; thus all Moynihan's forceps had circular ring handles, Halsted (p. 237) is spelt incorrectly, likewise Morison (p. 240). Proof-reading has not been all that it might have been; two misprints occur on page 190 alone, and the index is incomplete. Kocher's thyroid enucleator is so called in one place and in another illustrated as Kocher's plain enucleator. This instrument is, we believe, usually known as Kocher's dissector. The authors and publishers, however, are to be congratulated on producing, particularly at the present time, such a well-illustrated and attractive little volume at such a low price. It should prove very popular with the nurse in training.

Volume LXIII of the *Transactions of the Ophthalmological Society of the United Kingdom* covers the session 1943 and is published by J and A. Churchill at 40s. The contents include papers and discussions at the annual congress, when the main subjects were thyrotoxicosis in relation to ophthalmology and the scientific and clinical aspects of night vision; a report of the joint clinical meeting with the Section of Ophthalmology of the Royal Society of Medicine, with its miscellaneous bill of fare; and a report of the Oxford Ophthalmological Congress, 1943, at which Prof. E. D. Adrian gave the Doyné Memorial Lecture entitled "The Dominance of Vision." The volume also includes transactions of the North of England Ophthalmological Society and of the Irish Ophthalmological Society.

Polinosis, by L. HERRAIZ BALLESTERO and J. VICTOR MONTICELLI, is published in Buenos Aires by Libreria Hachette S.A. According to a foreword by Prof. C. Jiménez Díaz of Madrid, pollen allergy is particularly common in the Argentine Republic. In this monograph on pollinosis, a physician and a botanist report the results of a joint investigation of pollen allergies as they are seen in Argentina. The book is divided into two main sections, of which the first deals with the regional flora (including atmospheric pollen studies), and the second is concerned with clinical manifestations, diagnosis, and graph on pollinosis a physician and a botanist report the results of this is not a general treatise on pollen allergy; it is concerned solely with the problem as it occurs in Argentina. This necessarily sets a limit upon the interest of the work to readers in other countries. The bibliography, which is singularly weak in any but Spanish-language references, gives details of papers to be published by the same authors on findings in particular regions.

Preparations and Appliances

DEVICE FOR SPHYGMOMANOMETRY IN ANAESTHESIA

Dr. A. OWEN-FLOOD, L.R.C.P.I. and L.M., L.R.C.S.I. and L.M. (Crouch End, N.8), writes:

Perhaps I am more unfortunate in my use of adhesive tape than other anaesthetists, but I find it adheres to everything except the patient. The system of attaching the chest-piece of the stethoscope in the conventional position over the cubita fossa by this medium has resulted in my taking the blood pressure of the leg of the operating table, the plaster being unfaithful to the arm as usual.

The illustration shows an "all in one" device for taking pressure by the auscultation method. A plate 2 in. square is cut out to receive a "mica type" chest-piece. The aperture

fits neatly around the thread, and the plate is retained by screwing home the bezel of the chest piece. Convenient holes are drilled in the plate, and it is sewn to the lower angle on the border of the wide part of the fabric containing the inflation bag. The apparatus will thus be applied with the first winding of the inflation cuff, on the medial side of the upper arm over the brachial artery, and will be firmly fixed in position by winding the fabric around in the ordinary manner.

To avoid the trailing of numerous lengths of rubber tubing from the chest-piece to the ear-pieces, and from the inflation bag to the sphygmomanometer, I have connected these tubes by a pair of what is known in the trade as "male and female joints." These joints are routine fittings on the sphygmomanometer of the mercury column type. That connecting the ear-pieces to the chest-piece should be of a calibre not less than 3/16 in.

To use the apparatus all that is necessary is to "plug in" by connecting the joints, and take the pressure in the ordinary manner. This device renders it unnecessary to remove the arm from the side, or otherwise disturb the patient.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 25 1944

LOCAL GOVERNMENT IN ENGLAND AND WALES

A recent statement in Parliament by Mr Willink, Minister of Health, reveals that discussions are being held with the associations of local authorities about the structure of local government, and that some measure of reform may soon be introduced. In this connexion it may be recalled that the principles enunciated for health administration by the British Medical Association in 1943, based on the views of the Medical Planning Commission, included the formation of new local bodies covering wide areas and representative of the community served, the local medical profession, and the voluntary hospitals guided by a local medical advisory committee. These were to be regarded as foundation changes to be agreed before other changes in medical practice were initiated. The White Paper fell far short of this idea. It proposed to combine major local authorities in areas less spacious than the Association had in mind, to give the new bodies executive authority only for hospital and allied medical services, which would be exercised, so far as voluntary hospitals are concerned, by contract and not by integral association, and to make the new authorities responsible for the planning only of all the other health services administered by existing councils. An advisory Local Health Services Council was to be created, but neither the medical profession nor the voluntary hospitals were to have any status on the executive authority itself. This proposal is one of the most serious obstacles to acceptance by the profession of the Government's scheme for a comprehensive medical service. It may therefore be hoped that the White Paper is not the Government's last word on the subject, and that the wider review of local government which is impending will embrace the composition of executive and planning bodies.

It is a melancholy fact that the machinery of local government arouses little public interest. The *Times* of Jan 6, 1944, published a special article on the subject, with editorial comment. It stimulated little correspondence, restricted to members of local authorities; a Member of Parliament, and the National Association of Local Government Officers, but there were no comments from disinterested observers. The *Times* returned to the subject on Oct 5, 6, and 7 last, with even less response. Yet its special correspondent put forward a scheme of intermediate planning authorities for all local government purposes which resembles that suggested by the Council of the British Medical Association in the more limited field of public health and medicine, and which might have been thought sufficiently revolutionary to arouse discussion. The scheme envisages a new body compendious in func-

tion—i.e., planning and scheme making—for all local government services which require to be seen from a wider point of view than that of the county or county borough, and federal in composition—i.e., representative of the local authorities and so indirectly of the electorate. It is further suggested that while the bulk of its membership must be made up of representatives of local authorities, there is room for non-elected members who might be nominated by the central Government.

It must be realized that popular local government is deeply embedded in the British Constitution. It has emerged from the long constitutional struggle of our history firmly entrenched as a bulwark against autocracy, ensuring that freedom of the individual and his voice in affairs which is a guarantee of political stability. A similar system has steered the U.S.A. through the quicksands of phenomenal growth combined with racial problems of the gravest complexity. Countries which have failed in democratic local government and sought authoritarian shortcuts to efficiency in the governmental machine are perishing for lack of an instrument to express the people's will and carry its confidence. But the flight from democracy has not been due merely to antipathy to it; its failure has been the result of weaknesses from which we are not entirely immune—the uncompromising struggle between doctrinarism and conservatism, the outcropping of nepotism and other forms of corruption, and, above all, inefficiency arising from the love of power and vanity of elected persons who repudiate guidance from anyone but the advisers they choose for themselves. The genesis of Fascism and its nemesis both have their lessons for us.

In the nature of things the forms of democracy can never be final. Problems change, knowledge advances, new services emerge, communications improve, and populations shift. Elsewhere in this issue the structure of local government is described, so that the reader may at least see its outlines clearly. In this country it has been recognized since the Middle Ages that local affairs are a local concern, and that the function of central government is to see not only that they are dealt with but also that some degree of uniformity of policy is maintained. The extent of central control has varied greatly and has been exercised in several ways. In the Middle Ages the Crown nominated the county sheriffs, who in turn appointed the bailiffs of the hundreds and were themselves subject to correction by itinerant justices. In Tudor times the power of the sheriffs gradually passed to justices of the peace, also Crown nominees, removable by the Crown. In the eighteenth century the dismissal of local justices fell into disuse, so that the local magistrates became virtually all-powerful for life in the exercise both of justice and of administration. Standing more or less outside this regime were the chartered boroughs, many of which, by the early years of the nineteenth century, had developed their own peculiar form of corrupt autocracy, and were under little or no central supervision. Alongside this system had grown up a rudimentary form of local democracy in the parish, but it too was largely under the sway of the local justices and exercised its functions as to poor relief, roads, and sanitation by unpaid service. This machinery collapsed in face of the clamant problems of the industrial revolution, and was quickly replaced from

1834 onward by elective bodies, manifold in number, each for a special function and far from conterminous in areas of jurisdiction. The principle was established that local affairs should have local popular management. By the end of the century a further principle had been observed—namely, that local authorities should be compendious, and that, so far as possible, *ad hoc* authorities should be abolished. By the middle of the nineteenth century still another principle had been recognized—that local services such as police, education, etc., which are also of national importance, may be subsidized by the central exchequer, with close supervision of the local service by an appropriate Government Department. This practice has been extensively used to foster the personal health services during the time of their greatest growth throughout the past 40 years. It has never been possible, however, to hold firmly to the implications of those principles within the framework of local government for the time being. For hospitals, water supplies, prevention of river pollution, and many other purposes joint boards have had to be set up which are *ad hoc* authorities only indirectly elective. Other functions, such as factory inspection, some forms of public assistance, main highways, the National Fire Service, the health of cattle, and the supervision of the production of milk, have been, or are being, removed from the scope of local to central administration. The Benthamite code of compendious local administration within convenient, not historical, areas has been the model for much local government change; but it has been half-heartedly applied, and no sooner has it approached realization than circumstances have compelled departure from it. The growing conviction that there is no such thing as an area suitable for every phase of local government, and that, even if there were, it would be so large as to destroy local interest, lies behind the alternative proposal for an intermediate planning body over wider regions, into whose schemes the executive authorities would have to fit their services.

Whatever planning, administrative, or executive bodies may be created, their constitution requires the closest consideration. The principles of democracy demand that the elected representatives of the people should handle their affairs, but it does not follow that all the members of these bodies need be so elected. The numerous Acts of Parliament affecting local government provide for committees, containing non-elected members, to which specific matters stand referred. This is usually effected by co-option, limited as to numbers and optional. The power of co-option does not extend to joint authorities, except under the Cancer Act, 1939, which may never come into force. Co-option to education committees on the nomination of other bodies was provided for by the Education Act, 1921, but this method of adding to the members is not mentioned in the Act of 1944, although teachers still remain exempt from disqualification. An interesting exception to the general rule is contained in the Ministry of Agriculture and Fisheries Act, 1919, which empowers the Minister to appoint up to a third of the members of county agricultural committees. Generally, however, the provision for ensuring knowledgeable membership of authorities and their committees is narrow, and it tends to be grudgingly applied. While the constitutional case against its

wide extension may be strong where executive authorities are concerned, these arguments are not valid in relation to planning bodies. Realization that it is unlikely that *ad hoc* executive health authorities, other than joint boards consisting exclusively of local authority members, will meet with acceptance by Parliament, forces us to the conclusion that the Council of the British Medical Association is wise in pressing for a planning intermediate authority on which the profession and the voluntary hospitals will be adequately represented. It is equally necessary that the working committees, at least of executive health authorities, should have an infusion of experienced non-elected members, and that they should be advised by a council truly representative of the medical profession.

MORE ANTISEPTICS FROM PLANTS

The discovery of penicillin has aroused interest not only in antibacterial substances made by other fungi, but in the occurrence of such substances in the plant kingdom generally. The systematic study of other fungi from this point of view has now embraced many hundreds of species, of which a good number have been found to yield antibacterial substances. Some, indeed, produce several: according to Waksman and Geiger¹ *Aspergillus fumigatus* forms no fewer than four. The same substance may come from different fungi: patulin, for instance, now discredited as a cure for the common cold, is by no means unique, but a product of a number of moulds. Such substances have been given various names before their identity has been demonstrated: patulin itself is the same thing² as claviformin, originally described as a product of *Penicillium claviforme* by Chain, Florey, and Jennings³ in 1942. None of these more recently discovered antibacterial substances offers greater promise as a therapeutic agent than penicillin; some, such as flavacin, seem more or less identical with it. Helvolic acid⁵ somewhat resembles penicillin, differing from it in the highly desirable properties of longer persistence in the blood and of stability in the alimentary tract, whence it is absorbed, but suffering the grave drawback of toxicity to the liver, at least in mice. The supreme virtue of penicillin is its freedom from toxicity, and it is perhaps too much to expect that anything with this exceptional property should have a wider range of antibacterial activity. Nevertheless the possibility of such a substance remains. As Dubos⁶ has lately pointed out in a general review of naturally occurring antiseptics, the methods employed in wide surveys are unfortunately not such as to detect the more valuable type of agent. If hundreds of materials have to be examined, only simple *in vitro* tests of bacteriostasis are usually employed, whereas the virtues of the true chemotherapeutic agent only emerge in the experimental animal.

These investigations are by no means confined to the products of bacteria and fungi. The higher ranges of the vegetable kingdom are being explored in a tentative way,

¹ *J. Bact.*, 1944, 47, 391.

² E. Chain, H. W. Florey, and M. A. Jennings, *Lancet*, 1944, 1, 112.

³ *Brit. J. exp. Path.*, 1942, 23, 202.

⁴ Clara M. McKee, G. Rake, and C. H. Houck, *J. Bact.*, 1944, 47, 187.

⁵ E. Chain, H. W. Florey, M. A. Jennings, and T. I. Williams, *Brit. J. exp. Path.*, 1943, 24, 108.

⁶ *J. Amer. med. Ass.*, 1944, 124, 633.

with the interesting possibility in view that the supposed medicinal virtues of herbs and roots may prove in some cases to be due to the existence in them of a substance with antimicrobial action. E. M. Osborn⁷ has tested extracts of 2,300 species of flowering plants by the agar cup method for substances capable of inhibiting the growth of *Staph aureus* and *Bact coli*. Positive results were obtained in 135 species, the most active being among the *Ranunculaceae*. It is of course known that both essential oils and alkaloids may have a bacteriostatic effect, and until it is clear whether the active substance in a green plant is of this or some other nature, its possible therapeutic usefulness cannot even be conjectured. Another new departure is briefly reported by a team of workers in the University of California,⁸ the starting-point of which was the observation that certain algae make something which ultimately inhibits their own growth. From cultures of two species of *Chlorolla* they have extracted in impure form a substance, which they name *chlorellin*, with considerable bactericidal as well as bacteriostatic properties exerted against a wide range of bacteria, including *Bact coli* and *Ps pyocyanea*. This investigation is at far too early a stage to predict its future, but it extends the field of these investigations to a new area. The phenomena of mutual antagonism in the plant kingdom may yet yield up secrets of value to man.

It is now customary, in the American literature at least, to refer to all such substances as "antibiotics". The term is perhaps already too firmly entrenched for any protest to be availing, but it may nevertheless be suggested that this word is singularly ill chosen. The broadness of its derivative significance implies a general protoplasmic poison, whereas the only such substances of any interest are those whose action is highly selective. To serve any useful purpose they must poison the microbial cell and leave the cells of mammalian tissues unaffected. A term with this more descriptive significance would be preferable, even if we had to coin a new word. Why not simply "antimicrobics"?

PENICILLIN IN THE MOUTH

Penicillin production in this country has hitherto amounted to only a small fraction of that in the U.S.A. Outside the Services, which have lately been generously supplied from American sources for the treatment of casualties, the scarcity of the home-grown product has been a handicap. Clinical research on the scale, for example, of studies in the treatment of syphilis recently reported from the U.S.A.⁹ has been beyond our capacity. But this handicap has been turned to good account in at least one way. It has forced British investigators to devise economical methods of treatment. Economy in penicillin means local as distinct from systemic treatment, and when this is feasible it has two further advantages: it is far less troublesome to manage and involves the patient in none of the discomfort associated with continuous infusion or frequent intramuscular injections. The success of local treatment depends largely on taking measures to secure continuous action, to this end surgical technique has been modified and new methods of application have been devised. A fresh advance in this direction is reported on

page 686 by A. B. MacGregor and D. A. Long, who have devised a method for treating infections of the mouth and throat. The difficulty in this region is that the constant secretion and swallowing of saliva wash away anything intermittently applied. Penicillin was therefore incorporated in a slowly dissolving pastille, and the patient was instructed to insert another as soon as the previous one had disappeared. By this means the saliva could be kept fully bacteriostatic throughout the day, with a marked effect on its general flora as well as on that of the lesion under treatment. It has previously been noted by Garrod¹⁰ that the great majority of the numerous bacterial species found in the mouth are penicillin-sensitive, with the result that mixed and often predominantly anaerobic infections due to bacteria derived from the mouth are amenable to penicillin treatment. Three examples of such infections are that commonly found in fractures of the jaw compound into the mouth, in tooth sockets after extraction, and in the tonsillar bed after tonsillectomy. Judging from the few cases treated, sepsis in these conditions seems to have been well controlled by the use of penicillin pastilles. Among specific infections Vincent's gingivitis shows the clearest response: symptomatic relief and the disappearance of the causative organisms were both rapid. This is a most troublesome and unresponsive infection to treat by other methods in current use, and if penicillin will indeed relieve and eradicate it so conveniently, this is a minor victory of far-reaching consequence. There appears also to be a distinct effect on acute haemolytic streptococcal infections of the throat, including scarlet fever. This even wider sphere of usefulness evidently calls for further study from the clinical standpoint. The fact of the rapid disappearance of the organism is encouraging, and may, as the authors point out, have a useful epidemiological bearing. It may be significant from the same point of view that the carrier state can be suppressed temporarily. The return observed to the *status quo ante* was only to be expected, since the depths of the tonsils in which the organism lurks must be quite inaccessible to a surface application. This is the simplest form of penicillin treatment yet devised, and embraces very common if not usually very dangerous conditions. If its predicted value should be confirmed the demand for penicillin for these purposes will be an additional embarrassment to those in charge of the present limited supplies.

TRAINING FOR THE D.P.M.

The second interim report of the Committee on Psychological Medicine of the Royal College of Physicians of London puts forward some fairly precise recommendations which will make the new diploma a much more rigorous and satisfactory achievement than the existing one. The course, it is recommended, should occupy five years instead of the present single year, and the subject matter is to be comprehensive and thorough, including such ancillary medical and social sciences as are relevant to the proper understanding and treatment of psychiatric disorders. The first three years are to be spent in hospitals, clinics, and laboratories. A house-physicianship and also a post in a neurological department are considered essential. Child psychiatry, psychology, and industrial psychology are to be included. A notable arrangement proposed is that after the three years taken to pass the examination the diploma shall not be awarded until two further years of clinical experience have been spent in some special psychiatric field. The committee wishes to abolish the separation between the institutional psychiatrist and the psychiatrist engaged in private practice and also to limit the isolation

⁷ *Brit J Exp Path*, 1943, 24, 227.

⁸ *Science*, 1944, 59, 351.

⁹ *J Amer med Ass*, 1944, 128, 63, 67, 7.

¹⁰ *British Med. J. Journal*, 1944, 1, 523.

of "sub-specialists." A central board for examinations and for approving institutions for training purposes is contemplated; and the comprehensive and well-thought-out recommendations include some attention to the difficulty of candidates finding the means to take them through the various stages of the course. It is pointed out that American experience does not suggest that the greater severity of the regulations for the diploma will limit the number of candidates.

SCIENTIFIC WORK OF THE R.C.S.

A year ago the Scientific Report of the Royal College of Surgeons of England recorded the plans which had been made to obtain material out of which to rebuild the Museum Collections destroyed by enemy action. This year's report shows a generous response of Fellows, Members, and friends of the College to the appeal for specimens. The accession list, however, does not include material being held in store at various centres outside London and abroad ready for transfer to the College when the appropriate time arrives. It is only from a great mass of material that a proper choice of specimens can be made—a process which we hope will take into account the needs of both the expert and the student. The task of selection will be in the capable hands of Prof. R. A. Willis, the newly appointed Collins Professor of Pathology, who will have the good wishes of every friend of the old Museum in his work. Prof. A. J. E. Cave, in his position as Assistant Conservator of the Museum, has performed well the valuable and onerous duty of conserving the surviving specimens of the old Museum and of recording the difficulties under which his work has been carried out. His reports during the past four years have in turn contained the story of loss, salvage, preservation, and now reconstruction. The foundations of the future Museum are being laid with patience and understanding. In spite of shortage of staff the Museum has been able to perform useful service to research workers in many fields.

The Research Laboratories have pressed forward their work on hepatic dysfunction. The relation of diet and of specific dietary components to the rate of recovery from hepatitis is a most important finding which has immediate bearing on recent work on wound healing. It also has a bearing on the question of excessive nitrogen loss after trauma, including simple fractures. The extensive liver damage found in severe infections and after burns has not been given the attention it deserves. If this damage can be repaired or averted, as the report suggests it can, there is a new approach to the treatment of burns and infections. Of interest in the same connexion is the observation that patients with hepatic disease are unable to produce antibody in response to antigenic agents at the same rate as normal individuals. Now that many infections can be controlled by penicillin and the drugs of the sulphonamide group these metabolic problems assume greater significance. Their solution must influence considerably the after-care of surgical patients in the future. The present occupant of the chair of surgery at Johns Hopkins has well said that "the recent decreases in morbidity and mortality rates in surgical patients are due more to advances in pre-operative and post-operative treatment than to any other factor." Experience in this war has shown how important are such abnormalities as dehydration, acid-base balance, and hypoproteinaemia in influencing the recovery and as factors in the production of shock. Without a considerable increase in knowledge of hepatic function our treatment of such abnormalities must remain empirical. The work on carbon tetrachloride poisoning opens up a new approach to the problem of

hepatic dysfunction following anaesthesia. Miller and Whipple¹ demonstrated that methionine could prevent fatal liver damage after chloroform anaesthesia in dogs depleted of protein. This report shows that methionine can exert a curative action after the damage has occurred. Of even greater theoretical and practical interest is the discovery that in renal failure associated with liver damage choline is an effective therapeutic agent. It is obvious that not all cases of renal failure can respond to choline, but the discovery that the type of renal failure described by Griffiths² occurs in man and can be treated by choline is of first-rate importance. Work on nerve injuries and regeneration of nerves after suture is being carried on by Dr. F. K. Sanders at Oxford. His recent publications have contained observations of great interest, and in association with Prof. H. J. Seddon and Dr. J. Z. Young he has thrown much light on the mechanism of nerve regeneration after injury and suture. We note with interest the way in which the laboratory staff have made use of clinical material for their study of the fundamental problems recorded above. This is the method used so successfully by what may justly be claimed is the English school of clinical science—the method of Ferrier, Head, and Lewis.

TUBERCULOSIS WORK IN WALES

We are fortunate in being able to gain through the thirty-second series of annual reports of the Welsh National Memorial Association a bird's-eye view of the tuberculosis work as it can be carried out in a considerable yet varied population. As usual, the reports are lively and informative. Dr. Norman Tattersall (principal medical officer) has a good word to say for the new treatment allowances. The social work for patients is administered through the counties and county boroughs, unlike the dispensary and institutional work, which, in Wales, is directed by the Memorial Association and its branches. Dr. Tattersall thinks that this dual system leads to better understanding between the central organization and the counties. Mass radiography is going ahead, and Wales is the only part of Britain which has a truly mobile apparatus, accommodated in a motor van which is independent of main electrical supplies. Experience accumulated shows that about 5% of the subjects examined have to return for a large x-ray film, and 1% require observation for tuberculosis. Apparently Welshmen are becoming more "x-ray conscious"; there is a tendency for chest films to be demanded on unnecessary or trivial grounds; in Cardiff the welcome change is the patient's desire for more contact examinations. Problems, chiefly nursing and domestic, keep the waiting-lists for admission to sanatorium high, and nowadays the average length of treatment is one year—much longer than it used to be. The old "shyness of treatment" is disappearing, and with the combined influence of the Rushcliffe scales of salaries and help given by the Ministry of Labour, the staff shortages are being slowly overcome. Supported by a special gift from the Davies family, Prof. W. H. Tytler continues his research into the use of promin. The only sad and irrevocable note in these reports is the obituary of the late Lord Davies, the founder, creator, and inspirer of this patriotic Welsh movement since its inauguration 32 years ago.

We regret to announce the death of Sir Robert Kelly, consulting surgeon to the Liverpool Royal Infirmary and emeritus professor of surgery in Liverpool University. A memoir will appear next week.

For injection treatment of VARICOSE VEINS

• A careful technique can be
time wasted, in the injection treat-

ment of varicose veins, unless use is made of the best available
sclerosing agent, ethanolamine oleate.

'Ethamolin,' a solution of ethanolamine oleate, is of standard
purity and potency, ensuring consistent results. It produces a
firm, adherent thrombus, but accidental leakage from the vein
is not followed by sloughing. Pain after injection is infrequent,
and recanalisation seldom occurs. Being bactericidal, 'Ethamolin'
minimises the risk of infective phlebitis.

GLAXO LABORATORIES

ETHAMOLIN
BRAND OF ETHANOLAMINE OLEATE
2 cc. ampoules in boxes of 6 and 100 Bottles 15 cc. and 30 cc.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX. BYRON, 3434

In Childhood... and Adolescence

In childhood and adolescence, the total haemoglobin increases with growth, and the store of iron in the body must be maintained proportionately. It is acknowledged that this added need for iron may be difficult to obtain from the food and, consequently, must be supplied as medication. Excellent results are offered by the use of specially prepared iron (easily assimilated ferrous sulphate) incorporated in 'Plastules.'

Formula: Exiccated Ferrous Sulphate B.P. 5 grains,
Dried Yeast 2 grain, Excipient sufficient quantity.

'PLASTULES'
BRAND *Hæmatinic Compound* REGD
For Anaemia and Debility
In two varieties: PLAIN • with HOG'S STOMACH

'KEPLER' TRADE MARK

COD LIVER OIL WITH MALT EXTRACT

Helping to build the men and women of tomorrow

'Kepler' provides valuable supplementary Vitamins A and D together with readily assimilable fat and carbohydrate.

There is no finer product of its kind. The high standards of quality for which more than one generation of medical men has esteemed 'Kepler' have in no way been lowered because of wartime difficulties. 'Kepler' Cod Liver Oil with Malt Extract contains Cod Liver Oil 23% v/v with Malt Extract; each tablespoonful provides not less than 3000 International Units of Vitamin A and 300 International Units of Vitamin D.

LOCAL AUTHORITIES: WHAT THEY ARE

The answer given in an Act of Parliament of 1916 is "any person or body of persons who receive or expend the proceeds of any rate and any other public body which the Ministry of Health may determine to be a local authority." In the Local Government Act of 1933 a local authority is defined as the Council of a County, County Borough or non County Borough Urban or Rural District, or Rural Parish.

The principal local authorities in England and Wales to-day are.

62 County Councils, with populations varying from 18,000 to 1,880,000.

83 County Boroughs, with populations varying from 26,000 to 1,000,000.

29 Metropolitan Borough Councils, with populations varying from 23,000 to 271,000.

309 Non-County Boroughs, with populations varying from 900 to 200,000.

572 Urban Districts, with populations varying from 760 to 188,000.

475 Rural Districts, with populations varying from 1,400 to 135,000.

In addition there are 7,000 Parish Councils and 4,000 Parish Meetings (rural parishes not entitled to elect a Parish Council), there are some 600 miscellaneous authorities created for specific purposes ranging from local fisheries committees to Trustees of London Squares and more than 1,100 joint boards or committees dealing with hospitals, water supplies, sewerage, burials, gas, town planning etc.

This mass of governmental machinery is perplexing in structure, and there is perhaps no subject affecting so substantially his daily life in which the ordinary citizen displays less interest. The relation between the powers and functions, administrative areas, populations and financial resources of this 'loose hierarchy of elected councils is illogical and inconsistent. Some authorities with small populations and limited revenues enjoy wider powers and higher status than others with large populations and abundant financial resources. Thus the County Borough of Canterbury, one of the smallest towns in Kent, with a population of 26,000 and a rateable value of £216,000, has comprehensive local government powers, while Harrow, one of the largest urban districts in the country, with a population of 188,000 and a rateable value of £2,110,000, exercises only the restricted powers of a district council. Nearly two thirds of the 1,530 local authorities in the country serve populations of less than 20,000. In 8 non-county boroughs the rateable value exceeds £1,000,000, in 14 it is below £10,000. The product of a penny rate is £448 in one county and £84,000 in another. The rateable value of one town is £3,100 and of another £6,000,000.

Although the foundations of our system of local administration date back to the townships, hundreds and shires of Saxon times, local authorities in their present form are the product of the last 100 years or so. Their status and constitution are at present governed by the Local Government Act, 1933. This Act provided that for local government purposes England and Wales (excluding London) should be divided into administrative counties and county boroughs, the administrative counties being divided into county districts—either non-county boroughs or urban districts or rural districts. What are the differences between these local authorities? Broadly county boroughs are autonomous bodies responsible for all local government functions within their areas, the remaining authorities form component parts of the county. The county council which administers certain services for the whole administrative county, is financed partly by rate precepts upon the borough, urban, and rural district councils, each of which performs local functions in its own area. The county council is charged with the duty of conducting a decennial review of the areas of these district authorities and has certain responsibilities for the organization of electoral areas in the county.

County Councils

County councils were established by the Local Government Act of 1888. They were elected bodies with mainly supervisory powers although the Act transferred to them certain administrative business previously undertaken by Justices of the Peace in Quarter Sessions. The 62 county councils of to-day are those enumerated in the Local Government Act, 1933, and

the London County Council. They consist of county councillors elected by the local government electors, and county aldermen elected by the county council from their own number or from persons qualified to be county councillors. The maximum number of aldermen is one third of the county councillors. The aldermen hold office for 6 years, the senior half retiring triennially. The county councillors hold office for three years. A county council is statutorily required (a) to elect annually a chairman and vice-chairman, the former by virtue of his office becoming a Justice of the Peace for the county, (b) to appoint certain officers, including a Clerk, Medical Officer of Health, Treasurer, Surveyor, Analyst, Chief Constable, Clerk of the Peace, Registrars of Births, Deaths, and Marriages, Inspectors of Weights and Measures, and the necessary officers for the administration of public assistance and mental hospitals. The council is empowered to appoint such other officers as it thinks necessary for the efficient discharge of its functions. The meetings and proceedings of county councils are regulated by the Local Government Act, 1933, and by Standing Orders which that Act authorizes. At least four meetings a year must be held.

Municipal Corporations

Municipal corporations existed long before the Municipal Corporations Act of 1835. Many townships had obtained Charters of Incorporation from the Crown enabling them to be represented in Parliament, to control local trading, to appoint their own officers, and to collect their own taxes. Population or the size of a town was no criterion for the grant of a Charter—some villages had municipal corporations while important towns such as Manchester and Sheffield had no Charter before the 18th century. The Tudor monarchs exercised freely their power of creating boroughs by Charter. Many 'rotten or pocket boroughs were created during the reign of Queen Elizabeth to enable the Crown to obtain political representation in Parliament. In Yorkshire, Aldborough and Boroughbridge were in the same parish and each returned two members at the time when Birmingham was not represented in Parliament. Until 1835 the boroughs were governed by various close corporations constituted on an oligarchical basis. The right to vote was restricted by Charter to members of the governing body of the borough—usually self elected and not responsible to anyone for the management of municipal affairs. They existed not primarily for the good administration of the borough but as organizations for returning members to the House of Commons. The extent to which Charter Boroughs had grown is revealed in the Great Reform Act of 1832, by which 56 boroughs in England were disfranchised absolutely and 31 others each lost one member. In 1835 the principle of popularly elected municipal councils was established. This and subsequent measures to secure a uniform system of municipal government were consolidated in the Municipal Corporations Acts of 1882 and 1883. The municipal boroughs to-day are those named in the Local Government Act, 1933, with the addition of any new boroughs constituted since then.

County Borough Councils

County borough councils were established in 1888. The Local Government Act of that year constituted a separate administrative class of some 60 large boroughs which were either counties of themselves or had populations of 50,000 or more at the passing of the Act. The creation of a new county borough requires a local act, and a minimum population of 75,000 is now essential before a non-county borough can apply for the higher status. A municipal corporation is defined in the Municipal Corporations Act of 1882 and in the Local Government Act of 1933 as 'the body corporate constituted by the incorporation of the inhabitants of a borough'. In 1888 boroughs were divided into county boroughs and non-county boroughs and by the Local Government Act, 1933, the corporation is given power to act through the borough council, consisting of a mayor (or Lord Mayor), aldermen, and councillors. The mayor is elected annually by the council from its own members or from persons qualified to be aldermen or councillors. During his term of office the mayor becomes a Justice of the Peace for the borough and a Justice of the Peace for the county in which the borough is situated. The mayor is empowered to appoint a deputy mayor. The

aldermen, one-third in number of the councillors, are elected by the latter from their own number or from persons qualified to be councillors. They hold office as aldermen for six years, but the senior half retires triennially. Councillors are elected by the local government electors for the borough and hold office for three years, the senior third of the members for each ward (or for the whole borough if it is not divided into wards), retiring annually on Nov. 1. The number of councillors is fixed by the Charter or other legal measure and distributed among the wards into which the borough is divided for electoral purposes in the proportion of three councillors, or some multiple of three, to each ward.

A borough council is statutorily required to appoint a Town Clerk, Treasurer, Medical Officer of Health, Surveyor, Sanitary Inspector, Auditor(s), Chief Constable (where the borough maintains its own police force), and other officers as set out under county councils, unless the borough is a non-county borough, in which case there is no power of appointment of Analysts, Registrars of Births, Deaths, and Marriages, Poor Law officers, and mental hospital officers.

Urban and Rural Districts

The "parish pump" so often criticized to-day has played a prominent part in local government. It was the parish which was taken as the local administrative unit when the first Poor Law was introduced in 1601. Over 230 years later parishes were combined into Poor Law Unions for the administration of poor relief by Boards of Guardians, though some "unions" remained single parishes. In 1848 a Central Board of Health was established, not responsible to Parliament, with power to create local boards of health in urban areas. Under the Public Health Act, 1872, the country was divided into urban and rural sanitary districts; the Poor Law Boards of Guardians were made the sanitary authority in rural areas and the borough councils and local boards of health in urban areas. The rural sanitary district was defined in the Act as "the Poor Law Union taken as an area for sanitary administration." The titles "urban district council" and "rural district council" were first used in the Local Government Act, 1894, under which urban district councils replaced the old local boards of health in urban areas and rural district councils took over the public health functions previously exercised by the boards of guardians in rural areas. The same Act established a parish meeting for every rural parish, and a parish council for every rural parish with a population of more than 300.

The urban and rural district councils of to-day consist of councillors elected by the local government electors for areas and a chairman, elected by the councillors, who in virtue of his office becomes a Justice of the Peace for the county. The district council may appoint a vice-chairman. The term of office of district councillors is three years, one-third of the council retiring annually on April 15 unless the county council, at the request of the district council, has directed that the members of the district council shall retire together in every third year on April 15. For electoral purposes an urban district may be divided into wards, and a rural district is divided into areas which are either parishes, or combinations of parishes, or wards of parishes. Urban and rural district councils are statutorily required to appoint a Clerk, Medical Officer of Health, Surveyor, Treasurer, and Sanitary Inspector.

The qualifications for registration as a local government elector are set out in the Representation of the People Act, 1928. The qualification is based primarily on the occupation of land or premises as owner or tenant. Among those disqualified are persons under 21 years of age and those subject to any legal incapacity, including aliens, persons of unsound mind, and those convicted of treason or felony.

The Medical Society of the London County Council has been formed with the aim of encouraging contact between the medical staffs of L.C.C. hospitals and of neighbouring municipal and voluntary hospitals and general practitioners; and to collaborate with the Clinical Research Committee of the L.C.C. Public Health Department. The inaugural general meeting is to be held in January, 1945. All whole-time medical officers of the medical service of the L.C.C. who have completed at least six months' continuous service are invited to apply for foundation membership to the secretary of the society (County Hall, S.E.1) by Dec. 1.

Reports of Societies

GASTRITIS

At a meeting of the Section of Medicine of the Royal Society of Medicine, with Dr. GEOFFREY EVANS in the chair, the subject of discussion was gastritis.

Introduction

Dr. T. IZOD BENNETT said that little was known of the aetiology of gastritis, its morbid anatomy was obscure, symptoms were often absent, and prognosis was doubtful. The one thing about which they could speak with certitude was the treatment: there was not any! During the present war articles had appeared on dyspepsia as a source of invalidity in the Services, in which it was shown that this was a common cause of disability; but in the course of a considerable experience he had not once succeeded in definitely establishing a diagnosis of gastritis in any member of the Services suffering from dyspepsia.

An entirely new light had been thrown on the condition by the introduction of a safe and reliable type of gastroscope, and on gastroscopy the diagnosis must principally rest, though even gastroscopic diagnosis must be accepted with reserve. Great care must be taken in drawing conclusions from the observations of the gastroscopists. He mentioned the remarkable studies, to which attention was recently called by the late Sir Arthur Hurst, in a book entitled *Human Gastric Function*, by Wolf and Wolff, which furnished a warning against the extreme danger of drawing conclusions from a single gastroscopic examination of any subject, and if gastroscopy was to be performed at least twice the difficulties of this method of examination were more than doubled.

The advent of fractional gastric analysis had led to the recognition of the relative commonness of the condition named "achylia gastrica." Work which he had done with Ryle on this subject on normal medical students suggested that complete achylia gastrica was present in 3 or 4% of normal healthy young adults. It was to be regretted that the gastroscopists had not yet investigated such cases, but it was certain that they occurred. Why, indeed, should a person with severe gastritis have any symptoms? A considerable proportion of patients after gastrectomy were symptomless, so that it was clear that obvious symptoms might not be produced by the mere destruction of the gastric mucosa.

Dr. Bennett concluded with the remark that an intelligent view of this subject could only be expected after reliable observations had accumulated enabling them to agree that certain data fully justified the diagnosis of a disease that at present was undoubtedly diagnosed with a frequency for which there was no justification whatever. Schindler and his collaborators wrote (*J. Amer. med. Ass.*, 1937, 108, 465) that "chronic gastritis is a very frequent and often a very severe disease." This ridiculous assertion epitomized the literature which had so long misled them in their search for knowledge of this obscure subject.

Gastroscopic Pitfalls

Dr. F. AVERY JONES (Central Middlesex County Hospital) discussed gastroscopic pitfalls in the diagnosis of gastritis. The mucosa might be thicker than normal; more uneven, more rugose, giving a pebble-beach appearance. This was commonly called "hypertrophic gastritis," but Rogers and Magnus had failed to demonstrate any inflammatory changes, and Dr. Jones had confirmed this in a number of his own cases. This appearance was a constitutional change and probably within normal limits. A pebble-beach appearance could be produced by inflammatory reaction, but it was much more irregular and associated with patchy hyperaemia and an excess of mucus. Similarly atrophy of the stomach, non-inflammatory but endocrine or nutritional in origin, was liable to be called atrophic gastritis, and here again atrophy did follow inflammatory changes, but the appearance was much less uniform than with simple atrophy. A further pitfall was the change that might occur as an enotional reaction, which had been so well described by Wolf and Wolff.

all the appearances of secondary mucosal gastritis were to be seen also as primary forms, superficial and interstitial, the latter being sometimes hypertrophic and progressing to mammillary, polypoid, or cystic formations. He added that the use of the gastroscope had established the great frequency of mucosal gastritis, particularly after the age of 40, but the utmost care must be exercised in diagnosing a case as gastritis, above all in ascribing symptoms even to obvious disease appearances in the mucosa. In the course of some further discussion Mr. W. E. TANNER expressed his agreement with findings of Dr. Avery Jones and Dr. Hancock, and described the three types—thick, medium, and thin—into which, in his view, the gastric mucosa might be divided. Dr. FLETCHER commented on the fact that it was remarkable to hear a discussion without reference to the appearance in normal individuals. Further research on the normal was greatly wanted.

Dr. HANCOCK finally said a word in defence of Schindler, who had done valuable pioneer work in the early days of the gastroscope, though he had perhaps been carried away by enthusiasm in certain respects.

NUTRITION OF THE PREMATURE INFANT

At a meeting of the Section of Disease in Children of the Royal Society of Medicine on Oct. 27 the subject of discussion was the nutrition of the premature infant in the first year of life.

Dr. HELEN MACKAY, president of the Section, said that until recently the feeding and care of premature babies had been almost entirely in the hands of midwives, but there had been no systematic teaching, and each midwife and each paediatrician had to learn or fail to learn at the expense of the infants. Incidentally she stressed the importance of body temperature. A baby was much more likely to swallow or to suck if his temperature was between 98° and 100° than if it was between 96° and 98°; the cold baby would not take his food. She exhibited some tables indicating a scheme of feeding for premature babies in the first week of life, all the foods being constructed to provide 20 calories per fluid oz. In the case of the baby whose weight at birth was 3 lb., 30 calories were given on the first day, and this was increased until 150 were given on the seventh, a total for the 7 days of 610. In the case of the 5½-lb. baby, 40 calories were given on the first day, increasing to 270 on the seventh, and making a total for the week of 1,113. Her view was that the quantity of food given was much more important than the balance between protein, fat, and carbohydrates in different types of artificial feeds. The standardization of infant feeding in hospitals was of great value, as it enabled nurses and house officers to become thoroughly familiar with its details, and reduced to a minimum the likelihood of gross errors or sudden changes in food owing to changes in nursing or medical personnel.

Dr. MARY CROSSE (Birmingham) said that the feeding of the premature infant was not always easy. The infant had certain defects due to prematurity, such as feebleness, or sometimes absence, of the sucking and swallowing reflex, extreme liability to regurgitation, immaturity of the alimentary tract, and greater need for fluids. She put in a plea for catheter feeding through the mouth and not through the nose. In very small babies it was extremely easy to injure the nasal mucous membrane and render it infected. In her ward both oesophageal and stomach feeding had been tried out, and she much preferred the former because of less distension with air, and because the oesophageal feeding could be repeated without causing vomiting. In feeding the baby everything depended upon how quickly it tired. A beginning should be made with two-hourly feeds, going on to three-hourly. Nurses loved a spectacular gain in weight. In her hospital, however, it was survival that was stressed, not weight. The babies were weighed on the third, seventh, and tenth days. Little attention was paid if they had not gained on the third and seventh, but it was desired that they should gain by the tenth. It was not possible to get an infant of under 5 lb. to go regularly to the breast. It was always the practice in her ward to raise the head of the cot, and the baby was fed on the right side, thereby causing less cyanosis and distension, probably owing to the fact that the stomach emptied more quickly in that position. She found that a baby of 4½ lb. did not have a good appetite in a hot

humid atmosphere. Accordingly when babies reached 4½ lb. they were taken into a cool room, and it was found that their appetites improved markedly. If a small baby had a body temperature of 96° she did not mind, but she did not like it to go below that point. The stabilization of temperature was more important than its elevation.

Dr. J. O'REILLY said that an analysis of feeding charts for a number of premature babies had shown that the feeds must be increased gradually to about 60 calories a day before the majority would show consistent gains in weight. An average gain of 1½ oz. a day over a period was quite satisfactory. In general he found that when the babies were established on milk feeding no effect on the weight or on the condition of the child was produced by giving extra fluid. The fluid content of undiluted milk appeared to be sufficient. Small babies and babies born of toxic mothers were particularly liable to dehydration. Additional fluid in these cases caused an immediate gain in weight, but its continued administration had no effect after the dehydration had been overcome.

Major LAMB, U.S.A.M.S., believed the importance of humidity and the control of temperature had been underestimated. The amount of fluid that could be lost through the skin in a small baby could reach considerable proportions. It must be remembered that the smaller the baby the greater the skin area in proportion to the mass. He never allowed his babies to be weighed for at least a week after birth. The less the premature baby was handled the better. These were babies who still belonged to the uterus, and the more closely that environment could be approximated to the better. Dr. FRASER BROCKINGTON said that on analysing the cases of premature infants he had been astonished at the proportion who did not survive 24 hours, also that the proportion surviving were always very much the same in the same weight groups.

Dr. CROSSE, in reply to a question about the mortality of the premature infant, said that in her series babies weighing less than 2 lb. all died in the first 48 hours. In the case of those weighing between 2 and 3 lb., death might not take place until the next week. Babies of 3 to 5 lb. suffered most from intracranial haemorrhage, but this did not apply to those over 5 lb., from which point there were more deaths from sepsis and fewer from intracranial haemorrhage.

Two complementary papers on cinemicrography were given at the October meeting of the Association for Scientific Photography. Mr. H. Emmett first described the set-up used in one of the I.C.I. research laboratories. The second paper, by R. McV. Weston, entitled "Cinemicrography in Biological Research," dealt with many of the same problems, but described a more elaborate apparatus for higher-power micrography and using a 16-mm. Cine-Kodak special camera to record the images. Owing to the employment of living specimens, a rotating sector shutter was used to prevent overheating, and the whole of the microscope stage was enclosed in an incubator, the controls being outside. The heating elements were two 30-watt carbon-filament lamps shielded to prevent direct rays reaching the object and a chloroform-mercury thermostat next to it. As in the first apparatus the light was provided by a 100-c.p. pointolite lamp. After a full description of this apparatus and its mechanism for time-lapse cinemicrography, Mr. Weston projected a film showing the movement of leucocytes among the red corpuscles of the blood, and higher magnifications showed very clearly the triple nuclei and the movement of the grains within the white blood cell.

At a meeting of the Whipps Cross Hospital Medical Society on Nov. 3, the chairman, Dr. W. E. Joseph, presiding, the following cases were shown: (1) bilateral effusion into knee-joints; (2) cavernous sinus thrombosis; (3) polycystic kidneys; (4) secondary rash; (5) ulcerative colitis; (6) polycythaemia rubra vera; (7) spontaneous pneumothorax. The next meeting of the society will be held at 8.30 p.m. on Dec. 8, when Dr. Keith Simpson, Home Office pathologist, will lecture on "Common Sense in the Detection of Crime." This meeting will be open to non-members.

The following officers (1944-5) of the Association of Anaesthetists were elected at the annual general meeting on Oct. 25: President, Dr. A. D. Marston; vice-president, Dr. C. Langton Hewer; hon. treasurer, Dr. Z. Mennell; hon. secretary, Dr. W. A. Low.

Correspondence

Doctors for Germany

SIR,—In your issue of Sept 30 you very kindly gave publicity to UNRRA's probable need for doctors to assist in the control of displaced persons in Germany. At that date it appeared probable that the military occupation of Germany might be imminent; unfortunately it now looks as if we must wait a little longer for the consummation.

By earlier direct application and through the good offices of the Central and Local Medical War Committees we have now the names and records of a considerable number of doctors available for service. Arrangements are being made to interview selected applicants in the near future, and those not selected will be informed that there is either no, or no immediate, likelihood that their help will be required.

I am extremely grateful to the large number of doctors who have expressed their desire to undertake what would be an arduous and possibly thankless task—I am, etc.

ANDREW TOPPING

11 Portland Place, London W.1. Director of Health European Regional Office, United Nations Relief and Rehabilitation Administration

Episiotomy

SIR,—May I be permitted to comment upon certain aspects of Dr Gaskell's letter (Oct 14, p 511) replying to Dr O'Meara's criticisms (Sept 9, p 353) of his procedure in episiotomy?

The wisdom of giving pituitary extract before the end of the third stage under any circumstances has, of course, been a cause for some difference of opinion for many a day. This Dr Gaskell will doubtless concede, and in spite of his happy experience there are very many obstetricians who will continue not so to use it in the belief that as a general rule it is not sound practice. In this, as in many other instances, it is to some extent a question of deciding from general and personal experience that a particular belief is fundamentally sound and sticking to it. I think Dr Gaskell has perhaps objected to the apparent petulance with which Dr O'Meara says, "He doesn't like it, won't do it, and won't allow it to be done." The truth lies somewhere between, but I cannot help feeling that when Dr Gaskell says he has frequently given pitocin when the head is well down and the os fully dilated, however foolhardy a given practice might be deemed, the conditions here are relatively so well nigh foolproof that Nature would probably lend her aid to enable one to get away with it nine times out of ten. It has been stated "It now seems that parturition begins as a result of the gradual accelerating convergence of a number of factors—structural, humoral, nervous, nutritional, and circulatory. The heightened contractile powers of the uterus under the influence of oestrin and distension require for true labour the intermediation of integrating factors, for if intense contractions of the myometrium alone were sufficient for parturition the administration of an oxytocic drug would hasten the process without real danger of rupturing the uterine wall. This, however, is not the case." I may be wrong, but it seems to me that Dr Gaskell implies the not giving of pituitary extract before the end of the third stage is almost an old wives' tale.

I am equally out of agreement with him regarding some of his remarks on the use of ergometrine. I agree with Dr O'Meara that the giving of it as a practice before the placenta is expelled is not a good thing, so, apparently, does Dr Gaskell, based for the most part on the isolated experience of one occasion when a drastic result followed. Years ago I did some unpublished work on the use of ergometrine before the expulsion of the placenta in a large series of quite unselected cases. I gave it intravenously not once but literally hundreds of times, not wholly in ignorance, nor without thought, and I never had any untoward results, nor did I have to risk my popularity by calling on a large part of the honorary staff to deliver me out of my predicament. I found that the duration of the third stage was on the average definitely shortened, and the amount of blood lost quite appreciably diminished. Present circumstances make it very difficult for me to have access to my figures. My impression was that

ergometrine gave more even less erratic contractions than pituitary extract, though I had no positive proof such as kymographic tracings. In cases of p.p.h. I also felt that while I had locked the door with ergometrine I liked to bolt it with an injection of pituitary extract. This may have been over-caution, but I think even nowadays most obstetricians will forgive me a little of it in dealing with p.p.h. I suppose I used the same kinds of preparation as Dr Gaskell, but, even with my happy experience of the drug, I still don't suggest that it should be used before the placenta is out as a practice, and, also, that if one had gone on using it long enough I feel sure one may well have met the disaster Dr Gaskell relates. Lastly, although I am not in full possession of the facts, I cannot help wondering why Dr Gaskell was using chloroform for a delivery. There are quite a number of very eminent obstetricians who banished chloroform from the delivery room many years ago. Here, again, the truth, I admit, lies not wholly in the extreme, but why not use an anaesthetic less notorious for its relaxing effects upon the uterine musculature? I have always felt that the secret of good obstetrics lies no less in the intelligent anticipation of likely disaster and its judicious avoidance than in skilled manoeuvre if it does occur. It saves me trouble and almost invariably saves the patient trouble too. I agree with what the nurse said, but I wonder if I would agree with the reasons for having to say it—I am, etc.

H. VINCENT CORBETT,
Major R.A.M.C.

REFERENCE

Reynolds S.R.M. *Physiology of the Uterus*.

SIR,—The article by Dr J.D.S. Flew (*Journal* Nov 11) gives an excellent account of the technique, reasons for, and risks of this simple operation. I agree with him that the central J shaped episiotomy is the best one to perform, because not only does it avoid the risks of (a) haemorrhage and (b) trauma to Bartholin's duct, but it also prevents severing muscle fibres in the perineal floor. Division of the central tendon is the soundest anatomical and surgical procedure.

One has seen many cases of lateral episiotomies in post natal clinics and in quite a fair percentage of these the vaginal outlet is gaping owing to retraction of the cut muscle fibres which have not been approximated by the repair of their fascial sheath. In a central episiotomy, repair of the central tendon is easy and the result entirely satisfactory. The risk of extension of the central episiotomy into the rectum is avoided by the use of the curved incision, but writers such as Pratt, Hodgkinson, and Kennedy (*Amer. J. Obstet. Gynec.* Feb, 1942), who quote a series of 300 cases of straight central episiotomy, state that the risk of a third-degree extension is greatly exaggerated, and, secondly, that in the 10 cases of their series in which it occurred repair of the wound in layers, after the third stage of labour, resulted in complete healing by first intention.

The actual time at which the episiotomy should be performed is, as the writer states, when marked perineal bulging has occurred. Why is this the moment of choice? Because it is only then that one can decide whether or not an incision is necessary, and stretching of the perineum by demarcating the structures in it allows the operator to make the incision in the correct position. It should be stressed when teaching the technique of episiotomy that the actual incision is made during uterine relaxation, fundal pressure on the foetus being the only factor concerned in stretching the perineum.

I do not agree with the author's suggestion that midwives should be taught to perform an episiotomy, in his list of indications for its use a medical officer should be in attendance to deal with the complications mentioned, and it is the duty of the midwife to send for medical aid immediately she thinks any abnormality has arisen.

Lastly, no reference was made in the article to the method of repair or the material used for the repair, although Dr Flew stated that the sutures of a perineal tear are uncomfortable during the 7 to 10 days they are *in situ*. The repair must be done in correct anatomical layers, mass ligation by through-and-through sutures leads to pocketing of blood clot, which readily becomes infected in the perineum. The material used throughout should be No. 0-20-day (chromicized) surgical gut,

the skin layer being approximated by a subcuticular suture. I have repaired many in this way and have found that the results are excellent and the discomfort to the patient negligible.

IVOR HUGHES.

Aluminium Dust for Silicosis

SIR,—With reference to your leader on this subject (Nov. 4, p. 601) may I point out that the experimental results obtained by Denny, Robson, and Irwin are in no way dependent upon the obsolete theory that "silica exerts its injurious effects upon animal tissues through a slow transformation into silicic acid." Their results are in entire conformity with the modern belief founded upon the work of Sir Lawrence Bragg (and of Leroy Gardner on the experimental side) that silica is at its maximum chemical activity in the aerosol state, provided the particles are small enough. Indeed one of the methods—though by no means the best method—of satisfying the active silica surfaces and rendering them chemically inert is by converting the aerosol into a hydrosol. A better method is to satisfy the active surfaces of the dust particles by coating them with aluminium. This is what Denny, Robson, and Irwin have done. The unsatisfied oxygen atoms of the silicon-oxygen tetrahedra at the surfaces of the particles combine with the aluminium to form a surface layer of alumina. If we are to continue to describe such chemical reactions as "adsorption," then all silicates become "adsorption compounds."

The Americans are very careful, when writing of "solutions" of silica and of "silicic acid," to put these terms between quotation marks. For they know that there are no true "solutions" of silica and that "silicic acid" is a hypothetical or inferential "acid" which is not found in Nature, cannot be demonstrated by any indicator, and cannot be manufactured. What are found are varying suspensions of clumped silicon-oxygen tetrahedra—all characteristically colloidal. True "silicic acid" remains an unrealizable ideal, a ghost that has never materialized.

Pure or "classical" silicosis is a rare condition of the lungs, and is in all probability produced by the direct chemical action of active silica dust particles on the cells which take them up. Such active dust is typically produced by shot-firing or dry compressed-air drilling in quartz, quartzite, or quartzore rock, or by stonemasons dressing such rock with the chisel. The average pneumokoniosis met with in this country is a mixed condition in which silica dust may play a part, but which may be caused by the inhalation of almost any mineral dust, provided that it is in sufficient concentration and the exposure is long enough. Its development is greatly aided by any disease or condition which interferes with the mechanism of dust elimination from the lungs. In these cases the action of the dust is mainly mechanical by lymphatic blockage, and they may be described as "dust retention fibroses." There is little reason to doubt that even aluminium dust in dense concentration might in time, with prolonged exposure, lead to such blockage, and the German findings may not be so mysterious after all.

One other point: it is frequently assumed that if a large amount of silica is recoverable from lungs on incineration, the victim must have suffered from silicosis. The fallacy of his reasoning has been demonstrated over and over again, notably by Prof. Matthew Stewart of Leeds and his assistants. In classical silicosis of the South African type the amount of silica so recovered may be surprisingly small; but in a retention fibrosis the silica content of the ash may be enormous, with many large particles, although any action it exerted may have been merely the mechanical one of blocking up the lymphatic channels.—I am, etc.,

Chichester:

PATRICK HEFFERNAN.

Mass Radiography

SIR,—Dr. Norman Henderson in his letter of Oct. 28 (p. 574) criticizing the present national scheme of mass radiography, makes a number of statements not based on fact. In his first paragraph he writes: "Difficulties of equipment manufacture could be overcome if all x-ray manufacturers were invited to co-operate instead of confining the production mainly to one firm." Several manufacturers were in fact invited to submit designs to a committee of experts nominated by the Medical

Research Council's Committee on Tuberculosis in Wartime. The most suitable design was selected, and if other apparatus eventually comes to be designed and produced which is of equal or better standard there is no reason to assume that consideration would not be given to its approval by the Ministry. The Ministry of course does not "retain mass radiography in their own hands," but has allocated the units to local authorities so that the work can be conveniently linked up with the existing tuberculosis services.

The success of mass radiography depends largely on the discovery of early as well as chronic tuberculosis. Failure to find early cases will cause the public to lose confidence and the number of volunteers to diminish. The detection of early cases is only possible with the most meticulous technique, and the suggestions that girls who cannot get into radiography schools can be trained very quickly for this type of work shows astonishing ignorance of the technical advances made during the past few years. It is possible with one unit, with relays of technicians and a large clerical staff, to examine 3,000 individuals a day if the method were compulsory and the individuals rounded up by a special force. The anonymous manufacturer quoted by Dr. Henderson presumably has this idea in mind when he suggests that the unit, instead of working in factories, should examine all individuals "in an area of two or three square miles."

Dr. Henderson's advocacy of great speed shows no appreciation of the difficulties of diagnosis of pulmonary tuberculosis. Mass radiography has not made the diagnosis of pulmonary tuberculosis easier—it has, in fact, made it much more difficult by bringing to light latent or subclinical early cases. These cases require great tact and experience and often prolonged observation; many, we know, recover spontaneously. It is not the Ministry's policy to encourage slapdash "Continental" methods without regard for the subsequent care of the individuals found to show deviations from the normal.

Despite the introduction of mass methods into medicine the Ministry is still of the view that medicine is a profession and not a business.—I am, etc.,

London, S.W.1.

PETER KERLEY.

Ministry of Health and Radiography

SIR,—We cannot congratulate the Ministry of Health on its handling of x-ray diagnosis and early treatment. The official procedure has been: (1) in 1912 to transfer the Bismarck insurance system to Britain, and force it on the people and the doctors; (2) to omit the x rays from the list of benefits, depriving the whole nation for 30 years; (3) to reject (Mr. Neville Chamberlain) the findings of the Royal Commission recommending the x rays for insured persons; (4) to set up mass radiography without accompanying arrangements to provide beds for the cases selectively diagnosed; (5) to monopolize production of mass-radiography machines mainly to one firm (see *Journal*, Oct. 28, p. 574). The Australian Government has trusted the doctors to select the tuberculous soldiers from the majority, and to apply special radiography only to these. By so doing it has saved Australia much expense to the taxpayers, as well as eliminating the unfit.

The House of Commons may vote for social insurance and health regulation; who is to carry these out? Obviously not the present departmental personnel. Federalization of administration to London, Edinburgh, Cardiff, and Belfast is the first step to individual and national reconstruction.—I am, etc.,

Glasgow.

ARTHUR TURNBULL.

Artificial Insemination

SIR,—While having no practical experience in artificial insemination, I have been asked about it often by sterile couples, and hence have some knowledge of the different feelings which the matter arouses. The subject has been repeatedly referred to in these columns and has been singular, perhaps, for the lack of objectivity of your correspondents. The emotion of some of these writers suggests mainly that they are feeling about the matter as if it were their own problem, or their dogmatism suggests an experience too limited to appreciate how great may be the variation of other people's feeling on the matter.

which the results appear wrongly to justify. These cases, correctly handled, are the most quickly rewarding to all concerned. The following week a smiling mother brings a sleeping baby which has made a gain of anything between 8 and 12 oz. The stools are normal. Not only is the baby completely changed in manner and appearance from a sickly, irritable creature, the potential victim of intercurrent disease, but the mother almost equally so, partly due to relief from worry and restless crying, and partly due to an increased sense of well-being following an ingestion of proteins "for the baby's sake."
—I am, etc.,

London, N.W. 8

AUGUSTA BONNARD.

Infantile Diarrhoea and Vomiting

SIR,—It is possible that this condition varies in different parts of the country: it is certain that the features claimed by Dr. Leathart (Nov. 11, p. 637) as common in Birkenhead are uncommon in Sheffield. In the last fifteen necropsies I have performed on infants dying of D. and V. a pathological condition of the middle ears was found only twice, although looked for in all cases. This proportion is not significantly different from that found in infants of the same age group dying from other diseases. I do not quote the very much larger total numbers of necropsies performed on infants dying of D. and V., since the middle ears were occasionally not examined; the proportion showing any inflammatory lesion in this region was similar in those examined to that in the smaller series. Anatomically it seems unlikely that the mastoid could be infected by material travelling up the Eustachian tube without some signs of inflammation being visible in the middle ears.

Twelve of the fifteen infants had notable fatty changes in their livers. I have yet to perform a necropsy on a breast-fed infant who has died of D. and V.—I am, etc.,

Sheffield

H. E. HARDING.

Sulphapyridine by Ryle's Tube

SIR,—The article by Lieut.-Col. Ransome and his colleagues (Nov. 4, p. 594) interested me greatly. I was in India in 1940 and 1941 and was faced with the treatment of two patients who were extremely ill with lobar pneumonia. Both were vomiting profusely and the only drug available at that time was sulphapyridine. The intravenous form was not then available in our hospital. Sulphapyridine was tried, but this only made the vomiting worse, and both patients seemed to be going rapidly downhill. I had the idea of passing a Ryle's tube as far down as possible and introducing the drug in this way. I first aspirated the gastric contents and washed the stomach out with a weak solution of sodium bicarbonate. I then passed the tube further on, as I piously hoped into the duodenum, introduced the crushed suspension of sulphapyridine in water. This was repeated at four-hourly intervals, leaving the tube *in situ*. The result in each case was exceedingly gratifying. The temperature came down, vomiting ceased, and the patient started to pick up within twenty-four hours.

That the alimentary canal of dehydrated patients is capable of absorbing large quantities of fluid appears to have been amply demonstrated by your contributors, and if their results are borne out by others then this method should commend itself to us for two reasons in particular: first, that fluid is being introduced into the body in the way that Nature intended it to be, and, secondly, that it has the great merit of simplicity.—I am, etc.,

F. L. DYSON,
Capt., R.A.M.C.

Tuberculosis in Kent

SIR,—In a recent issue you published a summarized report of a debate in the House of Commons on a motion by Sir Waldron Smithers concerning the treatment of tuberculosis in Kent, and the circumstances regarding the admission of a certain patient to hospital when, in addition, strong criticism of myself as administrator of the tuberculosis work in Kent is implied. In order that this matter may be properly understood, I would be extremely grateful if you would allow me to comment briefly on this report, because, while criticism of my behaviour is of no interest to your readers, important principles, which concern all whose duty it is to carry out

public health administration, are involved. The facts which I shall give are not in dispute.

A patient was sent by his doctor to hospital for an x-ray of his chest. The doctor was told that the appearances were suspicious and consequently referred him to a tuberculosis officer on my staff. Pulmonary tuberculosis was diagnosed and the patient was placed on domiciliary treatment and his name put on the usual waiting-list for admission to sanatorium. Unfortunately, at the present time, owing to the length of the waiting-list, a long delay is unavoidable. During this period neither the patient's wife nor the doctor had asked the tuberculosis officer to call upon the patient. After about six weeks Sir Waldron Smithers, M.P., in whose constituency the patient resides, asked me for information as to the position, since the patient's wife had complained to him. I gave Sir Waldron Smithers a very full report, but it transpired that after having visited the patient he himself had succeeded by direct telephone contact in getting the patient forthwith into a London voluntary hospital.

Here it should be noted that the same hospital on three separate occasions previously had refused formal application from me for reception of tuberculous patients but had placed the patients on the waiting-list.

In addition to this interference with normal procedure, Sir Waldron Smithers took the unusual and, in my opinion, regrettable course of entering into correspondence with me, and also, unknown to me, with one of my tuberculosis officers at the same time in regard to the same patient. In the House of Commons Sir Waldron Smithers quoted from my letters, one or two sentences apart from their contexts, suggesting that I had little sympathy with the sufferings of the tuberculous and allowed officialdom to interfere with the prompt treatment of patients because I had referred to the fact that a tuberculosis officer dealing with one particular area would not be in a position to speak on the council's policy regarding tuberculosis in the county as a whole. In general, a more accurate and fairer statement of the facts of the case was given by Miss Horsburgh in her reply to Sir Waldron Smithers.

The facts as regards tuberculosis in this county have been frequently and fully reported to the Public Health Committee. The Ministry of Health is aware of the position, and, to the best of my belief, everyone concerned has done everything possible to alleviate a situation which is everywhere recognized as deplorable. It is, however, a national problem, not in any way confined to this county, and until young women can be persuaded to come forward to be trained as tuberculosis nurses long waiting-lists will continue, and, owing to delay in isolating the infectious, the circumstances will be likely to deteriorate.—I am, etc.,

Maidstone, Kent.

CONSTANT PONDER,
County Medical Officer.

Spontaneous Rupture of the Spleen

SIR,—I read with great interest Mr. Lionel Jones's paper on spontaneous rupture of an apparently normal spleen (Oct. 28, p. 561), and I would like to record a case in which much local discussion failed to elucidate the cause of the splenic rupture.

A married woman aged 33 was admitted to hospital on June 12, 1942. She gave this history: For two years she had had occasional attacks of fever and upper abdominal pain similar to the present attack. Between attacks she did not suffer from indigestion. The present attack began one week previously with pain in the hypochondrium on the right side, stabbing in character, passing through to the back and towards the right groin. Some nausea but no vomiting; normal bowel action and no micturition symptoms. Menses normal and no chest symptoms. Appendicectomy 1929.

On examination: T. 100.2°, P. 120, R. 26. General condition good but rather obese. Tongue moist and clean. In the abdomen there was tenderness all over the epigastric region but maximal in the right hypochondrium. Murphy's sign positive. A diagnosis of acute cholecystitis was made and the patient watched. Her symptoms became worse, and seven hours later following a sudden collapse a laparotomy was performed; the tentative diagnosis was a ruptured empyema of the gall-bladder. At operation the peritoneal cavity was full of blood due to a ruptured spleen. Splenectomy was begun, but after ligation of the pedicle the patient's condition was so poor that the peritoneum was closed with drainage. The spleen was not abnormally mobile. The patient died one hour later.

At post-mortem the gall-bladder and other organs were normal except for a small subpleural haemorrhage at the base of the left lung, and the spleen which measured 8 by 5 in. The enlargement was due to a large subperitoneal haemorrhage which had burst into the peritoneal cavity. Histologically it was reported as a subacute *serpiginous* spleen with a rupture and a suggestion of a myeloid reaction, which was not supported by the findings in the other organs. Leukaemia was therefore not considered as the diagnosis. The liver

At a meeting of the Paddington Medical Society on Tuesday, Nov. 28, at 9 p.m., in the Board Room of St. Mary's Hospital, Dr. C. C. Worster Drought will give a lecture on recent advances in neurology.

Universities and Colleges

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council held on Nov. 10 the following appointments were made: Dr. C. H. Bosenberg, registrar of the Children's Hospital, as temporary lecturer in diseases of children; and Dr. Andrew Wilson, as temporary lecturer in medicine for dental students.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At an ordinary meeting of the Council held on Nov. 9, with Sir Alfred Webb-Johnson, President, in the chair, Mr. V. Zachary Cope, Mr. C. E. Shattock, Mr. E. W. Riches, and Mr. W. H. C. Romanus were re-elected, and Mr. V. C. Pennell and Mr. A. J. Gardham were elected Members of the Court of Examiners. The Hallett prize was awarded to John Davis Green, B.M., B.Ch., of Oxford University. Mr. L. E. C. Norbury was nominated as representative of the College on the Central Council for District Nursing in London for a further period of three years. Dr. D. H. Tompsett was appointed Prosecutor to the College.

Diplomas of Membership were granted to R. A. Allen, and to the candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London published in the *Journal* of Nov. 4 (p. 612).

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College held on Nov. 7, with Dr. A. Fergus Hewat, President, in the chair, Dr. W. F. Haultain, O.B.E., M.C., was elected a Fellow.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At a meeting of the President and Fellows of the College held on Nov. 3 the following were admitted Licentiates and Members:

Violet K. St.G. Breakey, M.B., E. de Valera, M.B., S. P. O'Toole, M.B.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At the annual meeting of the Faculty held on Nov. 6 the following officers were elected for the ensuing year: President, Mr. William A. Sewell, Visitor, Dr. Geoffrey B. Fleming; Honorary Treasurer, Mr. Walter W. Galbraith; Honorary Librarian, Dr. W. R. Snodgrass, Representative on the General Medical Council, Mr. Andrew Allison.

The Services

Temp Surg Lieut D G Thompson, R.N.V.R., has been mentioned in dispatches. This name appears in a list of awards for gallantry, courage, skill, and determination in pressing home a successful attack on the Japanese naval base at Sabang.

Acting Surg Cmdr C. P. Collins, R.N., has been awarded the D.S.C., and Acting Surg Cmdr R. D. Bradshaw, Temp. Acting Surg. Lieut.-Cmdr. D. W. Burnford and G. D. Channell, and Temp Surg Lieut. R. G. G. Evans, G. C. Haywood, and D. A. Maciver, R.N.V.R., have been mentioned in dispatches for gallantry, skill, determination, and undaunted devotion to duty during the landing of Allied Forces on the coast of Normandy.

The *London Gazette* has announced the award of the M.C. to Fl. Lieut. R. N. Rycroft, R.A.F.V.R. The citation reads as follows:

Fl Lieut Rycroft was the only medical officer on one of the beaches of Normandy on "D" Day. Owing to the intense bombardment, it was not possible for him or any member of his unit to move off the beach for six hours. He worked for 48 hours tending casualties among the personnel of his unit and also aided some 75 American wounded. He was himself slightly wounded, but his efforts on behalf of others were untiring. He set an example of great courage and devotion to duty and was responsible for saving many lives.

CASUALTIES IN THE MEDICAL SERVICES

Previously reported wounded and missing at Arnhem, now known to have been shot dead while attending the wounded.—Capt. Gareth Fitzalan Howard Drayson, R.A.M.C.

Previously reported missing at Arnhem, now known to be a prisoner of war.—Capt. C. A. Simmons, R.A.M.C.

Missing at Arnhem, believed prisoner of war.—Lieut. P. S. Allenby, R.A.M.C.

Wounded.—Lieut. J. T. S. Buchan, War Subs Capt. L. G. Harper, M.C., Temp. Major R. H. C. Manifold, Temp. Lieut.-Col. J. J. Myles, R.A.M.C.

ANY QUESTIONS?

Treatment of Menopausal Menorrhagia

Q.—What is the modern treatment for menopausal menorrhagia?

A.—It is not possible to give a simple answer to this question since haemorrhage from the genital tract is so very common at the time of the menopause and may be due to such a variety of conditions.

In the case in which there is a true menorrhagia—that is, an increase of the loss of blood at normally occurring menstrual periods—and provided the pelvic organs are clinically normal, both on bimanual examination and on inspection of the cervix with a speculum, it may be possible to tide the patient over the menopause, which may last for no more than a few months. Anaemia should be combated by adequate doses of iron (18 gr. exsiccated of ferrous sulphate daily). It must be remembered, however, that many diseases of the pelvic organs are especially liable to occur at this time. These include metropathia haemorrhagica and, above all, malignant disease of the uterus. Every case in which there is severe haemorrhage or where the haemorrhage is prolonged or occurs at other times than at the normal menstrual periods should be submitted to examination under anaesthesia and curettage. Any gross pathological lesion, such as carcinoma or a uterine fibroid, should receive the appropriate treatment.

Opinion is divided on the best treatment for functional uterine haemorrhage, including metropathia haemorrhagica, at the time of the menopause. Many cases are cured by curettage of the uterus, and it is often worth while observing the effect of this simple and relatively safe procedure. If bleeding still continues there are two possibilities. An artificial menopause may be induced, and radium, radon, or x rays are all used for this purpose. Alternatively, the uterus may be removed either by the abdominal route or, especially in a parous woman, by vaginal hysterectomy. The advantage of this more radical treatment is that the danger of carcinoma of the uterus is for ever dispelled, and some ovarian tissue can usually be left so that the patient does not experience the severe general symptoms of the artificially induced menopause. The risk of carcinoma of the uterus after an artificial menopause is not negligible, and as I have seen three cases of rapidly spreading carcinoma of the uterine body after radium menopause in recent years, it is believed that removal of the uterus is usually preferable provided the patient's general condition is good. The disadvantage of the more radical procedure of hysterectomy is that the period of disability is longer, and the risk of death which a patient who undergoes a major operation has to face. Hormones, while of acknowledged value for the treatment of menopausal symptoms such as flushing, are disappointing for the treatment of menopausal haemorrhage.

Raspberry-leaf Extract

Q.—There is a demand among pregnant women in this district for tablets of raspberry leaves, or they drink an infusion of raspberry leaves to stop pregnancy vomiting. What are the pharmacology and toxicology of these leaves? Martindale and all my reference books give no information. Are there any dangers?

A.—It has been shown by Burn and Withell (*Lancet*, 1941, 2, 1) that raspberry leaves contain an active principle which causes relaxation of uterine muscle. It is presumably because of this principle that infusions of raspberry leaves have been found to give relief in painful menstruation, where the pain may be due to contractions of the uterus attempting to drive blood clots through a too rigid cervix. Similarly, infusions of raspberry leaves taken late in pregnancy may have the effect of making dilatation of the cervix an easier process when labour begins. There is no suggestion that raspberry infusions have any effect on pregnancy vomiting. There is no evidence of the presence of toxic substances in raspberry-leaf infusions, so that the practice of taking them is devoid of risk. (See also article in *British Medical Journal* by Sir Beckwith Whitehouse, Sept. 13, 1941, p. 370; and letter by J. H. Burn, Sept. 20, 1941, p. 418.)

pituitary. When the thyroid is removed it is possible that the basophils are stimulated into activity in an attempt to overcome the thyroid deficiency. Should there be an increase in both trophic hormones, the ovaries of some women may be so stimulated as to keep the blood oestrogen too high for uterine bleeding to occur. Another hypothesis regards the thyroid secretion as necessary for the healthy function of the ovaries.

The case notes given do not suggest acromegaly, but this condition could be excluded by a radiograph of the skull. Though no great reliance should be put on them, a B.M.R. and blood cholesterol done on her present intake of thyroid would help to decide whether she is having enough. These investigations can be done in "out-patients." The matter of the amenorrhoea really requires an endometrial biopsy for its elucidation, but it is not usual in this country to do this except on in-patients. As she is so difficult about investigations, it might be worth while to try giving 60 mg. of ethisterone by mouth for five days and repeating this at intervals of a month. Any treatment given without the most complete investigation is bound to be of the "hit-or-miss" variety.

Micturition Habits of Men and Women

Q.—Does the reason for the comparative, and at times embarrassing, infrequency of micturition in women lie in a greater bladder capacity? What is the incidence of nocturnal enuresis in females compared with the figures for boys and adult males?

A.—The larger pelvis of the female may be a factor in allowing tolerance of a full bladder, though there is no evidence that its capacity is normally greater than in the male. The relative infrequency of micturition in the female is probably chiefly due to habit, the opportunities for micturition being somewhat restricted under the conditions of so-called civilized life. Other factors of importance are that most women take a smaller volume of fluid than men do, and that they are less susceptible to cold, probably owing to more subcutaneous fat—as evidenced by their ability to wear scantier clothes, and when bathing to remain in the water longer than men—and are therefore less subject to the resulting diuresis.

Nocturnal enuresis is generally considered less common in little girls than in boys, and this will be found to be the experience of those who have charge of clinics where treatment is sought for this condition; but it should be noted that Still records 200 cases under his care as being made up of 102 boys and 98 girls. It is a relatively uncommon condition in adult males and very rare in adult females.

Arteriosclerosis

Q.—What are the present-day views about the cause of arteriosclerosis? Do dietary factors or alcohol or tobacco play a definite part? Is the condition reversible in its early stages (atherosclerosis)? I seem to remember that Aschoff said it was. Is a normal blood pressure common with it, and are those with it and a normal b.p. more likely to develop coronary thrombosis than those with a raised b.p.?

A.—Arteriosclerosis is an omnibus name which includes at least three conditions.

(1) Atherosclerosis is a patchy, intimal fatty change. A superficial resemblance to this condition has been produced in rabbits on a diet containing large amounts of cholesterol—a diet so unnatural that the conclusions cannot be applied with advantage to the human disease. Another recent view is that the atheromatous lesions occur as the result of invasion of the intima from the blood stream by phagocyte cells carrying lipid. Other views stress factors such as local mechanical stress, increased wear and tear, local anoxaemia, intimal haemorrhage, chronic toxæmia, and metabolic disorders. There is good reason to believe that the intimal fatty streaking associated with severe toxæmia is reversible.

(2) Monckeberg's degeneration is a senescent change which may occur prematurely and is then most frequently associated with diabetes mellitus. The degeneration is a necrosis and calcification of the media of medium-sized arteries.

(3) Arteriosclerosis is the name applied here to the ageing change which appears in arteries as a medial fibrosis and intimal-cellular hyperplasia; and in arterioles as a diffuse hyaline thickening. It is commonly, but not always, associated with essential hypertension. When it occurs with essential hypertension the picture is modified by a difference in distribution and an increase in severity of the changes. Neither Monckeberg's degeneration nor arteriosclerosis in this narrower sense is believed to be reversible.

There is no real evidence that dietary factors, alcohol, or tobacco play a part, but anything which hastens the coming on of age may reasonably be expected to hasten arteriosclerosis. Present-day views add little to Clifford Allbutt's conclusion that "it cannot be supposed that the stealthy hours carry away no qualities of tissue, no quantities of energy." A normal blood pressure is quite common with atherosclerosis. It is uncommon with severe arteriosclerosis, because, first, the aorta becomes less elastic in severe cases and there is a corresponding increase in the pulse pressure, mainly as the result of a rise in the systolic level; and, secondly, essential hyper-

tension is frequently associated with severe arteriosclerosis. There is very little correlation between the condition of the coronary arteries and that of the peripheral vessels, and it would seem that the patient with a raised blood pressure and cardiac hypertrophy is actually more likely to develop coronary thrombosis than the patient with arteriosclerosis of the peripheral vessels and a normal blood pressure.

Deamination of Amino Acids

Q.—Can you tell me where amino acids are deaminated? The theory was that it was done by enzymes in the liver; but several writers mention that it takes place in the kidneys as well. If deamination occurs in liver only, then excess of ammonia would indicate error in liver function; but if it occurs in kidney, this would not be so, and the ammonia/urea coefficient would have a different meaning.

A.—Amino acids are deaminated in the liver and in the kidney. In both these organs specific deaminizing enzymes can be demonstrated. It is possible that deamination subserves different functions in these two sites. Hepatic deamination is primarily concerned with the liberation of the non-nitrogenous residue of amino acid for energy purposes and the nitrogenous fraction is converted to urea. The renal deamination is essentially concerned with the acid/base balance and the excretion of ammonium salts in the urine. The ammonia/urea coefficient is more an indication of renal than hepatic function and its interpretation is complex. Further information may be obtained from J. P. Peters and D. D. van Slyke, *Quantitative Clinical Methods*, Vol. 1.

Perspiring Feet

Q.—Do you know any cure for perspiring feet?

A.—There is no satisfactory cure for perspiring feet. Some relief may be obtained with dusting powder containing 3% salicylic acid (without starch for obvious reasons); or with weak formalin solution, provided no dermatitis is thereby set up. In several cases sympathectomy has been carried out, but the benefit is temporary. In the writer's view x rays are undesirable because in obtaining an effective result the skin may be damaged. Scrupulous cleanliness is required, and if the socks after washing are soaked in saturated boric acid solution and allowed to dry some of the unpleasant effect of the excessive sweating are considerably modified.

Growth on Ear

Q.—A hard "warty" growth appeared on the tip of the ear over one year ago. Usual wart treatment applied (salicylic acid and cannabis indica); no effect. Later radium and direct-contact ray applied at different times; again no effect. Microscopical examination reveals excess fibrous tissue, epithelial cells, necrosis, no neoplasm. Site painful on pressure, showing signs of "wear and tear." What may be the exact nature, and any remedy or remedies?

A.—The original condition may have been a wart or a new growth with modifications in the tissues following radiotherapy. If the extent of the condition and the degree of "wear and tear" are considerable some form of surgical treatment may be required.

LETTERS, NOTES, ETC.

Lung Complications after Operation

Dr. W. J. YOUNG (Cambridge) writes: May I, as an old G.P. who has himself been in Mr. Bowen's hands, be allowed feebly but sincerely to say "ditto" to him in this important matter of the proper freedom of respiration after abdominal operations (Oct. 28, p. 573). I know how grateful and comforting it felt to be able to draw a deep breath.

Rest-breaks for Nurses

A scheme of rest-breaks was devised some time ago for women in industry, and now there are nine rest-break houses in being for industrial women workers. Thanks to the generosity of the British War Relief Society of the United States the first rest-break house for nurses and midwives has been made available. It is situated at Buxton in Derbyshire, in what is known as the Bedford Hotel. The Minister of Health has circularized local authorities and voluntary hospitals and other employers of nurses drawing attention to this provision. The idea is to give the tired nurse or midwife a complete change and rest for a period normally of a week or a fortnight. The charges will be two guineas a week for qualified nurses and midwives, and 25s. a week for student nurses and pupil midwives. The Minister expresses the hope that governing bodies of hospitals and other authorities employing nurses will do all that is possible to release those of them who are in need of such a change. He adds that the rest-breaks must not be confused with ordinary holidays or convalescence, and that those who are ill and in need of medical and nursing care are not eligible for these particular facilities. The Council for the Provision of Rest-breaks Houses for Nurses and Midwives, which is administering this first house, has its office at 179, Windsor House, Victoria Street, S.W.1.

"GROWTH" AND THE DIABETOGENIC ACTION OF ANTERIOR PITUITARY PREPARATIONS

II. GROWTH AND EXPERIMENTAL INSULIN-SENSITIVE DIABETES

B1

F. G. YOUNG, D.S., Ph.D.

(From the National Institute for Medical Research, London and St Thomas's Hospital Medical School)

In the previous paper in this series (Young, 1941) it was shown that, when treated daily with a dose of crude anterior pituitary extract greatly in excess of that required to produce diabetes in adult dogs, puppies respond with an increase in growth rate and fail to exhibit any symptoms of diabetes. It was then reported that when one puppy had been treated daily for nearly five months he ultimately became intensely diabetic, and then stopped growing despite continuation of pituitary treatment.

The present paper describes investigations into the relation between growth and the diabetic condition of this and other similar animals.

Methods

Animals—Normal adult dogs, normal puppies and adult dogs which had been rendered permanently diabetic by a short period of treatment with anterior pituitary extract (Young, 1937) were used. They were weighed daily and the urine excreted over 24-hour periods collected. Their diet was meat and vitamin concentrates, and unless otherwise indicated, they were allowed to eat *ad libitum* the amount of food consumed being determined daily.

Anterior Pituitary Extract—This was the Seitz-filtered crude alkaline extract of fresh ox anterior pituitary lobe previously described (Young, 1941). The concentration was such that 1 ml contained the material extracted from 2.0 mg of fresh anterior lobe tissue. It was injected subcutaneously.

Estimations—Urinary sugar was determined by Benedict's method, and urinary ketones by the method of van Slyke. The nitrogen contents of food, urine, and faeces were all estimated by the Kjeldahl method. Blood sugar was determined by the method of Hagedorn and Jensen.

Insulin Sensitivity—The available carbohydrate of the food consumed was computed from the formula $G + 0.38P + 0.1F$, where G = preformed carbohydrate, P = protein, and F = fat content of the diet. The figure for the daily intake of available carbohydrate minus the amount of glucose excreted in the corresponding 24-hour period gave the amount of carbohydrate utilized. When the diabetic condition of the animals had been controlled or almost controlled, by the daily subcutaneous administration of insulin, the available carbohydrate utilized was divided by the dosage of insulin given. In our experiments this quotient (g of available carbohydrate utilized per unit of insulin administered) has not differed significantly if two doses of ordinary insulin are given with two separate meals, or one dose of PZI administered and the animals allowed to consume the food over the whole 24-hour period. We have taken this quotient as an index of the insulin sensitivity of the diabetic animal (cf. Falta, 1936), and although it may vary from animal to animal it is usually substantially constant from time to time in any given diabetic dog (cf. Marks and Young 1939).

Results of Prolonged Treatment of Puppies with Diabetogenic Extract

Five puppies were treated daily with the crude extract for a period of 100 days or more and in every case they grew about twice as fast as control animals. Dogs 124 and 126 received a brief period of treatment with doses of extract which rose from 5 ml to 20 ml/day during the first four weeks of the experiment and then fell to and remained at 5 ml/day. The other animals received 5 ml day throughout the experiment. A brief summary of the history of these animals is as follows.

Dog 124 (male black-and-tan terrier, initial weight 2.44 kg) became diabetic after 131 days of treatment (weight 20.20 kg), but the diabetic condition disappeared shortly after pituitary treatment ceased. Details of this animal's history are given later in this paper.

Dog 125 (male cross-spaniel, initial weight 1.73 kg) became diabetic after 239 days of treatment (weight 13.40 kg), and the diabetic condition persisted after pituitary treatment ceased.

Dog 126 (female fox-terrier, initial weight 3.71 kg) developed an enlarged thyroid gland after about 80 days of treatment (weight 14.15 kg). The enlargement persisted until the animal was killed, without having developed diabetes, after 329 days of treatment (weight 29.10 kg).

Dog 134 (male black-and-tan terrier, initial weight 1.87 kg) became mildly diabetic after 126 days of treatment (weight 15.40 kg), but continued to grow for a time, and then became sugar-free again for a brief period. But a return of glycosuria, with a rise to nearly 50 g/day on day 157 (weight 19.70 kg), led to cessation of growth, and the animal was killed on day 166, daily injections of extract being still in progress (weight 19.30 kg).

Dog 137 (female black and tan terrier, initial weight 2.34 kg) died in her sleep from no obvious cause after 119 days of treatment, a diabetic condition had not then developed. When she died this animal weighed 15.80 kg at a time when her litter mate control male weighed 8.85 kg.

Thus it will be seen that of the four dogs surviving 150 days of treatment three ultimately became diabetic the date of appearance of diabetic symptoms varying between 126 and 239 days. The puppies were all 2 to 3 months of age at the beginning of the experiment and by the time they had become responsive to the diabetogenic action of that dose of pituitary extract which initially exerted a growth-promoting and not a diabetogenic action they were 6 months of age or more—i.e. they had become dogs rather than puppies. All three animals which became diabetic ceased growing after severe diabetes had developed, but dog 126, which developed an enlarged thyroid gland early in the experiment and did not become diabetic even after pituitary treatment lasting nearly 11 months, continued to grow throughout the experiment. Although the goitre subsided somewhat towards the end, at post-mortem examination the thyroid gland was found to be 10 to 20 times the size of that for a normal dog of similar weight, and it is

probable that this dog persistently suffered some degree of thyroid deficiency after the goitre had developed. It is possibly relevant that thyroidectomy diminishes somewhat the intensity of pancreatic diabetes (Dohan and Lukens, 1938), and of the diabetogenic action of anterior pituitary extract in the hypophysectomized-depancreatized toad (Houssay, Biasotti, and Rietti, 1934).

Histology of the Pancreatic Islets in the Long-treated Puppies

Dr. H. Hughes, of the Department of Anatomy, St. Thomas's Hospital Medical School, kindly examined histologically the pancreatic material from these animals, and his report will be published in full elsewhere. With his permission the following summary of his findings is given.

Dog 124.—Pancreas not grossly abnormal, though many β cells contained only a few specific cytoplasmic granules.

Dog 125.—Gross destruction of β cells, with some reduction in the number of α cells. Vacuolation of duct epithelium marked (cf. Richardson, 1940).

Dog 126.—Substantial increase in the number of β cells, some islets consisting solely of such cells. No vacuolation of duct epithelium observed.

Dog 134.—Intense hydropsis of β cells observed, with apparent increase in number of islets and total amount of islet tissue. The number of α cells was possibly abnormally low.

The histological findings are in general agreement with the metabolic observations.

Influence on Growth of Simultaneous Treatment with Diabetogenic Pituitary Extract and Insulin

The results of the above long-term experiments clearly supported the conclusion drawn in the previous paper that "an increase in body weight . . . can be regarded as neutralizing, for a time at least, the diabetogenic influence of the anterior pituitary gland" (Young, 1941). An interesting possibility now arose with respect to the grown "puppy" that had become responsive to the diabetogenic influence of pituitary treatment, and had then ceased to grow despite continuation of the same treatment as had initially stimulated growth without precipitating diabetes. Would such an animal grow if pituitary treatment were accompanied by the administration of sufficient insulin to suppress, or at least depress, the diabetogenic effect of the pituitary extract? Experiments were therefore carried out on these lines.

Dog 124.—Although sugar first appeared in the urine of this animal on the 131st day of the experiment, the rate of growth under the influence of pituitary treatment alone was initially unaltered, remaining at about twice that of control animals (Fig. 1). But when the glycosuria exceeded 30 g./day growth stopped, both body weight and glycosuria then remaining approximately constant for a period

of about 2 weeks. Thereafter the rate of excretion of sugar rapidly rose to about 200 g./day, and the body weight simultaneously began to fall. Cessation of pituitary treatment on day 156 was quickly followed by disappearance of glycosuria, while the body weight remained substantially constant, though subject to some fluctuation. These results illustrate well the reciprocity between the growth-promoting and diabetogenic actions of the crude pituitary extract (Fig. 1). Subsequently, daily pituitary treatment was resumed for a short period (days 188–193), and although the body weight showed an inclination to rise in response to this stimulus, glycosuria, accompanied by an alarming ketonuria, appeared (Fig. 2). On day 210 a single injection of extract induced a slight but definite excretion of

FIG. 2.—Data for dog 124 over period 24–37 weeks. The points indicated by the arrows are:—3: Daily injection of pituitary extract reinstituted. 4: Daily injection of extract stopped. 5: Single injection of extract given. 6: Daily injection of pituitary extract and insulin given from this point onwards.

sugar, which suggested that the animal was in a pre-diabetic condition. On day 224 the daily administration of 5 ml. of the pituitary extract was again begun, protamine-zinc-insulin now being simultaneously injected to control the diabetes thus induced. The initial daily dose of insulin was 20 units, but a dangerous degree of ketonuria developed, the daily excretion of ketone (equivalent acetone) rising above 10 g. despite rapid elevation of the daily dose of insulin to 120 units (Fig. 2). Ketonuria was almost entirely suppressed by raising the insulin dosage to 400 units/day, but even 2,000 units a day did not completely control the glycosuria (Fig. 2). Nevertheless, as the result of this simultaneous treatment with pituitary extract and insulin, the dog rose in body weight by nearly 7 kg. (Fig. 2 and Table I). It should be pointed out that the amount of food eaten by this animal was not controlled, and that he ate more as the result of the treatment with pituitary extract and insulin (Table I). During the last few weeks of the experiments samples of blood plasma from this dog were tested for anti-insulin activity in the rabbit (de Wesselow and Griffiths, 1936), with negative results.

Dog 125.—Unlike dog 124, this animal became persistently diabetic as the result of prolonged treatment (239 days) with pituitary extract alone. An experiment similar to that carried out on dog 124 was then performed on this animal, with the main difference that the food intake was controlled and fixed at 894 g. cal./day throughout the experiment and that the animal received a small daily dose of insulin before pituitary treatment began (Table I). This animal also increased in body weight as the result of simultaneous treatment with insulin and pituitary extract, the mean daily dose of insulin required to control the diabetic condition during pituitary treatment being 330 units, compared with 20 units/day for the period without simultaneous pituitary treatment. This experiment showed that the insulin sensitivity of the diabetes induced by the pituitary treatment was still low even when the food intake was restricted to a constant level, and, furthermore, that the growth-promoting action of simultaneous treatment with pituitary extract and insulin could be demonstrated under such conditions.

Dogs 115 and 132.—These were two adult (female and male respectively) dogs which had been rendered permanently diabetic by a short course of pituitary extract. Dog 115 had been diabetic for nearly 2½ years, and dog 132 for nearly 1½ year, when the experiments described here were carried out. Both animals were apparently adult at this time. Two experiments involving the simultaneous administration of insulin and pituitary extract were carried out with dog 132; in one of these the animal was allowed

FIG. 1.—Data relating to dog 124, treated daily with diabetogenic pituitary extract. (a) Growth curve for whole experiment. The data plotted are the mean weights for periods of one week. The control curve is based on data for four untreated animals of the same breed as dog 124. (b) Sugar excretion over weeks 18–25. (c) Daily variations in weight over weeks 18–25.

The points indicated by the arrows are as follows:—1: Excretion of sugar first observed. 2: Daily injection of pituitary extract stopped. 3: Daily injection of extract resumed. 4: Daily injection of extract again stopped. 5: Single injection of extract given. 6: Daily injection of pituitary extract and insulin given from this point onwards.

to eat 50% more food during the period of simultaneous treatment with pituitary extract and insulin (Table I), while in the other the food consumed was constant throughout. In the single experiment with dog 115 the food intake was constant (Table I). The three experiments on these two animals confirmed the relevant results obtained with dogs 124 and 125—namely, that when the diabetic dogs were treated with pituitary extract and insulin simultaneously they increased in body weight, but that the amount of insulin

often grew normally without exhibiting glycosuria until they have attained a weight of 200 g. or more, after which they may begin to excrete sugar (cf. Foglia, 1944). In his classical studies on the partially depancreatized puppy Langfeldt (1920) found that an operated animal might be free from symptoms of diabetes mellitus for many months, although ultimately, when the animal had grown, the sugar tolerance might decline

TABLE I.—The Influence in the Diabetic Dog of Simultaneous Treatment with Insulin and Anterior Pituitary Extract

Dog	Condition	Duration (days)	Control Period						Experimental Period (5 ml. of Pituitary Extract Injected Daily)							
			Energy Intake (kg. cal./day)	Energy Utilized (kg. cal./day)		Insulin Administered (units/day)	Available Carbohydrate Utilized (g. unit of Insulin)	Increase in Body Weight (g./kg./day)	Duration (days)	Energy Intake (kg. cal./day)	Energy Utilized (kg. cal./day)		Insulin Administered (units/day)	Available Carbohydrate Utilized (g. unit of Insulin)	Increase in Body Weight (g./kg./day)	Net Increase in Body Weight (Experimental minus Control) (g./kg./day)
124	Pre-diabetic	21	1,061	1,061	1,260	0	—	0.0	26	2,157	1,650	1,798	400–2,000	0.12	8.6	8.6

* Body surface in square metres calculated from the formula $0.112 \sqrt{W}$ (Lusk, 1928), where W = body weight in kg.

required to control the diabetes during the period of pituitary treatment was very large compared with that required in the absence of pituitary treatment (Table I).

It should be mentioned that insulin sensitivity was not, in most instances, constant throughout the experimental period. It fell rapidly after 2 to 3 days of pituitary treatment, and then tended to rise again after 6 to 10 days (cf. Haist *et al.* 1940). The data given in Table I are the mean values for the stated periods.

Discussion

Growth during Pituitary Treatment.—There is much evidence, direct and indirect, to support the view that pituitary-stimulated growth (together with the accompanying nitrogen retention) is dependent on an increased capacity of the pancreatic islets to secrete insulin. The intact rat does not become diabetic when treated with a pituitary extract which is highly diabetogenic in the adult dog (Young, 1938), and the amounts of islet tissue and of insulin in the pancreas of the rat are both doubled by such treatment (Richardson and Young, 1937; Marks and Young, 1940). Conversely, Marx *et al.* (1943) have recently found that treatment of partially depancreatized rats with a highly purified preparation of growth hormone increases the glycosuria of these animals. Growth is normally accompanied by nitrogen retention, and Mursky (1939) has presented evidence that the nitrogen-retaining action of anterior pituitary extracts is mediated, at least in part, by the islets of Langerhans of the pancreas, while Gaebler and Robinson (1942) believe that whether or not an anterior pituitary preparation will cause nitrogen storage or exert a diabetogenic effect may depend on the amount of insulin that the pancreas can supply.

In the present experiments it has been shown that during the period of natural growth in the puppy the administration of a pituitary extract which is diabetogenic in the adult animal leads not to diabetes but to an acceleration of growth. When, however, the puppy has reached adulthood under continuous pituitary treatment it may become diabetic and ultimately cease to grow. The treatment of such a diabetic animal, or even of a normal adult diabetic dog, with anterior pituitary extract together with insulin leads again to an increase in body weight, although the daily dose of insulin required to restrain the diabetogenic action of the anterior pituitary extract under these conditions may be very large. For instance, dog 124 required more than 2,000 units/day of P.Z.I. to suppress the diabetogenic action of the daily subcutaneous injection of 5 ml. of the pituitary extract, a dose of extract which during the first 20 weeks of the experiment induced growth uncomplicated by diabetes. It would be unsafe to deduce that during the period of pituitary-stimulated growth the pancreas of the puppy was secreting each day an amount of insulin equivalent in effect to the daily subcutaneous injection of 2,000 units of P.Z.I. It is common experience that rats partially depancreatized at an early age

and a progressive and ultimately fatal diabetes become manifest. The maintenance of normal growth may require less insulin than might otherwise be expected. Nevertheless it seems probable on the evidence available, that during the period of pituitary-stimulated growth the pancreatic islets of our puppies were secreting more insulin than would have been required for normal growth in the absence of the extra pituitary stimulus. Certainly once the endogenous insulin supply of our animals proved to be insufficient for further growth the amount of exogenous insulin required for the maintenance of the growth-promoting action of the anterior-pituitary extract was large (Table I). But there is no evidence that at the point when insufficiency of the endogenous insulin supply became manifest the insulin requirement for the control of carbohydrate metabolism remained unchanged; indeed, the requirement may have risen substantially.

It has been assumed in the present paper that the increase in body weight which occurred under the influence of pituitary extract and insulin was indeed representative of true growth. A study of the nitrogen retention during the period of alleged growth and of the composition of the tissues of the enlarged animal will be reported in detail elsewhere, but it may here be stated that the increase in body weight represents, to a large degree, a rise in the amount of protein containing tissue in the animal (Young, 1945). These results serve to emphasize once again the possible significance with respect to clinical diabetes mellitus of the relationship between the growth-stimulating and diabetogenic actions of anterior pituitary secretions.

TABLE II.—Insulin Sensitivity in Different Types of Insulin-controlled Experimental Diabetes in the Dog

Condition	No of Animals	No of Observations*	Mean				Standard Error of Mean	
			Maximum	Minimum	Mean			
Diabetes following pancreatectomy	8	20	6.30	1.79	3.73	0.277	$t = 2.98$ (Significant difference) $t = 9.13$ (Highly significant difference)	
Persistent pituitary diabetes	5	13	5.30	1.71	2.60	0.258		
Persistent pituitary diabetes treated with pituitary extract and insulin	4	5	0.33	0.12	0.23	0.038		

* Each observation is the mean value for a series of daily estimations, over periods of 1 to 4 weeks, at a time when the diabetic condition was under control, or nearly under control, as the result of the administration of insulin.

Insulin-insensitive Diabetes.—The diabetic condition exhibited by our pre-diabetic or pituitary-diabetic animals which are treated daily with diabetogenic anterior pituitary extract is clearly of an insulin-insensitive type. In Table II is given a

summary of the data for insulin sensitivity (grammes of available carbohydrate utilized per unit of insulin administered) for the three types of experimental diabetes we have studied. It will be seen that the previously claimed difference in insulin requirement between the depancreatized and the pituitary-diabetic dog (Marks and Young, 1939) is endorsed, and the very low insulin sensitivity of the diabetic animals, treated with both pituitary extract and insulin, emphasized. Statistical analysis shows that the differences between the insulin sensitivities of the three groups are all significant.

For many years Falta and his pupils have emphasized the differences in insulin sensitivity that are encountered in clinical diabetes mellitus. Falta (1936) divides clinical diabetes into three main classes according to insulin sensitivity: those which are insulin-sensitive and retain 2-3 g. of available carbohydrate for each unit of administered insulin; those of the middle class of insulin sensitivity, who retain 1-2 g./unit; and those whom Falta describes as insulin-resistant and who retain only about 0.1 g. of carbohydrate/unit of insulin injected. The insulin sensitivity of the insulin-resistant class of Falta agrees very well with that of our diabetic dogs treated with both pituitary extract and insulin. Dog 124, which required daily more than 80 units/kg. of insulin for (incomplete) control of the diabetic condition (i.e., 5,600 units for a 70-kg. man), appeared to be at least as insensitive to the action of insulin as the human diabetic usually classed as "insulin-resistant." It is therefore of interest that no "anti-insulin" activity of the plasma of this animal was demonstrable in rabbits, although some well-authenticated instances of a "de Wesselow-Griffiths" effect of blood plasma in human insulin-insensitive diabetes have been recorded (Marble, Fernald, and Smith, 1940; Rushton, 1940). But the fact that dog 124 was receiving such large doses of insulin may have complicated the results of this type of test.

Recently Best *et al.* (1942) have examined the effect of simultaneously administering P.Z.I. and diabetogenic pituitary extract to normal dogs. Their dose of diabetogenic pituitary extract was probably approximately equivalent to ours, and they found that an average of about 40 units of P.Z.I. was required daily to suppress almost completely the diabetogenic action of the anterior pituitary extract. Calculation on the basis of their published data shows that the carbohydrate equivalent of the exogenous insulin in their experiments was 2.49 ± 0.41 g./unit—i.e., the apparent insulin sensitivity of their animals was similar to that for dogs with ordinary pituitary diabetes. This suggests that a large increase in endogenous insulin secretion may occur in the normal dog treated with diabetogenic anterior pituitary extract, and rough calculation indicates that for a 10-kg. dog it may be equivalent to the effect of the daily subcutaneous injection of about 300 units of P.Z.I. As this is probably 10 to 20 times the normal rate of insulin secretion by the pancreas it is perhaps not surprising that degeneration of the pancreatic islets usually follows treatment with diabetogenic pituitary extract in the dog.

Summary

Daily injection of diabetogenic anterior pituitary extract into puppies induced an acceleration of growth uncomplicated by diabetes, which was maintained during treatment lasting four months or more. At varying times after this period three out of four animals became diabetic, and then ceased to grow despite continuation of pituitary treatment. The animal which did not become diabetic had developed an enlarged thyroid gland early in the experiment; this dog continued to grow in response to pituitary treatment lasting nearly 11 months.

Two of the grown puppies in which the growth-stimulating action of the pituitary extract had given way to a diabetogenic one were induced to resume growth when the administration of the pituitary extract was accompanied by the injection of large doses of insulin. Two adult pituitary-diabetic dogs likewise responded to similar treatment by a rise in body weight.

When diabetic or pre-diabetic adult dogs were treated daily with diabetogenic pituitary extract an extremely insulin-insensitive diabetic condition developed. One dog required as much as 80 units/kg./day of body weight for (incomplete) control of this diabetes.

The possible significance with respect to clinical diabetes mellitus of the relationship between the growth-stimulating and diabetogenic actions of anterior pituitary secretions is once again emphasized.

I am indebted to the Medical Research Council for a grant in aid of that part of the work which was carried out at St. Thomas's Hospital Medical School, and to Dr. J. W. Trevan, Director of the Wellcome Physiological Research Laboratories, for a gift of insulin.

AND

J. C. BROOM, M.D.

(From Archway Hospital and the Wellcome Research Institute London)

The experiments described below were designed to test whether penicillin inhibits the growth of leptospira in culture, and if so, whether the drug would cure leptospiral infections in guinea-pigs.

In Vitro

Material and Method

Nine strains of *Leptospira icterohaemorrhagiae* were used. Six had been obtained from human infections (Jackson, Hick Wijnberg, K.L., Barber, Rachmat); two had been isolated from rats (wild rat and W.P.R.L.); and one from a dog (L.S.). The strain of *L. canicola* maintained in the National Collection of Type Cultures was tested also. Some of these strains are virulent for guinea-pigs, and others are completely non-virulent. For the test a solution of penicillin was prepared containing 200 Oxford units per ml.; and serial fivefold dilutions were made from it. 0.25-ml. volumes of these dilutions were added to 3 ml. of Fletcher's broth. After mixing, the medium was seeded with 0.25 ml. of a heavy culture of leptospira. The final concentrations of penicillin were thus 50, 10, 2, etc., down to 0.016 Oxford unit in 3.5 ml.

In some later experiments the two highest concentrations were omitted. Most of the tests were carried out with calcium penicillin; in a few parallel experiments crude filtrate of the growth of *Penicillium notatum* in a protein-free medium (Alston, 1944) was used with similar results.

Results

The growth of all these strains was prevented by penicillin in concentrations of 0.4 o.u. and upwards in 3.5 ml. (0.11 o.u. per ml.). With lower concentrations variation of sensitivity to the drug was apparent. Since leptospira multiply more slowly than such bacteria as staphylococci, inhibition of growth compared with controls first becomes noticeable only after about three days' incubation. It was noted that cultures which were inhibited after three days showed no further sign of growth when examined at intervals up to 14 days. Penicillin thus either kills leptospira or maintains its activity against them for one to two weeks at 32° C. It was also found that penicillin cultures which appeared to be multiplying during the first three days might show marked diminution in numbers when examined at the end of a week.

This possible lethal, as opposed to inhibitory, effect was examined in another experiment. A well-grown 7-day mass

culture of leptospira was distributed in 9 ml amounts in test-tubes, and 0.5 ml of serial dilutions of penicillin diminishing by 50%, were added. The final series contained 240, 120, down to 0.5 ou in 10 ml. The mixtures and controls were incubated at 24° C and were examined at intervals. As before, counts were made of the number of living motile leptospira in standard microscope fields.

It was found that concentrations of less than 1 ou of penicillin in 10 ml had no apparent effect on the leptospira. After 12 days' incubation the number of living leptospira was greatly diminished in higher concentrations but the organisms were not entirely eliminated after three weeks' contact with penicillin. No abnormal morphological forms were noted such as occur when staphylococci are acted on by penicillin.

This lethal effect of penicillin on leptospira associated with lysis and destruction, is similar to the action on staphylococci described by Rantz and Kirby (1944).

In Vivo

A series of animal experiments was planned to test (1) whether infection of guinea-pigs by virulent leptospira could be prevented by the simultaneous administration of penicillin (2) whether the course of the established disease could be affected by giving the drug once symptoms (fever or jaundice) had become apparent. Before the experiments were carried out Heilman and Herrell (1944) reported that large doses of penicillin, administered at frequent intervals beginning shortly after infection, will protect guinea pigs against virulent leptospira. The aim of this work differed from our own so preliminary experiments were undertaken on the lines originally intended.

It was found, however that guinea pigs inoculated intraperitoneally with virulent *L. icterohaemorrhagiae* and given 60 units of calcium penicillin (also intraperitoneally) immediately thereafter and again 48 hours later died in about the same time as untreated controls. This dosage corresponds to 140,000 units for a man of 70 kg. It was also found that penicillin had no therapeutic effect when treatment was begun after the onset of symptoms—i.e. on the sixth or seventh day after infection. In these experiments guinea pigs received in some cases, doses corresponding to 140,000 units for a man of 70 kg. In further experiments the administration of penicillin was started two to four days before symptoms were expected to appear. The results were irregular and no definite conclusions could be drawn from them.

We finally carried out one experiment in an attempt to confirm the findings of Heilman and Herrell. Fifteen guinea pigs were inoculated intraperitoneally with a virulent strain of *L. icterohaemorrhagiae* and treatment with sodium penicillin suspended in an inert oil (arachis oil) was begun 18 hours later in 7 of the animals. Each received 200 ou at 10 a.m. and 5 p.m. and 400 units at 10 p.m. The dose was divided—4/5 was injected subcutaneously and 1/5 intraperitoneally. This treatment was continued for 13 days and on the two following days 400 units were given at 10 a.m. and 5 p.m. Each guinea pig thus received 12,000 units corresponding to more than 1,000,000 units for a man of 70 kg.

The result was that 4 of 8 control guinea pigs and 6 of the 7 treated animals survived. The seventh treated animal showed no signs of leptospiral infection at necropsy, and its tissues were not infective when inoculated into other guinea pigs. So far as it goes therefore, this experiment supports the view that penicillin, if given early enough will reduce the death rate of infected guinea pigs. In treatment of human beings the use of continuous therapy is a factor which could be expected to increase greatly the efficiency of the treatment and to allow it to be effective in later stages of the infection by maintaining a steady concentration of the drug in the blood stream. In other ways the experience in guinea pigs is valuable because human beings and guinea pigs are very similar to one another in susceptibility to infection by virulent strains of *L. icterohaemorrhagiae* as well as in morbid anatomy of the disease produced.

Serological Tests

It seemed of interest to test the agglutinating titre of the serum, and the resistance to reinfection of those guinea pigs which had recovered after penicillin treatment, compared with

the control animals which had withstood infection. It might be that the treated animals would show less immunity if the drug had reduced their contact with leptospiral antigen. No such tendency was apparent. The sera of 13 animals which had recovered in various experiments with penicillin treatment, agglutinated *L. icterohaemorrhagiae* in dilutions of 1 in 30 or 1 in 100. Of 7 control animals, the sera of six gave similar titres while the seventh serum did not agglutinate at all. These agglutination levels are very low as compared with those of convalescent human cases but we have found previously that guinea pigs do not produce high titres after either infection or inoculation with leptospiral vaccines. Ten of the animals treated with penicillin were again inoculated with virulent leptospira. None of them showed any sign of infection while all of four fresh control guinea pigs died with typical symptoms.

These tests show that penicillin does not prevent the normal development of immunity in this infection.

Toxicity of Penicillin to Guinea-pigs

Heilman and Herrell (1944) found, in confirmation of Hamre *et al.* (1943) that penicillin in large doses is toxic to normal guinea pigs. The former writers report that young guinea pigs receiving from 1,000 to 5,000 units of penicillin daily in divided doses frequently died after several days. Sodium and calcium penicillins from four different sources all produced this effect. Death was preceded by apathy, anorexia, loss of weight and other signs but the only obviously abnormal post-mortem finding was dilatation of capillaries throughout the tissues.

Heilman and Herrell believed that some of the infected guinea pigs which died without the usual signs of leptospirosis were killed by penicillin. This may be so, but in our experience especially when the course of the disease is unusually rapid guinea pigs sometimes die of leptospiral infection without showing either jaundice or haemorrhages, and the infection can be transmitted to other animals.

Rake *et al.* (1944) reached the conclusion that the rapid death of guinea pigs after large doses of calcium penicillin was attributable to calcium. Solutions of calcium chloride in equivalent amounts were even more toxic. They also found that the toxic effect of sodium penicillin was greater in guinea pigs than in rabbits or mice. This however, was observed only after multiple injections and death was delayed up to six days. The position is not yet clear because Heilman and Herrell used calcium penicillin and the toxic effects which they attribute to that drug were of the same kind as those which Rake *et al.* observed with the sodium salt.

The toxicity of the penicillin salt used in the last of our experiments was controlled as follows. Six normal guinea pigs also received 800 units of sodium penicillin daily for 15 days. No change in weight, appetite or behaviour was seen. Three weeks later the same animals were given 1,100 units of sodium penicillin twice daily for three and a half days. Again no ill effects were observed. This total dose of almost 20,000 units per animal would correspond to about 5 million units for a man of 70 kg.

Summary

Nine strains of *Leptospira icterohaemorrhagiae* (the causative organism of Weil's disease) and one of *L. canicola* (the cause of another form of leptospiral infection of men and dogs) were found sensitive to penicillin, which has a lethal as well as an inhibitory effect on multiplication.

Penicillin has a curative action on leptospiral infections in guinea pigs provided administration is begun very soon after infection.

The curative action of penicillin does not prevent the development in guinea pigs of serum antibodies or resistance to reinfection.

Toxic action of penicillin on guinea pigs which has been reported by others, was looked for but was not found.

We are indebted to our technicians Mr E. N. Martin and Mr R. J. Reed, for careful and skilful help in these experiments.

A CASE OF WEIL'S DISEASE TREATED WITH PENICILLIN

BY

V. LLOYD HART, M.R.C.P.

Physician, Royal Bucks Hospital and E.M.S.

The following report of a case of Weil's disease which seemed to respond to treatment with penicillin may be of interest

Case History

On the first day of the illness the patient, an Italian male aged 26, complained of feeling hot and of a pain in the right side of the chest. On the second day a slight cough developed, and he was admitted to hospital on the third day. Examination revealed the following: T 102°, P 112, skin hot and dry; a few fine crepitations at both bases, other systems normal. Radiographs showed some opacity at the left base. A tentative diagnosis of pneumonia was made and therapy with sulphamezathine begun.

On the fifth day of the illness the patient's condition was not improved, the fever continued, and the radiologist reported that the films already taken suggested atypical pneumonia. In view of this the sulphamezathine was discontinued. On the sixth day the patient became slightly jaundiced, pale stools and bile pigments in the urine were also reported. The liver was slightly enlarged and tender. Conjunctivitis was present. An interpreter elicited that the patient had worked in ditches and canals. A low-fat high-protein

some time. It can, however, be regarded as at least very possible that the penicillin was responsible for the destruction of the organisms in this instance, and, if this be assumed, the following conclusions may be drawn from the case:

1. In view of the small dosage at relatively long intervals it would appear that the organism can be eliminated rapidly and easily, being relatively susceptible, as suggested by experimental work in animals.

2. That the diagnosis must be established at the earliest possible moment, and penicillin administered. From a study of this case it will be seen that recovery had begun before the organisms could be found in the urine. In this connexion the great value of an early increased white cell count with relative and absolute granulocytosis is again deserving of emphasis. It may well prove that in view of the difficulty of establishing the diagnosis completely until relatively late in the disease—save for those cases in which the organisms may be demonstrated in the blood in the early stage by dark-ground illumination (though unfortunately this is not always successful)—a case suspected of being Weil's disease, with a typical white cell count, should have penicillin immediately when ample supplies become available.

3. The penicillin did not appear to hasten recovery in any way, the jaundice diminishing no more rapidly, and remaining until the 42nd day. In a case in which recovery is already taking place spontaneously this might be anticipated, since

Day of illness	White Cell Count	Icteric Index Units	Agglutination of Formalized Culture of <i>L. icterohaemorrhagiae</i> (Human Strain) with Patient's Serum	Presence of <i>Leptospira</i> in Alkaline Urine of Patient	Penicillin Administration

high carbohydrate diet was ordered, with additional vitamins and a saline purge each morning. Precautionary measures were instituted.

On the seventh day the jaundice was more pronounced and the temperature still raised (100.2° F), the patient was rather drowsy, and for the first time his condition gave rise to some anxiety. By the ninth day his general condition had begun to improve, and by the 20th day the temperature was normal, with the jaundice markedly improved. At no time during the illness did the patient show any haemorrhagic tendency.

The laboratory investigations together with details of penicillin administration are set out chronologically in the accompanying Table.

Conclusions

Unfortunately this case cannot be regarded as proof that the penicillin was responsible for the disappearance of the organisms from the urine, since they tend to disappear spontaneously in the natural course of the disease, though they may remain present in the urine for as long as 40 days. Indeed, to offer complete proof that penicillin will destroy the leptospira in vivo a series of cases will have to be treated, and in view of the comparative rarity of the disease this may take

obviously the damaged liver will take some time to resolve. It suggests, however, that, if spontaneous recovery is already occurring, penicillin may not benefit the course of the disease, its value at this stage being to render the patient free from the risk of infecting others earlier than might otherwise be the case, and in preventing a relapse—sometimes spoken of as "after-fever"—which is said to occur in from 25 to 40% of cases during the convalescent period.

The Bristol Hospitals Fund has issued its fifth annual report. In 1941 the hospitals decided to use the Fund as a collecting agency for all employers' contributions formerly sent to the individual hospitals direct. The Fund's total revenue in 1943 was £56,411, an increase of £3,017 over 1942. In an epilogue the report states: "The failure of the Government in the White Paper on a National Health Service published on Feb. 17, 1944, and its failure in the subsequent Parliamentary debates, to give any certain indication of the retention of the contributory scheme organization in the proposed new National Health Service, or to allay the fears of the voluntary hospitals as to their future chances of survival in a vast bureaucratic structure, is disquieting and calls for deep and earnest thought."

or the finding of amoebae in the stools will suggest amoebiasis, but it should be remembered that carcinoma and amoeboma may coexist in the colon just as in the rectum.

In the early stages of the tumour formation the whole mass will melt away miraculously after emetine treatment.

A soldier had a history of dysentery 13 months ago; now pain in the anal region and retention of urine. Sigmoidoscopy showed a firm irregular tumour on the posterior rectal wall covered with mucus. Examination of the stools and mucus showed no amoebae or cysts. After a course of injections of emetine the tumour totally disappeared within one month.

When the amoebic lesion has been present for a long period, however, the superadded result of chronic secondary infection, of the colon may prevent the mass disintegrating. In such cases excision of the tumour may be necessary not only to treat the ill-health, recurrent diarrhoea, and obstructive symptoms, but also because it is impossible to exclude carcinoma.

"Squad. Ldr. X., aged 44, had diarrhoea in Mombasa 17 months ago and recurrent attacks since. During the past 6 months he had increasing and recurrent abdominal colic with pain in the right iliac fossa, anorexia, loss of weight, and slight fever. A large tender mass was palpable in the right iliac fossa; w.b.c. 17,000; sigmoidoscopy—amoebic ulcers in rectum; active *E. histolytica* in stools. Given two courses of emetine and one of carbarsone; after each course the mass was much smaller, the patient improved in health, became aphyrexial, and was allowed up and about. (Seen by Gp. Capt. C. W. Flemming.) Barium meal and enema showed a large tumour bulging into the caecum and pushing it upwards. The ileo-caecal junction could not be demonstrated with certainty, though it was thought to be above the main mass. The intraluminal projection was quite smooth. Diagnosis: ? amoeboma—unlike a carcinoma. Two months later the mass again became larger and the patient was not so well; he was transferred to the M.E. Rectal Centre. The tumour was thought to be an amoeboma, which as a result of prolonged secondary infection did not subside completely with emetine. Pre-operative blood transfusion, sulphasuxidine, and a few grains of emetine were given.

Operation—A huge inflamed mass was present in the caecum, attached to the anterior and posterior abdominal walls; many adherent coils of small intestine were separated; one loop formed a fistula with the mass (this was where the x rays suggested the ileo-caecal junction); mobilized with difficulty. Ileo-caecal resection—lateral ileo-colic anastomosis—sulphathiazole powder locally—drainage of retroperitoneal tissues—abdomen closed. Emetine 8 gr. was given after operation. Uneventful recovery; secondary anaemia treated with blood transfusion and iron.

Even after its removal and macroscopic examination the tumour was thought to be an amoeboma until examined microscopically.

Pathological Report (Capt. A. W. Morgan, R.A.M.C.)—"Specimen consists of 8 in. of terminal ileum, a caecal tumour, and the ascending colon. The terminal ileum disappears into the tumour and there is a fistula between the ileum and the mass. On section the tumour is pale white, mottled with areas of fat, haemorrhage, and necrosis. The last 2 in. or so of ileum winds through its substance. The tumour has pushed upwards into the lumen of the ascending colon, terminating in a valvular opening (? site of ileo-caecal valve)."

Histology—Adenocarcinoma, Grade II, with mucoid degeneration. One gland examined was not invaded. No evidence of amoebiasis.

The marked decrease in size of this tumour following the use of emetine, the finding of amoebae in the stools, and amoebic ulceration in the rectum, make it probable that this patient originally had both a carcinoma and an amoeboma, and the latter disease had reacted to the emetine.

Amoebic Typhlitis and Appendicitis

The differential diagnosis between amoebic typhlitis, acute appendicitis, and appendix abscess often presents difficulty, since the most important diagnostic fact—the typical history of acute appendicitis—may not be forthcoming, and, further, obstruction to the lumen of the appendix may result from amoebic infection.

Operation is undesirable in the presence of uncomplicated active amoebiasis of the caecum and appendix: a high mortality rate was reported in the Chicago epidemic. Surgical treatment, however, must not be delayed when the typical history, symptoms, and signs of acute "obstructive" appendicitis are encountered within the first 24 to 36 hours, whether or not the patient has amoebic dysentery. If at operation both the caecal wall and the appendix are found to be uniformly inflamed

and the case is likely to be dysenteric, it is best not to remove the appendix unless it is obstructed and/or its blood supply is in jeopardy. Further, when there is typhlitis only, the normal appendix should be left. When appendicectomy is necessary in the presence of inflammation of the caecal wall at the appendix base, sulphathiazole or sulphanilamide powder should be sprinkled locally and adequate drainage instituted. Immediate post-operative specific treatment of amoebiasis will prevent local complications, such as skin ulceration or persistent faecal fistula.

When a mass is palpable in the right iliac fossa, though it may be impossible to distinguish between an appendix abscess and amoebiasis, its treatment, however, is the same—namely observation of the patient and of the mass and a strict Ochsner-Sherren regimen. If indications for surgical intervention arise treatment should be limited to simple drainage with minimal disturbance of the inflamed mass.

When amoebic infection is proved or suspected emetine should be administered. It may be assumed that a mass resolving spontaneously without emetine treatment is undoubtedly not due to amoebiasis.

Amoebic Ulceration of Anal Skin: Amoebic Fissure in An

Painful fissures are sometimes due to amoebiasis of the skin. They are usually multiple, but may be single. The edge of the ulcer is sharply defined and irregular, with undermining and sometimes slight heaping-up. The base has a dirty yellow unhealthy appearance, with no surrounding induration and little inflammatory reaction, somewhat resembling synergetic gangrene of the skin. Cutaneous amoebic ulceration vanishes in a dramatic way soon after the administration of emetine. One case undergoing treatment with carbarsone developed typical amoebic anal ulcer: emetine produced an immediate improvement.

Operations on the Anal Canal and Rectum in the Presence of Amoebic and Bacillary Infection

The danger of operating upon haemorrhoids, fissure, etc. in a patient with recurrent diarrhoea soon became known. Painful, unhealthy, non-healing ulceration of the anal canal and rectum was seen in cases referred to the Centre for opinion. The cases had active bacillary or amoebic infection, or, when no specific cause could be found, sigmoidoscopy always revealed proctitis of varying degrees. One officer had been in a hospital for 2½ months with ulceration of the anus following haemorrhoidectomy performed soon after an attack of diarrhoea. The appropriate medical treatment and simple local irrigations soon produced a cure.

An instruction was circulated pointing out these dangers, and sigmoidoscopy was carried out before every rectal operation. It is unwise to do even a minor rectal operation within 6 weeks of an attack of diarrhoea, and dysenteric infection must always be excluded before operation.

The accompanying photomicrographs are reproduced by the courtesy of Dr. Habibi, pathologist, the Faculty of Medicine, Iraq.

AN INVESTIGATION INTO THE USE OF SULPHASUXIDINE IN OPERATIONS ON THE RECTUM AND COLON

BY

D. H. MACKENZIE, B.A.

It has been shown by previous workers that administration of succinyl sulphathiazole (sulphasuxidine) causes profound change in the stools of the recipient, the change most relevant to the present discussion being the decrease in the number of Gram-negative organisms. Prior to the work described here investigations were carried out to study the action upon the intestinal organisms of sulphasuxidine, sulphaguanidine, and sulphathiazole. The technique used was that of Holt and Wright (*J. Path. Bact.*, 1942, 54, 248). 0.5 g. of faeces was thoroughly mixed with 4.5 c.cm. of nutrient broth, and serial

dilutions were made up to 10^{-2} . One standard loopful of each dilution was plated on to selective media—MacConkey and desoxycholate citrate agar. Colony counts were made after 24 hours at 37°C . Films were examined wet and by Gram's stain.

The Investigation

Thirty cases were examined; eight of these received sulphasuxidine—three 20 g. per day and five 10 g. per day—and eight received 10 g. of sulphaguanidine per day. The remaining fourteen cases received sulphathiazole—six having 2.5 g. and eight having 5 g. per day. It is not intended to record the full colony counts of these earlier experiments or to include clinical details of the diseases and their courses; but an account of the results, which were remarkably consistent, is given.

Colony counts and studies of films showed in cases receiving 20 g. per day of sulphasuxidine, a universal decrease in Gram-negative organisms. Although the results varied slightly from person to person, there were many occasions when no coliform organisms were grown from the 10^{-2} dilution, and sometimes they disappeared from the 10^{-1} dilution. In cases receiving 10 g. per day the "sterilization" was less consistent and more time was required to effect an adequate reduction in Gram-negative organisms. A dosage of 5 g. per day appears to be ineffective (see Appendix).

With the exception of the abolition of pathogenic non-lactose fermenters, the action of sulphaguanidine did not emulate that of sulphasuxidine upon the intestinal flora. Even after five or six days' treatment there was frequently a confluent growth of coliform organisms when the 10^{-1} , 10^{-2} , and, sometimes, the 10^{-3} dilutions were plated out.

The use of sulphathiazole as a pre-operative treatment has certain obvious disadvantages. It is more likely to cause toxic symptoms than either sulphasuxidine or sulphaguanidine, and is far more likely to give rise to renal complications. However, even with the small doses given in these experiments, there was a greater effect than that obtained with sulphaguanidine. There was a decline in Gram-negative organisms, and with a dose of 5 g. per day it was common for *B. coli* colonies from the 10^{-2} dilution to number less than 20.

No toxic symptoms or complications were observed in any of the cases in this series. Blood concentrations remained low, particularly with sulphasuxidine, figures about 1 mg. per 100 c.c.m. being common. Figures for sulphaguanidine seldom exceeded 3 mg. per 100 c.c.m., while the smallness of the doses of sulphathiazole kept the absorption low.

Estimations of sulphonamide concentrations in the faeces were carried out in many cases. This is an unsatisfactory estimation, however, because it is difficult to ensure that all the drug has been extracted from the faeces, and concentrations will vary according to the consistency of the stools and the number passed per day.

With sulphasuxidine there is an added difficulty owing to the fact that the drug is being continually broken down into free sulphathiazole. The percentage of this drug which is excreted as sulphathiazole is small, and unless stools are passed very infrequently the breakdown is unlikely to exceed 5%, and is often considerably smaller. With sulphaguanidine the concentration usually lies between 500 and 2,000 mg., while with small doses of sulphathiazole the concentration is usually below 100 mg. per 100 c.c.m. These are only approximate figures, and exceptions are common.

The accompanying Appendix demonstrates the effect of various doses of sulphasuxidine. The drug appeared to exercise no effect on the growth of enterococci. Except where otherwise stated, colony counts were made from the 10^{-2} dilution only, by the technique described previously, MacConkey's medium being used in all cases.

Summary

Sulphasuxidine is capable of causing a profound decrease in the Gram-negative organisms of the intestine, as shown by colony counts and by the study of films. It will be noted that a direct swab from the carcinoma showed no Gram-negative organisms.

A dosage of 20 g. per day for four days before operation appears useful.

The same effect cannot be produced with sulphaguanidine, but can, to some extent, be obtained with sulphathiazole.

This investigation was prompted by Brig. C. Naunton Morgan, with whose help and co-operation this work was done. Some of the earlier experiments were carried out by Sergt. J. Pilling, R.A.M.C., and Sergt. L. C. Wilson, R.A.M.C. All the laboratory work was done under the direction of Lieut.-Col. R. J. V. Pulverstat, R.A.M.C., A.D.P., M.E.F.

I wish to thank Col. H. D. F. Brand, late R.A.M.C., commanding (Scottish) General Hospital, and Col. J. S. K. Boyd, late R.A.M.C., D.D.P., M.E.F., under whose general direction the investigations were made.

A. O. John (*Tubercle*, 1944, 25, 69) records a case of tuberculous endometritis in a woman aged 35, in whom a symptomless, pleural effusion caused a suspicion of tuberculosis. Irregular menstrual bleeding followed by curettage led to the tubercle bacillus being discovered in the endometrium. Death took place from tuberculous meningitis.

Surg. Lieut., R.N.V.R.

In ships and establishments where a case of smallpox occurred the following action was taken: (1) All possible contacts were revaccinated immediately. (2) Direct contacts were paraded for medical inspection daily for 14 days; and their drafting was stopped for this period. (3) The ships and establishments concerned were not put in quarantine nor were

contacts isolated (4) No drafting of naval personnel other than direct contacts, was stopped provided they had been vaccinated and showed good scars

Course of the Epidemic

By March 2 (thirty six days after the first case had occurred in the Navy) there had been six naval cases of these three showed no scars indicative of previous successful vaccination, and a fourth had only a very small scar. It was decided, therefore, that the scheme was not working satisfactorily because all personnel were still not vaccinated and that more drastic steps must be taken to obtain 100% immunity. Consequently, all leave to and from the base was stopped and liberty men were not allowed ashore unless in possession of documentary evidence of vaccination within the past two years.

These restrictions especially the former had the desired effect of making all naval personnel and particularly officers, smallpox conscious and vaccination minded. From this date onwards there was a noticeable increase in the numbers presenting themselves for vaccination and the epidemic in the Navy rapidly subsided. It was possible to raise the ban on leave by March 12.

Conclusions

1. In this epidemic the type of smallpox was virulent the three fatal cases all ending within a week of admission to hospital.

2. All patients who had no scars of successful vaccination died. Only one patient who showed good scars contracted the disease, and no patient died who did possess any scars even if very small, of previous successful vaccination.

3. Good scars of previous vaccination were good evidence of immunity in all or in a very high percentage.

4. In the case of the corvette and the converted fishing trawler—both small ships where contacts must have been close and prolonged—all personnel had been successfully vaccinated and there were no secondary cases. In the latter ship another officer actually shared a cabin with the skipper who died in four days of confluent smallpox.

5. It was found that issuing advice and instructions alone did not obtain 100% successful vaccination. This was achieved only when restrictions were placed on individual privileges.

6. For some time after the last naval case had occurred the epidemic among the civilian population continued.

Medical Memoranda

Human Infection with *Pasteurella septica*

Human infection with *Past. septica* is of rare enough occurrence to warrant recording the following case.

CASE REPORT

An African woman aged about 20 was admitted to the Maternity Hospital, Accra, Gold Coast, on Dec. 13, 1948. She was 28 to 30 weeks pregnant and complained of abdominal pain and headache. Temperature 104°, pulse 138, respirations 28. On Dec. 15 she gave birth to a premature infant, which survived only a few minutes. Her temperature did not settle and a blood culture was made on Dec. 20. On Dec. 28 the left knee joint was very swollen and a considerable amount of pus was aspirated. The joint was again aspirated on Dec. 30. The patient was discharged from hospital fit on Jan. 14, 1949.

Bacteriology.—From the blood and the two specimens of pus an organism, morphologically and culturally very suggestive of *Past. septica* was isolated in pure culture. The patient's serum on Dec. 30 agglutinated a suspension of 1 in 640. White mice injected with pus from the knee usually died in 1 to 2 days. One survived 72 hours and showed peritonitis and septicaemia.

The cultures were sent to Prof. G. S. Wilson, London School of Hygiene and Tropical Medicine, who, after thorough cultural, serological, cross immunity, and pathogenicity tests, reported the organism to be a typical strain of *Past. septica*.

Strains of *Past. septica* have been isolated on several occasions in this laboratory from the local wild rat (*C. gambianus*) population but this is the only human infection met with so far.

I wish to express my thanks to Prof. G. S. Wilson for the trouble he took over the investigation of the strain and to Dr. W. M. Howells O.B.E., Acting Director Medical Services Gold Coast for permission to record this case.

PHYSICAL METHODS IN PSYCHIATRY

An Introduction to Physical Methods of Treatment in Psychiatry. By William Sargant M.B., M.R.C.P., D.P.M. and Ehot Slater M.D., M.R.C.P., D.P.M. (Pp. 171. 8s. 6d. plus 4d. postage.) Edinburgh, E. and S. Livingston, 1944.

In this well written book descriptive of physical methods of treatment in psychiatry the fundamental thesis is that in a considerable proportion of psychiatric illnesses, and in a sense in all of them there is a physical substratum. Although this is a presumption and not as the authors are careful to explain a matter of immediate knowledge, none will deny that they have made an excellent presentation of their case. This view does naturally with an emphasis on constitutional factors as predisposing so largely in the occurrence of abnormal reactions under stress. The authors point out that psychiatrists have unfortunately been divided into two camps: those who are preponderantly interested in the psychological and those who are mainly interested in the physical aspects of mental disease. The authors plead with evident justification for a union of the physical and psychological ways of treatment in psychiatric syndromes and throughout the book they leave their readers in no doubt as to the need for supporting physical with psychological therapy. Drs. Sargant and Slater have pondered their experience with insight, and their clinical observations are often shrewd and original. Most of their work has been done with neurosis of war and they are careful to say that the physical methods they advocate for the treatment of neurosis are apt to be less successful with the more complex neurosis of civil life. This unfortunately makes it impossible to be quite so enthusiastic as the authors about some of the methods they describe.

The various techniques—continuous narcosis, prefrontal leucotomy, etc.—are described in detail and some relevant comments are made—for example the need to treat epilepsy with more discrimination than is customary, taking into account the environmental circumstances instead of focusing only on the dosage of the drug employed, and they emphasize the usefulness of controlling their administration with electroencephalograms.

Since the book is likely to have a deservedly large sale it is as well to enter a caveat. The essential ingredient of all treatment is a human outlook. It is not that the book lacks it, but readers less experienced than the authors may be tempted into a very mechanical attitude towards the patient. Nowhere is it more necessary than in psychiatry to think first of all of the patient as a personality with hopes and fears, rather than as a mechanism to be experimented with.

DOCTOR IN THE MAKING

Doctor in the Making: The Art of Being a Medical Student. By Arthur W. Ham M.B. and M.D. Salter Ph.D. (Pp. 120. 9s. 6d.) London: Medical Publications Ltd.

This is an excellent book which should be read by all studying in medical schools and those considering the medical profession as a career. It deals with the motives and mental equipment necessary for the successful medical student. The authors deplore the fact that so many people drift into medicine without the right basic education and ability and for no better motives than "because my father is a doctor" or "because my parents wanted me to be a doctor." There is an excellent section dealing with the enemies of success, which gives most useful practical advice on how to work, how to improve powers of concentration, how to organize knowledge. The importance of understanding as opposed to memorizing is especially stressed. The chapters on the causes of maladjustment are clear and concise and free from technical terminology. The means for improving adjustment by the change of the ratio between demands and realization are well presented. The need for understanding and applying the scientific method of approach in medicine is emphasized, though the authors remark rather despairingly—perhaps the result of years of teaching medical students—that "it almost seems that scientific thinking is unnatural to man."

MEDICAL MALPRACTICE

Medical Malpractice By Louis J. Regan M.D. LL.B. (Pp. 256, 25s)
London: Henry Kimpton

This is probably the first monograph of its kind in this country the subject would not afford the material for more than a longish paper, in America it is so much more important, both in quality and in quantity, that Dr. Regan has had no difficulty in writing a fair-sized though highly condensed textbook "Malpractice" is a comparative newcomer to the vocabulary of law. It is not strictly a legal entity, for it goes beyond negligence—failure to use proper skill and take proper care—to wrongs which come in quite a different category, such as assault by intervention without consent, and even the betrayal of confidence, invasion of the "right of privacy," and the making of a necropsy without legal authority. These last three wrongs illustrate the difference between the American point of view and our own, for the first is only doubtfully actionable here and the second and third are not at all. The American practitioner has therefore more ways of going wrong than we have, and he seems much more likely than we are to be sued for damages if he strays into any of them. Perhaps American cases are more completely reported than ours, perhaps American patients are more litigious. The fact remains that whereas an English writer would have difficulty in finding two dozen good malpractice cases, Dr. Regan cites several hundreds from the reports of the different States. His method is to state each proposition of law in general terms and then follow it with a number of head notes and extracts of judgments from decided cases in order to throw light on particular aspects of the position. The largest part of the law which he formulates is identical with our own, and so his book will be found not only interesting but practically valuable to British doctors. The reader must, however, be alert for divergencies between the two systems. For instance, eugenic sterilization Dr. Regan says is provided by the law of twenty-nine of the States, and some States prohibit non-therapeutic sterilization. The consent of the widow or next-of-kin is necessary before a necropsy can be legally performed except by a coroner or other authorized person, for the wrongful dissection of a dead body is actionable at the suit of the person entitled to the possession and control of the body for burial. Doubtless the conditions which protect a person's right of privacy, and prohibit such infractions of it as the taking of a cinema film of a patient during an operation or the unauthorized publication of likenesses, might well be adopted here. Many States extend privilege from disclosure in evidence to communications made in confidence by a patient to his doctor and the protection sometimes extends to hospital records in so far as they tend to disclose what physicians have said in their attendance on a case, and also to facts known to a nurse through being present and assisting a physician and hearing communications between him and the patient.

Dr. Regan gives some useful forms of consent to operations and to disclosure of privileged information, and forms of indemnity against the hospital and the attending physician to be signed by a patient who leaves against advice. His self-test for "malpractice vulnerability" is very exacting, and would floor all but one or two exceptional practitioners in this country. How many would get full marks for their answers to the questions whether their records are so kept that they would not be embarrassed by the production of these in court, whether they fully realize their responsibility for the negligence of a partner, an employee, an assistant, an associate, and a substitute, or whether they have some understanding of the doctrine of *res ipsa loquitur*? Nevertheless Dr. Regan regards a good mark as highly necessary for relative safety in "hot-bed" areas. He is caustic about the part frequently played by what he calls the physician instigator—the doctor who cannot refrain from criticizing the conduct of a predecessor. His chapter on prophylaxis makes some exacting recommendations but is well worth studying, especially the advice which he summarizes as "Don't talk so much."

Preparations and Appliances

AN IMPROVED FIELD SUCTION APPARATUS

Major A. H. SALEH, R.A.M.C., writes.

The need for a simple, improvised, and efficient suction apparatus in the field has always been felt. The appliance supplied to some field units has an old-fashioned foot-pump which entails much energy to cause a vacuum in a Winchester bottle, furthermore, it requires an orderly whole employed in pumping. The apparatus described here is a modification of it.

The Pump is an American box-type, as supplied with Dodge and other American trucks. The barrel is opened and the shallow cup shaped rubber washer is reversed, so that it faces the opposite direction (see diagram). The ball-bearing in the valve connecting the pump to the rubber tubing is displaced to the distal end of the spring (see diagram).

The Suction Head consists of a No. 8 silver catheter to which a bulbous end has been fitted. The other end of the catheter fits into a "negative" clip made to my design by an R.E.M.E. workshop.

The "Clip" consists of (i) a metal tube $1\frac{1}{2}$ in. in length and of a diameter to fit over the narrow pressure tubing used, (ii) a ring to keep the rubber tubing in position, (iii) a trigger lever; (iv) a spring. (See half-scale diagram).

A Winchester Bottle connected to the pump and the suction head.

Function—Two strokes of the pump will cause a vacuum in the bottle. The apparatus is now ready. During the course of an operation, such as a laparotomy, with much blood, etc., in the abdominal cavity, the operator inserts the end of the catheter into the fluid, and with his thumb depresses the trigger lever, when suction instantly comes into play. When the lever is released the tube is kinked and the vacuum in the bottle is conserved for further use. The process can be repeated as long as necessary, with an occasional stroke of the pump to ensure full vacuum.

This apparatus has been in use in a C.C.S. for the last six months and has been found extremely efficient. The vacuum is powerful enough to suck the fluid but not powerful enough to damage any viscera which may get in its way.

TENDON HAMMER

Mr. J. P. CURRIE writes from the Glasgow Royal Infirmary.

The accompanying illustration shows a tendon hammer which I designed some time ago and which has now been produced by Chas. F. Thackray, Ltd., of Leeds. The hammer is entirely of metal and chromium plated. I have found it more useful than

Approximately scale

any other available types because of its greater weight and better balance. The pointed handle is useful for eliciting the cremasteric, abdominal, and plantar reflexes. The hammer has the obvious advantage of being unbreakable and having no perishable parts.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY DECEMBER 2 1944

ARTIFICIAL INDUCTION OF LACTATION

When Folley and his colleagues at the National Institute of Research in Dairying demonstrated¹ that copious lactation could be produced in virgin goats by injection of he, udders with stilboestrol, wide prospects of practical application were opened up. Any measure likely to increase the milk production of Britain during wartime was obviously of first class importance and the Lactation Committee of the Agricultural Research Council authorized large-scale field experiments to be undertaken. Reports of the results of these investigations fill the current issue of the *Journal of Endocrinology*. The papers are long but fortunately the results can be summarized quite briefly. Hammond and Day from the School of Agriculture at Cambridge agree with Folley and Malpress² that plentiful lactation may be induced in maiden or nulliparous heifers or in dry cows by the subcutaneous implantation of tablets of synthetic oestrogens: both papers, however, stress that the response is extremely variable, ranging from nil to normal lactation levels. The daily absorption from the tablets was of the order of 5-25 mg. of hexoestrol or stilboestrol, but there appeared to be no correlation between the amount absorbed and the amount of milk yielded. A disadvantage of the treatment was that it caused nymphomantic symptoms, which led to frequent mounting and consequent pelvic fracture in as many as 20% of the animals in some experiments. Folley and Malpress⁴ were able to induce lactation in heifers by oral administration of hexoestrol, stilboestrol, or dienoestrol in doses of 20-200 mg. daily, given either in the drinking water or in food. Only about 10% of these doses are apparently utilized in the body. This treatment did not lead to such pronounced nymphomania, nor were any pelvic fractures sustained, but, on the other hand, the level of lactation was lower than with tablet implantation, just as variable in degree, and again apparently unrelated to dose. Essentially similar results followed the implantation of tablets of 50% hexoestrol, 49% lactose, and 1% stearic acid, which Folley, Stewart, and Young³ found to be more slowly absorbed than pure hexoestrol tablets. Parkes and Glover⁵ were able to cause lactation by single injections of appropriate esters of stilboestrol. The best results were achieved when 50 mg. of a slowly absorbed and of a rapidly absorbed ester such as the dilaurate and dipropionate of stilboestrol were injected together. Folley and Malpress² made detailed studies of the composition of the milk they obtained and

found it to be initially colostrum in type, changing to normal milk as the daily yield increased, so that a daily output of 5 lb. or more was a guarantee of normal composition. Parkes and Glover⁵ similarly found the milk to be of normal or high quality. Lawson Williams, and Stroud⁶ analysed samples of the experimental milk from Shinfield and Cambridge for any contained oestrogen. They found the maximum concentration to be 1 µg. per pint, but the average very much less. There can therefore be no doubt that oestrogen treatment is capable of increasing the country's yield of good-quality milk, but unfortunately the variability of response and chances of damage due to nymphomantic symptoms at present make the treatment too uncertain and risky for anything but veterinary trial in isolated cases. The hope that it might be possible to give a route similar to milk production during the winter months cannot yet be realized.

The reasons for the extreme variability in response are not clear and presumably they will not be understood until it is known exactly how oestrogens provoke lactation. The cow is an expensive animal to use for experimental purposes and only the urgency of war accounts for the precipitate large scale field trials without preliminary laboratory investigations, even though such investigations may fail to give the desired information since species differences in mammary physiology add much confusion to the subject. At present the theory generally held is that oestrogen induces udder development directly, and in appropriate doses stimulates the pituitary gland to secrete the hormones necessary to initiate and maintain lactation. If, however, the oestrogen dosage is too high the pituitary may be inhibited instead of stimulated. Failure to induce lactation may therefore be caused either by inadequate oestrogen dosage or by overdosage, and, in fact, instances of both are to be found in these reports—instances where minimal lactation was markedly improved by giving additional oestrogen treatment, and other cases where removal of the implanted oestrogen tablets increased the milk yield. Hammond and Day also point out that failure to initiate lactation is more frequent in cows than in heifers, and they attribute this to the inhibitory action of persisting corpora lutea, if such corpora are removed during the period of oestrogen treatment the milk yield goes up. The authors regard this as analogous to the condition in pregnancy, where persisting corpora lutea prevent lactation despite fully developed mammae. All the authors are agreed that there is a cessation of follicular growth and that the ovaries are quiescent during the period of oestrogen treatment, which must therefore exert an inhibitory action on the secretion of pituitary gonadotrophin. It is apparent that rigorous control of dosage is one of the prerequisites of successful application of these findings to normal dairy-farm practice, and one suspects that tablet implantation is not the method to ensure this. It is noteworthy that Dr. Parkes, in spite of his great part in the discovery and development of the tablet-implantation technique, has here preferred to administer the oestrogens by injection, which, in view of the very large wastage that occurs with oral administration, appears to be the most hopeful line for further investigation.

DISPERSAL OF OFFICE WORKERS

Since the days of Queen Elizabeth the growth of London has been a problem. With every fresh development of transport it has become more insoluble. Various writers have during the present century emphasized that something ought to be done, but how that something should be done has been less clear. The war produced an experiment on a large scale. Hundreds of people of the clerical and administrative groups had, for security reasons, to leave London whether they wished it or not. These have adjusted themselves, some successfully, others unsuccessfully. The Bank of England posed the problem whether clerical, administrative, and allied departments could in normal times be efficiently worked away from London. The National Council of Social Service was asked to undertake the survey.¹ It was clear from the beginning that reliable evidence would be difficult to obtain. The sorting of facts from assumptions emotionally motivated, not to mention the border-line information between the two, was in itself formidable. People compulsorily removed from their familiar surroundings and living under makeshift conditions naturally compared the often purely imaginary amenities of pre-war days with the present discomforts. Making all allowances for the necessarily unscientific comparisons, there seemed to be certain advantages believed with reason by many people to be inherent in London which could be checked. These included greater choice of accommodation and type of district, wider choice of schools and better provision of scholarships, better chances of promotion and wider choice of employment, better marriage chances for women, and unequalled prestige and glamour. Employers thought there were better contacts between various offices and also with leading consultants. The disadvantages were the amount of travelling involved in getting to and from work and to the country, the discomfort of the overcrowded vehicles, the higher cost of living, and the high rent of offices.

This report was concerned chiefly with clerical workers earning between £200 and £500 a year, most of them men and some women. There were some women, most of whose families did not exceed £250. The problem was concerned with their probable dispersal to provincial towns of medium size, roughly from 40,000 to 100,000 in population. What is the health problem? So far as general practitioners are concerned there was no evidence that the provincial doctor was inferior to his counterpart in London. Some people stressed the view that the provincial doctor was likely to have a more varied experience and a more stable connexion with families. Consultants and specialists, however, are not likely to be found in a small town unless there is a special reason for their presence—for example, in a university town where there is a medical school, or in a spa where invalids congregate. The resident in a small town is in this respect at a disadvantage; he will have either the expense of travelling to see the specialist or the still greater expense of bringing the specialist to him. A number of special hospitals exist, both large and small, to deal with

specific classes of illness—e.g., diseases of the ear and throat—or for specific classes of persons—e.g., children, women, or seamen. The distribution, however, of these is very uneven: the tendency is increasingly to deal with most kinds of cases at large general hospitals. Many families attached importance to the provision of private beds. The number of beds reserved for private patients in each voluntary hospital in the country and the fees charged vary considerably. The range of fees is rather wider in London than in the counties. On the whole the provision for confinements at moderate fees is scanty, and is less satisfactory in small towns than in great cities. Special services such as massage or electrotherapy and some of the newer methods of diagnosis are not so easily obtainable in small towns. Although most provincial towns of any size will have competent dentists, yet, at present medical and allied services are on the average inferior except where there is a university.

Quite apart from the problem of the treatment of sickness when it has occurred there is the provision for those public health services necessary for the preservation of health. Wherever dispersal was discussed with those who had to leave London it was found that living accommodation was uppermost in the minds of many employees. Many were living in most uncomfortable circumstances and there was no chance of renting a house. Office accommodation is also important, and there is no doubt that many makeshift and unsuitable buildings have been the only possibility. While employees will put up with these discomforts during the war, they will not be content to do so after the war. It must be admitted that employees often overlooked that there are some extremely unsuitable offices in London. It is also very difficult to discover what exactly people mean by London. Large numbers of the population who live in a London suburb rarely leave the suburb; they may go to the West End or the City for occasional excursions, but so also do people from many miles away. There was much evidence that people had the idea of the possibilities of education and amusement that existed, even if they never or only rarely used them. Perhaps the bedrock idea is the dislike of being uprooted. It might well be that if hundreds of people hitherto resident in a small town or village had to leave they might equally resent removal, even though it were to London.

The report recognizes that those of the present generation who have to migrate will find life difficult, but that it will be very different for the next generation who will be free from London ties. The long-term balance-sheet of advantages and disadvantages differs from the short-term balance and is more favourable. In the national interest several great cities ought to be gaining, not losing population. Many provincial towns of moderate size would gain by an increase of population, and such an increase would facilitate social, educational, and medical improvements. The committee held that such powers as the local authorities will need to enable them to play the part adequately should be granted by the Government. Legislation is necessary. The public services to be considered are water, electricity, gas, sewage and sewage disposal, transport. The local authority will have to consider provision for more children, and the public health depart-

¹ *Dispersal*. An Inquiry made by the National Council of Social Service. Oxford University Press, 1944. (3s. 6d.)

nents will have to see if extra hospital accommodation or clinics are necessary. This means that the reception areas will have much careful planning to do. There is a list at the end of the report of towns of medium size within 80 miles of London with populations from 20,000 to 100,000.

The committee recognized that it will be no easy matter to reverse the trends of centuries, and the report has considered only the clerical workers. There is the analogous problem of the industrial worker.

PENICILLIN AND SPIRAL ORGANISMS

Although penicillin and the sulphonamides cover much common ground, each has fields of activity in which the other takes no part. Perhaps the most important direction in which penicillin is of value while the sulphonamides are none is in the treatment of "spirochaetal" infections, using that word in its broader and less legitimate sense. The place of penicillin in the treatment of syphilis is now almost assured; if long-term results are satisfactory it may replace the arsenicals altogether, at least for the primary form of the disease. It would be rash to assume that all spiral organisms will react in the same way, since they include a number of widely distinct genera, but scattered items of information are coming to hand which suggest that some degree of susceptibility to penicillin is a common property among many of them. The rapid disappearance of *T. vincenti* from the lesions of Vincent's gingivitis reported by MacGregor and Long in this *Journal* last week is one such piece of evidence from the clinical field. Others are so far experimental only: an effect on *p. minus* and on *T. recurrentis*, first reported by E. M. Laurie and H. O. J. Collier,¹ has been confirmed by F. R. Leilman and W. E. Herrell² and by H. Eagle and H. J. Magnuson³ respectively. The former authors found penicillin curative in experimental mouse infections due to either *Sp. minus* or *Streptobacillus moniliformis*; both forms of rat-bite fever may therefore prove amenable. Eagle and Magnuson, studying infection with *T. novyi* in rats and mice, found that, although 50% of cures could be obtained with a dose of about 100,000 units per kg., 95% are called for 400,000 units per kg., a dose of which the equivalent in man is about 25,000,000 units. If all species of *Treponema* causing relapsing fever behave in this way, and if findings in mice prove applicable to man, penicillin is unlikely to displace arsenic for the treatment of this disease.

Leptospirosis infections must be regarded differently, because arsenic is useless for them. Even should *icterohaemorrhagiae* be only moderately susceptible to penicillin, the treatment of Weil's disease should still be attempted, since there is no chemotherapeutic alternative. Some indications that this treatment may prove useful are to be found in two papers in our present issue. J. M. Johnston and J. C. Broom began by determining the concentration of penicillin which would inhibit the growth of 9 strains of the organism in cultures; all were inhibited by 0.4 unit of penicillin in 3.5 ml. of medium—i.e., a concentration of just over 0.1 unit per ml. This is about five times the concentration necessary for preventing the growth of a normally sensitive staphylococcus, but the tenfold dilutions used do not enable an exact comparison to be made between the two organisms. The first therapeutic test failed, evidently owing to infrequent dosage; the second, penicillin was administered three times a day

in oil, with the result that 6 out of 7 treated animals survived, the seventh dying apparently of some other cause, while 4 out of 5 controls died. These findings, although inconclusive owing to the small numbers of animals used, encourage further observations. In the patient with Weil's disease described by V. Lloyd Hart, penicillin was given at too late a stage to judge its effect on the course of the disease, but may have contributed to eliminating the organisms from the urine. So far as they go, these observations justify the clinical trial of penicillin in the treatment of Weil's disease; early diagnosis and perhaps generous dosage will be necessary.

DENTAL SERVICE REPORT

The Inter-departmental Committee on Dentistry, of which Lord Trenchard is chairman, has issued an interim report to the Minister of Health and the Secretary of State for Scotland which is published as Cmd. 6565 by H.M. Stationery Office at 6d. The committee unanimously recommends that a comprehensive dental service should form an integral part of, and operate simultaneously with, the Government's National Health Service, and that it should be available to all who want to use it and be paid for by the community as a whole. It recommends also the establishment of a general dental practitioner service broadly analogous in principle and structure to the proposed general medical practitioner service of the National Health Service, and that dental health centres on experimental lines should be set up in suitable areas without compulsion either on dentists to work in them or upon patients to attend them. The committee recommends that measures to stimulate the recruitment of dentists should include every step to encourage suitable ex-Service men and women to enter dentistry and that dental teachers should be released from the Forces at the earliest moment. Another main point is that the public should have more dental health education, dealing with questions of diet and dental hygiene, as well as stressing the need for regular inspection and treatment. Further reference to the report will be made in a later issue.

THE R.A.V.C. IN THIS WAR

Sir Clifford Allbutt would not work in blinkers; he had to see all round him. He often pleaded the cause of comparative pathology, and in effect what he said was: there is only one Medicine, and we all have a lot to learn from each other. The *Veterinary Record* for Nov. 18 contains an article by Major A. V. Franklin on the work of the Royal Army Veterinary Corps in the Mediterranean theatre. By reason of the progressive mechanization of the Army the outbreak of this war found the Corps shrunk to a shadow of its former self. Major Franklin traces its history from the early days of mobilization to the present time. The primary cause of its regrowth was the formation of a Cavalry Division for service in Palestine. After 1940 the horse, mule, and camel began to come into their own again, and with them the R.A.V.C. During that year all ranks were trained to be ready in the event of heavier calls, so that they could form a sturdy framework for further expansion. In 1941 the duties performed by the Army Remount Service were transferred to the Corps; this unity of control led to a notable increase in efficiency and economy. In the campaigns of Eritrea, Greece, and Syria the R.A.V.C. played an active part. In 1942 further important duties were assigned to it—meat inspection and the administration of livestock depots. The campaign in Italy gave the Corps its first occasion in this war to play an active part in large-scale operations. The difficult nature

¹ *Ann. trop. Med.*, 1943, 37, 700.

² *Proc. Staff Meet. Mayo Clin.*, 1944, 19, 257.

³ *Publ. Hlth. Rep. Wash.*, 1944, 59, 583.

of the country made heavy demands on mule transport, and it became the responsibility of the R.A.V.C. to meet all requirements. This work called for intimate knowledge of the remount side and also for vigilance on the part of purchasing officers to prevent such scourges as glanders, epizootic lymphangitis, and mange from being introduced into the distributing depots. These and other activities led to rapid expansion of the officer strength. High credit is due to the administrative staff for the way in which the Corps, greatly diminished owing to mechanization, expanded so quickly and so successfully while taking over the additional duties of a remount service. Medical men who made friends with veterinary colleagues while serving in the last war will be glad to know how the R.A.V.C. has risen to the occasion after a period of enforced decline.

PACKAGING OF MEDICAL SUPPLIES

With the prospect of increasing war activity in the Far East the preservation and packaging of war supplies, including medical supplies, becomes of growing importance. Stores may have to be landed on beaches instead of at ports and carried on muleback or on men's shoulders far into the jungle, exposed to the rigours of tropical climate. In the earlier days of the war vast quantities of stores arrived at their destination in a useless condition owing to improper packing at the source. The "global" nature of the war lends special interest to an exhibition of packing methods, in which the British and American Army authorities have co-operated, at the Central Ordnance Depot at Feltham in Middlesex. A section is devoted to medical stores, and here we can witness the American genius for packing. The eye is caught by 100,000 Oxford units of penicillin packed in a bottle large enough for the distilled water necessary to produce the required concentration. The bottles are packed in a divided carton inside a corrugated box; this again goes inside a larger corrugated box, around which is a waterproof-bag liner, and the whole is placed in a nailed wooden box. Plaster-of-Paris bandage, susceptible to damage by water, is sealed inside a metal-foil laminated package; this is cartoned and put into a waterproof-bag liner which is nailed up in a wooden box. Surgical instruments are cleaned and preserved, then all contacts and moving points are press-fitted with small pieces of aluminium foil; the entire instruments are laid between sheets of the same foil and sealed inside a laminated, padded cellulose bag. A waterproof-lined wooden box encloses these envelopes. Each unit of blood plasma is packed in two bottles—one containing distilled water, the other the cakes of blood plasma. Each bottle is sealed in a tin, together with the rubber and glass tubing, needles, bottle hanger, and auxiliary caps needed for the transfusion operation. The units are cartoned, and a wooden box lined with waterproof material holds several cartons. Sulphuric acid is packed in glass containers fitted with rubber-gasketed plastic caps. Several bottles of this are packed in a divided case entirely surrounded by material made out of rock wool. An emergency refrigerated serum box uses dry ice and sufficient thickness of bitumen-treated creped cellulose wadding to maintain serum at a temperature of -10°F . for nine days. This is used only when refrigerated transportation is not available. X-ray tubes are enclosed in a canvas bag suspended in a wooden frame and put in a corrugated fireboard box with greaseproof wrappings, and this again in a nailed wooden box. X-ray film is put in a tropical bag, and this again in a metal box with soldered seams and tear-off strip.

The purpose of the exhibition is to impress upon manufacturers that it is part of their job to ensure the proper

packing of their goods. The Army services units cannot be expected to be specialists on the 150,000 different types of stores at an ordnance depot. The use of preservatives against corrosion, the provision of protective layers between the atmosphere and critical metal surfaces, the value of neutralizers for finger-prints, the compressed-air method of drying, and the never-failing serviceability of greaseproof wrapping-paper, waxed cartons, and waterproof envelopes are brought home to the least expert observer. Of equal importance is the precise labelling of each package so that there may be no unnecessary opening and exposure to ascertain its contents.

DIAGNOSIS OF ANGINA PECTORIS

In many cases the diagnosis of angina pectoris depends entirely on the patient's account of his subjective symptoms. Nothing may be apparent on examination, and the electrocardiogram may be normal. Records taken by chance during an attack of angina have shown changes in the T wave or the R-T interval. Sometimes these transient changes have resembled the more permanent features of the curves of myocardial infarction. In this way the part played by myocardial ischaemia or anoxaemia in their pathogenesis has been established. Recently in the United States, Master, Nuzie, Brown, and Parker¹ have studied the effects on the electrocardiogram of what they have called the "two-step" exercise in patients suspected of having disease of the coronary arteries. They have devised a simple standard step exercise, graded according to the age and weight of the patient. The five leads of the electrocardiogram were first taken at rest, and the pulse and blood pressure were recorded. Immediately after the test the curves were taken again, and then ten minutes later. In normal persons no changes in the curves were noted. In 13 out of 20 persons with disease of the coronary arteries transient abnormalities appeared in the T wave or the R-T intervals. In order to prove that the change was due to myocardial anoxaemia the patients were made to breathe an atmosphere containing only 10% of oxygen. The result of this was to produce curves similar to those which were obtained after the exercise. This procedure was not entirely free from unpleasant consequences. Patients with valvular disease also showed signs of relative coronary insufficiency, presumably the result of diminished output from the left ventricle. Patients with effort syndrome also gave positive results, due, it was thought, to the poor output of their hypoplastic hearts.

It is doubtful whether these procedures are of real practical value in ordinary clinical practice. Special technique is needed to take the curves quickly enough after the test to record the transient changes, and each patient requires at least six films. The chief disadvantage is that in about a third of the cases with coronary artery disease results are negative; also in some instances the results are positive although disease is absent. It is interesting to observe that breathing air with a diminished oxygen content caused the same curves to appear as those which were found after exercise. The diagnosis of angina pectoris must still mainly depend upon the accurate and careful taking of the history and upon a clear understanding of the nature of the symptoms, negative findings in all available methods of examination notwithstanding.

We regret to announce the death of Sir Joseph Arkwright M.D., F.R.S., for many years honorary bacteriologist to the Lister Institute, and joint author, with his colleague the late Sir John Ledingham, of *The Carrier Problem in Infectious Diseases*.

¹ *Amer. J. med. Sci.*, 1944, 207, 435.

A gathering in B.M.A. House last week of medical men from eight European countries, which was arranged by Dr. George de Swiet, was in itself an example of how much can be gained even at an informal meeting between doctors of different nations. The meeting was in a sense an opportunity for saying *Ave atque vale* to men and women who hope soon to return to their own countries to deal with the terrible aftermath of German invasion. Dr. Dain, the Chairman of Council, struck a note that found a ready response among all those present when he observed that if there were a wider diffusion of the spirit that permeated medicine, the prospects of future peace might be made secure. There were, he said, no frontiers in medical knowledge, there were no monopolistic restrictions in medical discoveries. Medicine was truly international. British doctors had a big sense of obligation and gratitude to their foreign colleagues, because we were conscious that we had been spared the misery and destruction to which almost the whole of Europe had been subjected. If, therefore, out of that meeting there came some movement for giving a permanent expression to the bonds which hold together doctors of different countries, then the British Medical Association would feel it a privilege to give all the help it could to make such a movement successful. Dr. Dain's welcome was endorsed in a few words from Dr. C. Hill, Secretary of the B.M.A. Dr. Alfie Cox then gave those present a most interesting short history of the Association Professionnelle Internationale des Médecins: recalling how the proposal to hold the Annual Conference in Prague in 1938 was defeated by the German delegate, who considered this an insult to the master race. Dr. Cox felt now as he felt in the early days of the A.P.I.M., that an international organization of doctors should take as its field of activity what might be described as medical sociology or medical politics. Such an organization should provide a framework within which doctors of all countries could discuss common professional problems, and should not attempt to include medical science, which was well covered by various international congresses for various branches of medicine. The idea of the A.P.I.M. came originally from Poland and was enthusiastically taken up by Dr. Decourt of France.

The views of many were summed up by the Norwegian Minister of Health when he said that in the new kind of world which they were hoping to reconstruct after the war medical services would have to some extent to be reconstructed also. But they should remember that the medical profession, through its doctors, had over a period of hundreds of years become moulded into the society of which they formed a part, and that any attempt to break this mould might be harmful. That the doctor should prove a beneficial force in society outside his strictly professional sphere was a view put forward by another speaker. Among them all was a clear desire for common organization, so that in peace the profession of medicine at least could see that national rivalries were transcended. Those foreign delegates who spoke were: Dr. C. Meissner (Chairman of the Polish Medical Association), Dr. Karl Evensen (Norwegian Minister of Health), Dr. J. Ungar (Czechoslovakia), Col. C. F. Koch (Dutch Army), Dr. M. Sekulić (Yugoslavia), Col. B. A. Osipov (Soviet Military Mission), Dr. A. D. de Smet (Belgium).

FOREIGN DOCTORS: A MEETING AT B.M.A. HOUSE

The University Extension and Tutorial Classes Council, in co-operation with the Provisional National Council for Mental Health, is prepared to hold this year, provided sufficient applications are received, the usual course on mental deficiency and allied conditions. It is hoped that the course can take place, as in recent years, at the London School of Hygiene and Tropical Medicine, Keppel Street, Bloomsbury, and the date fixed is March 12 to 23, 1945. Students must arrange their own residence. The course is intended for qualified medical practitioners, more especially those who are engaged as school medical officers, certifying officers to local authorities under the Mental Deficiency Acts, or as medical officers in institutions. Detailed time-tables and other information will be sent out to each person proposing to attend the course about a week before it begins. As the course can be held only if sufficient applications are received, intending candidates should apply at the earliest possible date, but in any case by Feb. 24. The registration fee of 10s. 6d. must be paid at the time of application and the fee for the course before March 3. If applicants withdraw before this date the fee of £5 15s. 6d. will be returned or carried forward to another course as preferred. Should the course have to be cancelled all fees will be returned. Cheques should be made payable to the Provisional National Council for Mental Health, and crossed to Barclays Bank, Ltd. All communications should be addressed to Miss Evelyn Fox, C.B.E., c/o University Extension Department, University of London, 39, Queen Anne Street, W.1.

Correspondence

Interchange of Medical Information

SIR,—The surgeons with the B.L. Armies are bitterly disappointed that so few of the follow up postcards (VF 13216) which they have enclosed in the envelope containing the field documents of wounded men evacuated to U.K. have so far been returned to them by E.M.S. surgeons treating these patients subsequently.

The Consulting Surgeon to this group (Brig. A. E. Porritt) has written (Oct., 1944). If only the E.M.S. would realize how eagerly these cards are awaited over here, I am sure they would make a greater effort to return them. Not more than 1% have been returned since D Day. Quite apart from the natural interest and eagerness of individual surgeons to hear how their cases have progressed this information together with comments and constructive criticism is a valuable factor in improving the standard of surgery in the field.

Instructions on the employment of the follow up postcard issued by the Army and E.M.S. are almost identical and quite explicit. Naturally enough, the Army surgeons cannot understand why a system which worked between the forward and base hospitals in M.E.F. and C.M.F. should not work equally well between the Army hospitals in France and Belgium and the E.M.S. hospitals in the U.K. It is scarcely surprising, therefore, that our surgeons are inclined to blame the E.M.S. for its failure in this instance. It would be a great pity if this mutually beneficial liaison between two large groups of the profession cannot be improved, particularly as both are doing such splendid work on the same job.

It is not easy to discover why these cards are not returned. I suspect that the different systems of documentation are mainly responsible. I believe the plan tends to break down at the point where the essential clinical information which should be written on the field card is first transferred to the E.M.S. case sheet. The follow up card is either missed or returned to the Army envelope to be dealt with later—and thereafter forgotten, because to the surgeon who has to plan the patient's treatment it is of little clinical importance.

Whatever the cause, I am quite sure that the majority of E.M.S. surgeons are quite unaware that there has ever been any complaint. I am equally convinced that as soon as their attention is directed to this a remedy will be found and this valuable system of interchange of information will work smoothly. Therefore, with the above object in view, and with the approval of the E.M.S. authorities I have decided to request you to publish this letter.

I feel that a personal and unofficial appeal on behalf of the surgeons of the B.L.A. in your popular and influential columns is assured of a wide individual attention and will receive a sympathetic hearing—I am, etc.,

D. C. MONRO
Major-Gen. Consulting Surgeon to the Army

Service Medical Officers and Demobilization

SIR—The statement on demobilization by the Central Medical War Committee makes it clear that release of medical officers both in Class A and in Class B must depend to a large extent on the continued recruitment of medical practitioners who have not yet been called up for service.

At present there are considerable numbers of medical men holding appointments under the Emergency Medical Service who qualified in the earlier years of the war and in some cases several years before the outbreak of hostilities. Many of these are now well over five years qualified and most of them over the age of 28. This group of practitioners has worked hard and efficiently, but it must be borne in mind that in comparison with their contemporaries who joined the Services they have had exceptional opportunities for obtaining valuable clinical experience in all branches of medicine and surgery which have not been usually available to those in the Services. Moreover, a considerable proportion have been able to take higher qualifications. In addition, they have had little interference with their domestic lives and liberties.

Medical officers in the Services, many of whom have been overseas for years, unable to acquire higher qualifications, and often with few facilities for obtaining clinical experience, will feel themselves unfairly dealt with if they are retained in the Services while the younger members of the Emergency Medical Service remain in civilian life. I trust, therefore, that the Ministry of Health will accept the recommendation of the Central Medical War Committee with regard to the continued recruitment of doctors up to at least the age of 35—I am, etc.,
Guy's Hospital London S.E.1 J. J. CONYBEARE

National Thoracic Surgical Service

SIR—In your leader of Nov. 11 (p. 633), which is devoted to an appeal for the formation of a national thoracic surgical service, it is suggested that the regional medical staff "should be composed of a director, or assistant director, a number of surgical officers of the standard of registrar, and house surgeons, physicians and radiologists." If the staff appointment is to be in the order of importance indicated by the first four, then it would seem that the two latter are considered the least important. Presumably the director is to be a thoracic surgeon who has had the training indicated as desirable in the second paragraph of the second column on p. 633, for we are told in an earlier paragraph that the time has passed, or should have passed, when the physician calls upon or directs his surgical colleague to perform some particular operation upon the chest. The operative procedures necessitate a high degree of surgical skill and must be supported by an equally skilled anaesthetic technique.

The acquisition of skill in the highly specialized technique is no small achievement in this sphere, and the desirability of a co-operating team to assist must be acknowledged, but as "the understanding of thoracic diseases alone requires considerable experience," has the time passed when the direction should pass out of the hands of the physician? With the use of drastic and heroic surgical measures which the patient may now survive it would seem that more than ever it is essential for an experienced physician to be at the helm, and as so much depends on radiological interpretation he should preferably have the helpful co-operation of an experienced radiologist. They have the experience that even the graver chronic lesions in pulmonary tuberculosis can be cured or alleviated and endured often cheerfully for 20 or more years by patients who are able to continue to do their duties, and that pneumothorax, unilateral or bilateral may fail to collapse a cavity, that this may not be accomplished even with the aid of division or resection of pleural adhesions, avulsion of the phrenic nerve and/or pneumoperitoneum, that the lung may fail to re-expand that the pleura may become thickened and fixed, and that thoracotomy is not always successful in obliterating the empty space, and that when this is done the disease may then express itself in the opposite lung. To repeat the series of operations on the remaining side would logically appear to be as essential but alas! We were always taught that the best method to assist the tuberculous patient was to build up his resistance. It is difficult to believe that a patient who could withstand such a series of operative measures and overcome the disease would not have done so without, even a fit man would have difficulty in surviving.

The history of a child who had been discovered to have clubbed fingers by the school doctor, who rightly suspected a pulmonary lesion, for which pneumothorax was followed successively during the next 18 months by bronchography, bronchoscopy, biopsy, an unsuccessful attempt at surgical removal, deep x-radiation, multiple tapplings for the removal of fluid, a second unsuccessful surgical attempt at removal, deep x-radiation, and finally death, makes one think there was great need for a kindly physician who would have treated the patient rather than the radiographic appearances.

From my experience I should say it was highly desirable that any surgical work on the chest should be directed by an experienced physician. The merit of the work of the general physician or surgeon is that it is within the reach and grasp of the student and general practitioner, but specialization such as this tends to keep aloof and avoid the criticism which is so desirable. Would not specialization under a State system be even further removed from criticism?—I am, etc.,

Birmingham

J. F. BRAILSFORD

A National Renal Service?

SIR,—It is to be hoped that the recommendations of the Society of Thoracic Surgeons of Great Britain and Ireland for the institution of a national thoracic surgical service, as outlined in your admirable leading article, will soon be implemented. There is little doubt that such a service would be an immense boon to a large class of sufferers hitherto not able to receive the full benefits that current knowledge, modern technique, and specialist skill are able to supply.

Somewhat similar, and equally valuable, suggestions have recently been made, I believe, for national services based on area organization in the fields of orthopaedic surgery, maternity, paediatrics, and the rheumatic diseases. The principle is obviously one that could with advantage be extended to other special branches of medicine. In one, at least, I am certain that its adoption would prove of inestimable benefit: I refer to the not yet recognized specialty that deals with the medical diseases of the kidneys, and, more particularly, to those disorders generally included under the heading of "Bright's disease." This group is, directly and indirectly, probably responsible for more deaths in this country each year than cancer, primary heart disease, or, indeed, any other group of allied and commonly fatal diseases, and yet there is practically no organized provision for the special needs of its numerous victims.

If, Sir, your readers will substitute the words "renal medicine" for "thoracic surgery" and "renal surgeon" for "thoracic surgeon" in the leader to which I have referred I am sure they will be in no doubt as to the urgent need for a national renal service.—I am, etc.,

A. A. ÖSMAN.

Incidence of Peptic Ulcer

SIR,—In your leading article on this subject (Nov. 18, p. 665) you stress the need for statistics of the total incidence of peptic ulceration in our population. An excellent opportunity for obtaining these figures presents itself at the moment, owing to the need for certificates for extra milk and eggs for cases of peptic ulceration. Figures of total applications over three months might be obtainable from the Ministry of Food; and general practitioners could keep records of their individual cases.

I have kept records of applications for these certificates in my practice over the last three months, in a largely industrial area of mixed types of occupation. Of my total panel 2.55% have gastric or duodenal ulcers proved by x-ray examination. My panel consists almost equally of men and women. Of all my ulcer patients 93% are men, and the age groups are made up as follows: 10-20, 2.5%; 20-30, 10%; 30-40, 10%; 40-50, 65%; 50-60, 12.5%. The absence of younger cases with this condition might be partly due to absorption in the forces, but such cases would be likely to be discharged by W.—I am, etc.,

elwyn Garden City, Herts

J. S. ROSB.

Peptic Ulcer

SIR,—The article on this subject (Nov. 18, p. 655) is certainly disquieting, and it throws a great responsibility on the general practitioner, for the results of treatment in established cases are so unsatisfactory that the most hopeful outlook is diagnosis at a much earlier stage or, at least, recognition of those conditions that may be looked upon as the possible precursors of ulcer, where treatment might have a better chance of substituting a remedial course for a vicious circle. The great majority of peptic ulcers have some past history of dyspepsia, but, of course, the great majority of cases of dyspepsia are not embryo peptic ulcers, so it comes to be the hard task of the general practitioner to recognize conditions that may lead to trouble. Cases that recur in spite of treatment will suggest inquiry as to home surroundings, diet, social and economic conditions, hours of work, and the many psychological conditions that are putative progenitors of peptic ulcer.

The doctor will, or should, have the opportunity, if required, of treating his patient in a district hospital bed, where instructions as to rest, diet, and medicine will be carried out. The latter is of special importance, for, although the alkalis most valuable are now generally agreed upon, the time of administration is too often vaguely stated. This is especially important in cases treated at home, where the diet is so often, by force

of circumstances, to a large extent the ordinary family food. Lately, for another purpose, I asked a chemist with a "high-class" clientele to find out for me the directions given in 15 prescriptions of alkalis obviously for dyspepsia: of these, 11 were simply "t.d.s., p.c."; only two had any further instructions as to time in relation to food. "After food" is also the direction given with most of the proprietary alkali powders now so very largely used by the public. This direction, so far as I have generally found, is taken to mean soon after a meal, which, of course, is a convenient time from the patient's point of view. Some authoritative statement on this point might be useful. It has been stated that in general in the case of an ordinary or light diet the alkali should not be taken until at least two hours after the meal, as otherwise the essential acid process of gastric digestion would be interfered with.—I am, etc.,

Westbury, Wilts.

CHAS. E. S. FLEMING.

Episiotomy

SIR,—In the correspondence on episiotomy which appeared in the *Journal* within recent weeks the importance of the operation as a means of avoiding subsequent prolapse was not emphasized. This omission has now been remedied by J. D. S. Flew in his article in your issue of Nov. 11. The fact that a woman is more fortunate in sustaining a perineal tear than in having her perineum preserved at the expense of a longer second stage, and consequent overstretching of the paravaginal muscular tissue and disruption of its attachments, has perhaps been recognized and taught more widely and for a longer time than Dr. Flew suggests. Yet the old idea dies slowly—particularly among the nursing profession—and he has rendered a service in again bringing the matter to notice. The immediate advantages to the mother and child (and obstetrician) and the remote benefits to the mother of a well-timed episiotomy are beyond question, and, being in entire agreement with Dr. Flew's main thesis, may I comment on some of the interesting side issues which he raises?

His statement that apart from vault prolapse, as in the nullipara, a low cystocele and low rectocele are the only types of vaginal prolapse cannot be accepted. Prolapse occurs in an infinite variety of forms, affecting both upper and lower vaginal walls and the uterus, sometimes with a hernial pouch or peritoneum, sometimes without. Moreover, a high vaginal prolapse, usually rectocele or enterocele, may be present without any uterine prolapse. Although vaginal and uterine prolapse often occur together in different combinations, it is nevertheless helpful to consider them separately.

Having reminded us of the well-established clinical observation that prolapse, particularly uterine, is rare in patients who have a complete perineal tear, even of long standing, it is a pity that Dr. Flew concludes that the pelvic floor forms the most important support of the uterus and vaginal walls. Apart from the evidence he gives, there is much to substantiate the view that the chief uterine supports are the cardinal and utero-sacral ligaments, together with the fibromuscular fascia which spreads down around the upper vagina, and that the vaginal walls are mainly supported by the fascia lying deep to them. The perineum offers only a subsidiary support; in the upright position the vaginal walls, lying in apposition and sloping upwards and backwards, rest on it, and so does the uterus to a lesser extent, but probably only when it is already in the first stage of prolapse. If the main supports are weakened a strong pelvic floor will not prevent prolapse, whereas if the main supports are intact complete destruction of the pelvic floor does not result in prolapse.

The nearest approach to pure uterine prolapse is seen in the nulliparous type, where the uterus, together with the vaginal vault, descends through an undamaged introitus and lower vagina. Although nulliparous prolapse is not common, it should not lightly be dismissed from consideration—it may have much to teach us regarding the aetiology of uterine prolapse in the multipara. Its predisposing and fundamental cause is an inherent weakness of the supports around the cervix and vaginal vault, this weakness becoming accentuated by atrophic changes associated with the climacteric. The activating factor is sometimes increased pressure from above which results from heavy physical work, a chronic cough, etc.

But not all women whose uterine supports are developmentally weak are destined to remain nulliparous, and the greater number marry and have children. In such case it takes very little damage to the cardinal and adjacent ligaments during pregnancy and childbirth to determine the onset of prolapse of the uterus, either at once or following the climacteric. This does not mean that all such women would ultimately have developed prolapse if they had remained childless, although some would undoubtedly have done so. It means that pregnancy may reveal even minor defects in the supporting system—defects which in themselves might not have resulted in prolapse had not the strain of pregnancy been imposed. It is open to dispute what part an inherent weakness in the uterine supports plays in the development of prolapse in multiparous women, but it is probably an important one. This explains why prolapse may follow an easy confinement and not necessarily a difficult and complicated one. Moreover, it is sometimes possible to foretell in girls and young women that they will subsequently develop uterine prolapse if they have a child. In such the weakness of the supports is indicated by the ease with which the cervix pulls down to the vulva with a vulsellum, and sometimes by an unusually short vagina with a low-lying cervix and generalized atony of the pelvic musculature. Another developmental feature—an unusually low pouch of Douglas—must at times also be an aetiological factor in prolapse—at least in the formation of an enterocele, which, again, is seen in both nulliparous and multiparous subjects.

It is usually stated that vaginal prolapse by pulling on the cervix may ultimately cause uterine prolapse. This is probably true when it is the upper vagina which is affected, especially as the fascia deep to the upper anterior vaginal wall appears to play a part in supporting the uterus, but it is difficult to believe that a low cystocele or rectocele, separated from the cervix by an upper vagina with intact supports, as postulated by Flew, can operate in this way. Indeed, it is difficult to say what particular mechanism operating during pregnancy or labour weakens the uterine supports. It can hardly be the softening and stretching of the ligaments occurring during pregnancy, followed by faulty involution; otherwise prolapse following Caesarean section would not be so uncommon. The injury occurs for the most part during the birth process, and, although many explanations as to how it happens have been attempted, none are thoroughly convincing.

From the above it would appear that not all cases of uterine prolapse can be prevented by episiotomy—some patients are destined to suffer it by reason of the supports of the uterus being insufficiently developed to stand even a minimal stress of pregnancy and labour. Yet there is little doubt that episiotomy does protect a large number of patients from uterine prolapse. How it does it is not clear, but probably by releasing the upper anterior vaginal wall and its underlying fascia and, indirectly, possibly the paracervical tissues as well, from the downward pull of the foetal head.

Vaginal prolapse is even more likely to be prevented by episiotomy, which, apart from reducing the risk of general overstretching of the vaginal walls and fascia, releases the anterior vaginal wall from the tendency of the descending head to drag the pubocervical fascia away from its attachments behind the pubis. In particular the patient is least likely to develop a cystocele when episiotomy is performed.

Flew mentions that infection, by leading to subinvolution, may cause prolapse. This is largely a theoretical consideration. The entrance of infection into the area around the cervix, particularly following a tear of the cervix and vaginal vault, nearly always fixes the uterus to some extent and is almost a guarantee against its prolapsing. Similarly, the vaginal wall which is torn and infected rarely prolapses—it is usually the area above it, which has avoided the tear but has been stretched, which descends.

Two further points merit comment. First, whilst agreeing that the duct of Bartholin's gland should be avoided in all operations if possible, if only to preserve the supply of normal lubricating secretion, yet it should be pointed out that if it is cut or ligatured a Bartholin's cyst rarely results. In some types of perineal repair the duct is always divided, and yet it is exceptional to see a cyst of either gland or duct develop. It would appear that complete severance of the duct results in the gland ceasing to function. Secondly, Flew's statement that the vagina is attached to the cervix about the level of the internal os should not be allowed to pass unchallenged. If it were so, the "supravaginal cervix" would cease to exist.

In conclusion, may I repeat that I hope the above comments on some of the more academic questions raised in Dr. Flew's paper will not detract in any way from his main contention—that prolapse, particularly cystocele, can to a large extent be avoided by episiotomy, and that in any case it is an operation which, in the interests of the immediate welfare of both mother and child, should be carried out whenever there is the slightest delay in the second stage of labour, and certainly in every forceps and breech delivery in a primigravida.—I am, etc.,

T. N. A. JEFFCOATE.

Liverpool.

Sir,—I should like to thank Dr. Flew for his article on episiotomy, and particularly for his advice "concerning the exact way in which it should be carried out." But one feels that his advice about "the cases in which it should be performed" can hardly be taken seriously.

Dr. Flew tells us that in a series of 135 primigravida private patients he performed episiotomy in 53.3%, and implies that the "practical result would be that an incision would be necessary" in multiparous patients episiotomized as primips, "since the old scar would rupture." Is it not a reasonable deduction that in over 50% of all labours perineal suture will be necessary?

Dr. Flew advocates that midwives be permitted to perform episiotomy, but the suturing of the wound should be left to a medical officer. I do not think many of us will agree with the former, and we might all be rather surprised by the large amount of extra work, remunerated by a meagre fee, produced by the latter.

One of the main reasons for early episiotomy brought forward by Dr. Flew is the prevention of vaginal tears at the time of labour and prolapse subsequently. Are not vaginal tears due to disproportion between the size of the baby's head and the diameter of the vagina? It is a little difficult to see how an episiotomy is going to alter either of these diameters.

One cannot help feeling that Dr. Flew is viewing this problem through his specialist glasses, which are perhaps a little too concave; but to show him how much I appreciated his article I am going to ask him to write a further article (with equally clear diagrams) telling us the exact details of the technique of suture of the perineal wound following episiotomy.—I am, etc.,

Rotherham

ERIC COLDREY.

Sir,—Dr. J. D. S. Flew is to be congratulated upon the firm stand he has taken with regard to episiotomy. I am particularly glad to see that he stresses that, in the primigravida, episiotomy is necessary in over 50% of cases to prevent irreparable maternal and foetal injury during labour, that a timely episiotomy will often make an otherwise unavoidable forceps delivery unnecessary, and that bilateral episiotomy must not be done under any circumstances.

Without wishing to detract from the value of his paper, I should like to point out that the "author's method" of episiotomy was described by Douglas Miller in the *British Medical Journal* (1936, 2, 4), and the harmful effects of conserving the perineum at the expense of the intracranial structures of the child and of maternal tissues more difficult to repair than the perineum, by myself in the *Journal of Obstetrics and Gynaecology of the British Empire* (1943, 1, 260), in both instances without any claim to originality by the author.—I am, etc.,

Newcastle-upon-Tyne.

WILLIAM HUNTER.

Erb's Paralysis

Sir,—In your issue of Oct. 21 (p. 548) the query was put forward: "What is the treatment of Erb's paralysis in an infant—the result of a very difficult confinement?" From the way in which the question was framed I visualized the inquirer with an infant a few days old on his hands asking for a method of immediate treatment, and it seemed to me that the answer given would be of little help to him.

I doubt if any surgeon would advocate operative intervention in the newborn, and the application of an aeroplane splint is a practical impossibility in a child a few days old requiring bathing, feeding, and attention to the bowels and umbilical cord. The orthopaedic textbooks on the whole give little help in this important problem beyond advocating fixation in flexion, abduction, and supination without any definite explanation as to how it should be done. In this district, mainly owing to the early recognition of these conditions at child welfare centres, I rarely see these children later than a few days after birth, and the good results obtained by early and continuous fixation in the optimum position warrant, I think, a more widespread knowledge of the following simple procedure. It is almost certain to have been published before, although I have not come across it either in the literature or in practice since it was taught me as a student by the late Prof. Archibald Young of Glasgow many years ago.

wished their symptoms to recur. Sir Arthur Hurst wrote to the *Times* to call attention to his opinion that "excessive smoking is undoubtedly one of the most important causes of unexpectedly high incidence of duodenal ulcer." He also mentioned that Sir Maurice Cassidy had drawn attention to the same subject. My own experience is very small, but one patient told me that he could always get sick leave by smoking cigarettes for a week or two before his medical board.

In the articles referred to above no mention is made of tobacco, but with such authority supporting the suggestion that tobacco is of very great importance in the aetiology of duodenal ulcer I venture to hope that cigarette smoking may receive attention, while the psychological and nutritional causes are also investigated. I would like to relate that several years ago I asked a sympathetic medical friend why no one with a voice that would be heard and listened to had not raised this point. His answer was cynical: "Not likely, all Harley Street has its money in Imperial Tobaccos."—I am, etc.,

Newbury.

V. S. HODSON.

The Metric System and Medicine

SIR,—Few medical men, if they give any serious thought to it, can doubt the advantages to be derived from the use of the metric system in medicine. At present it is used by a small minority of the profession, and this surely leads to confusion rather than simplification. Indeed, those who use it are still after many years using it either inconsistently or incompletely. One sees Gilbertian instances of this from time to time in certain wards. Aperients may be ordered in the metric system, but if they do not have the desired effect an enema is given, and being measured, always I believe, in good old-fashioned pints and ounces, it usually has a most gratifying result. I well remember looking at the chart of a patient who drank in cubic centimetres but vomited in ounces (the stomach is a true British die-hard). Even physicians who are most enthusiastic supporters and users of the metric system still speak of their patient's temperature in degrees Fahrenheit.

I agree with Surg. Capt. Lambert Rogers (Nov. 11, p. 639) that if we should make up our minds to change to the metric system it should be done overnight. But it must be after careful consideration and preparation and by the whole of the medical and nursing professions as well as by all pharmaceutical personnel. But even then some may say, and possibly rightly, that this is unwise so long as Britain does not adopt the metric system for everything.—I am, etc.,

London, W 1

JOHN HOSFORD.

Débridement

SIR,—In teaching students and in other connexions I use the word "toilet" for the above. To students it has to be explained fully.—I am, etc.,

Cardiff.

A. W. SHEEN.

R.M.B.F. Christmas Gifts

SIR,—You very kindly published my appeal in October on behalf of the Christmas Gifts Fund of the Royal Medical Benevolent Fund. I am very grateful to those who have already forwarded their contributions, but may I ask those of your readers who are in sympathy with our work and who have not as yet sent their donations to forward them as soon as possible to the Honorary Treasurer, Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, London, S.W.15, marked "Christmas Gifts." This appeal is urgent as we have not as yet received the sum required to meet the distribution of gifts.—I am, etc.,

THOS. BARLOW,
President.

G. S. Erwin (*Tubercle*, 1944, 25, 35) records 14 cases of tuberculous tracheo-bronchitis in adults aged from 19 to 64. Factors contributing to the onset were fatigue, malnutrition, fevers, and silicosis. The cardinal symptoms and signs were cough, sputum, evening pyrexia, haemoptysis, pain in the chest, and loss of weight. X-ray examination showed no evidence of acute parenchymal disease, though occasional hilar adenitis of the type seen in childhood is

Obituary

SIR ROBERT KELLY, C.B., F.R.C.S.

Sir Robert Ernest Kelly died at his home in Liverpool on November 16 at the age of 65. As a vice-president and member of the Council of the Royal College of Surgeons, a member of the General Medical Council, and a member of the Army Medical Advisory Board, regional consulting surgeon and chairman of the Local Medical War Committee, there was much for him to do in these troubled times. A man of peace, with a deep love of his country, he would be found giving a hand wherever the city had been "blitzed." His loss will be felt deeply by those who appreciated his kind disposition, engaging perseverance, and the whole-hearted enthusiasm to advance the art and science of surgery. He belonged to a rapidly diminishing group of craftsmen, who with ease turn from one branch of surgery to another and perform cranial, abdominal, vascular, and orthopaedic operations with admirable skill and success.

Born in 1879, he was educated at the Liverpool Institute. He took the B.Sc. Victoria, and was one of the first graduates of the University of Liverpool. His early training in physiology and association with Sherrington undoubtedly influenced his subsequent career, bringing with it a remarkable delicacy in the handling of tissues and a keen desire to further research. His research was objective and had the safety of the patient ever in view. An exponent of the open method of administering ether, he introduced the intratracheal method into this country following upon a visit to America.

The outbreak of the last war interrupted his career as assistant surgeon to the Liverpool Royal Infirmary. He went to Salonika, there to make Thomas splints and start rehabilitation centres. He became consulting surgeon to the British Salonika Force and was awarded the C.B. Shortly after his return he was appointed professor of surgery. His lectures were popular and practical and well illustrated, for his hobbies included colour photography in all its forms, in addition to golf and the 'cello. In 1937 he had the honour to be invited to take charge of the Surgical Unit at St. Bartholomew's Hospital for a period of one month.

Keenly alive to the changed circumstances under which the teaching hospitals were working, Robert Kelly urged a fusion of local hospitals to build one worthy of the city—the foundation stones of which he would have welcomed. Twice President of the Liverpool Medical Institution, he conducted its centenary proceedings in a manner worthy of the best tradition of that society. He could be relied upon to give all organizations interested in medical welfare his closest support. He received a well-deserved knighthood in 1939, and was appointed emeritus professor of surgery and honorary consulting surgeon to the Royal Infirmary. He leaves a widow and one daughter.

Prof. HENRY COHEN writes:

It is hard in the immanence of his passing to write soberly of Robert Kelly. Twenty-five years ago he was my teacher, and for nearly twenty years my surgical colleague. With the years the admiration of the student grew into the love of a friend for a gentle and unassuming personality, devoid of malice and guile, with never-failing tenderness and courtesy. His junior colleagues sought him out in their troubles and perplexities, and he was never too busy to give them encouragement and sympathy. Not Liverpool only but all British surgery is the poorer for his loss.

His career was one of unbroken success. He early recognized that an understanding of bodily function is no less significant to the surgeon than a knowledge of anatomy, so he interrupted his medical course to take an honours degree in physiology under Sherrington,

who was then at Liverpool 'laying the foundations of modern neurophysiology. One of the greatest of ancient lyricists wrote, "Principibus placuisse viam non ultima laus est"—if Horace did not err Kelly must have been a happy man when Sherrington testified in 1921 that "during my eighteen years at the University of Liverpool I never had a student of greater promise." Physiological principles permeated his surgical teaching and practice throughout, but did not prevent him from becoming a superb craftsman. His manual dexterity was proverbial, and with the simple tools of his work he was an acknowledged master; even in the tying of a knot he showed a consummate artistry. But he delighted especially in the mechanically ingenious instrument, many of his students spent laborious hours providing the motive power for a hand-driven de Martel's trephine, but they were rewarded by those eyes which shone in admiration whenever, with almost human prescience, the drill stopped at the dura. The skill with which he used Souttar's craniotome may be seen in a film, contributed to the Kodak Library, on the removal of a cerebral tuberculoma. His enthusiasm for intratracheal anaesthesia, which he introduced into this country after a visit to America in 1912, owed not a little to his admiration for the physical principles of the apparatus. His zest for new adventures in surgery never flagged. In his sixtieth year his keenness and enthusiasm would put to shame the complacency and contentment of many surgeons twenty years his junior. His surgical versatility and knowledge were outstanding; except for chest surgery, there was no branch of the art in which he would not have been regarded as a peer by those with narrower interests.

But his skill never outstripped his judgment. Nor did he fall a victim to the many conditioned reflexes of the surgery of his time. For him "peptic ulcer" was not a specific stimulus, with surgery as an inevitable response. Few surgeons realized earlier than he the impermanence of surgery in that ultimately unrewarding Platonic absolute—the "chronic appendix." By instinct and persuasion he was a true physician ever seeking to understand the workings of Nature, and never so arrogant as to believe that his plumbing, carpentry, or architecture were more than minor contributions to the processes of healing and repair.

He wrote little by which he will be remembered, but his example and influence have left something in the structure of surgery more durable than his own brief life. For he was a model teacher. Even his systematic lectures had the intimacy of the wards. His style was simple and direct. He lacked (or did he shun?) the felicitous phrase and polished period of the seasoned orator, but his teaching was no less effective and his apt similes and illustrations had more than local fame. His students will recall vividly the annually produced orange with which he demonstrated the sites of cleavage in compression fractures of the skull, and the stick of chalk which illustrated the mode of production and the difficulties of reduction of spiral fractures of the tibia. He was no mean artist, and his lucid line drawings made with the traditional multicoloured pencil, which his senior colleague Thelwall Thomas (to whose encouragement and training Kelly never failed to pay affectionate tribute) had introduced, were a regular feature of his demonstrations.

From the day of his appointment as professor of surgery in the University of Liverpool he threw himself wholeheartedly and with great energy into its academic life and into the medical life of the city. Not only here, but in the wider spheres of his college, the General Medical Council, and those Government Departments with which he was associated in an advisory capacity, he revealed qualities of statesmanship which did not surprise those who knew his original and reflective mind. His unexpected gifts as an administrator were unasked when, as consulting surgeon to the Salonika Army, he "controlled the surgical work and supervised the surgeons working in at one time as many as 21,000 hospital beds." There his "services were of the greatest value," and earned for him the highest praise from the Director of Medical Services, Major-Gen. M. P. Holt. A revealing comment on Kelly is that during the Salonika campaign his chief recreation lay in reading Bayliss's *Principles of General Physiology*.

His tact and the belief of his colleagues in his complete integrity and selflessness were major assets in the delicate negotiations which led to the formation of the Associated Voluntary Hospitals Board in Liverpool, and later to the conception and legal realization of the union of the four general teaching hospitals in Liverpool as the Royal Liverpool United Hospitals. In committee his sense of justice and his intuitive understanding of people and things made him an accepted leader; he never dominated, his sole aim was to help. He did not feign disinterestedness in the rewards of his professional labours. Each fresh honour—and few open to the surgeon were denied him—cheered and heartened him; but he gave his energies and laboured unstintingly in many fields which yield no laurels. His knighthood, conferred on his retirement from the chair of surgery, was a recognition of the spirit and example of a tenure during which many who now hold high places in the world of medicine came under the spell of his inspiration and magnetic personality.

Kelly's interests were not confined to medicine. He was a man of wide culture and diverse facets. He loved art and music. He

was a competent cellist, and though he rarely missed a *phulharmonie* concert, he preferred the more intimate charm of chamber music. The theatre was one of his many hobbies; colour photography, both still and kinematic, another. He was a supporter of the Liverpool Playhouse, and not the least attraction of his frequent visits to London on official business was the opportunity of a night at the theatre. He played golf, but his captaincy of the Wallasey Golf Club mirrored the affection in which he was held rather than his prowess on the links. But his main recreation was reading. He read widely, not only in the literature of medicine, but in history, biography, travel, and especially modern science. The more popular works of Einstein, Rutherford, Bragg, Eddington, Jeans, Aston, Dingle, and other modern physicists were his mental stimulants when a long operation list had earned an evening's physical relaxation.

The sorrow of his loss was shown by the large and distinguished congregation representing his many scenes of endeavour which gathered to pay its tribute at the Liverpool Cathedral. Few men have by their lives more cogently compelled the epitaph: *Nihil quod teigit non ornabit*.

E. W. HEY GROVES, F.R.C.S.

Prof. G. GREY TURNER writes:

Your admirable notice of my old friend Hey Groves may be supplemented by mentioning that in 1916 he obtained the Jacksonian Prize at the Royal College of Surgeons for an essay on "The Methods and Results of Transplantation of Bone." At that time he was already attracted to bone surgery and had done much experimental work on the subject, but I think he was greatly encouraged by the award, and it had much to do with finally focusing his attention on bones and joints. Nevertheless, he remained a general surgeon, and almost the last time I saw him at work in Bristol, in April of 1939, he showed some cases in which he had transplanted the ureter, and in one of these he proposed to do a further operation for exploration of the kidney on the following day. More years ago than I care to mention Hey Groves rather startled a London audience at the Royal Medico-Chirurgical Society by a paper on gastrectomy, in which he advocated removal of the great omentum when that operation was carried out for malignant disease. During the last war one of his activities was the splint factory which he set up in Alexandria and supervised up to the time he left Egypt. It was wonderful to see the Arab workmen turning out splints in large numbers, mostly to patterns devised by Hey Groves. As long as he was there to supervise things all went well, and I shall ever feel grateful for the demonstration he gave us on gunshot limb injuries in the wards of the 21st General Hospital. But apart from the technical side of his work Hey Groves was a delightful personality. He loved foreign travel, and I think probably got more enjoyment out of our many tours on the Continent than most people. At the meetings of the editorial committee of the *British Journal of Surgery* Groves was usually in his best form, and except for the wartime (1914-18) I remember his being absent on one occasion only, and that was in consequence of illness. He and Moynihan, who was chairman of the *Journal* until his death, made a very good combination, but I always felt that Groves did not get quite enough credit for the enormous amount of tedious editorial work he undertook without the slightest complaint. He was always ready to shoulder more; and if ever there was difficulty in deciding who should review some book, often in a foreign language, he was willing to step into the breach.

FRANK ARTHUR HEPWORTH, F.R.C.S., died at his home in Saffron Walden, Essex, on Nov. 5, after a long illness, at the age of 65. He received his medical education at St. John's College, Cambridge, graduating B.A. (1st Class Natural Sciences Tripos) in 1900, and at St. Bartholomew's Hospital, taking the M.A., M.B., and B.Ch. in 1904, and F.R.C.S.Eng. in 1907. During the last war he served in the R.A.M.C. with the rank of major, and was appointed senior resident surgeon at Wharfedale, and later at the County of Middlesex War Hospital. For his services he received the O.B.E. In 1919 he came to Saffron Walden to take up general practice. He was elected to the staff of the hospital in 1920, and in 1940 he became senior surgeon, a post he held until his death. In the years that I have known Hepworth as a neighbouring practitioner I have always been struck with the quite remarkable devotion and affection that his patients felt for him. He was a good deal more than the family doctor to them. They brought him all their troubles, for they knew that he would apply himself to their problems in that thorough and painstaking way that was his particular characteristic. One may say that he did too much for his patients, for it was this excessive devotion to his work that finally undermined his health. As a colleague I shall always remember with gratitude his unflinching readiness to help at operation or in consultation, however awkward the hour or however tired he may have been.

* Subsequently published in the *British Journal of Surgery*, vol. 5, p. 185.

Although he chose to remain in the ranks of the general practitioners, he was a surgeon of great competence. His judgment was sound and his knowledge very wide, for he somehow found time for extensive reading. This and his vast experience in general practice made him a mine of information to anyone needing his help, and in particular to his fellow practitioners at the hospital. He died in middle life, while still at the height of his powers. The name of Dr. Hepworth will be long remembered in Saffron Walden and in the surrounding villages, for he was one who combined in his personality the finest qualities of the traditional family practitioner with the progressive and scientific outlook of to-day.—A. G. S.

Dr. JAMES J. PATERSON, late medical officer of health for East Berkshire, died from illness in Italy on Oct. 24; he had been appointed to U.N.R.R.A. in June. He studied at the Cardiff Medical School, where he won a scholarship, and entered St. Bartholomew's Hospital as senior science scholar, graduating B.Sc.Lond. in 1903, M.B., B.S. in 1908, and M.D. in State Medicine in 1911. At Bart's he was for a time junior demonstrator in physiology. He entered the public health service as assistant R.M.O. to the Croydon Borough Hospital, then became assistant M.O.H. to the county borough of St. Helens, and moved to Maidenhead in 1911 as M.O.H. for the East Berks United Sanitary Districts, school medical officer for the borough of Maidenhead, and superintendent of the infectious diseases hospital. Dr. Paterson joined the B.M.A. in 1909, was honorary secretary of the Section of Public Health at the Annual Meeting of 1922, and chairman of the Windsor Division in 1928-9. A. T. writes: By the sudden and untimely death of Dr. J. J. Paterson, U.N.R.R.A. has lost an extremely valuable member of its medical staff. Everyone interested in public health work, particularly in its international aspects, knows how much he did to develop and foster it. The conclusion of his long and successful tenure of the post of M.O.H. to East Berkshire would have seemed to most men a fitting moment to retire from active work. Paterson, however, thought otherwise, and was one of the first to volunteer to work on Balkan relief. He survived a strenuous summer in refugee camps in the Middle East, and it was just as he was on the point of leaving Italy for Yugoslavia that he collapsed and died. Ten minutes before his death he had been busily engaged in discussing plans with the other members of the Mission, and seemed as bright and efficient as ever. He died, as he had lived, in harness, and those who knew him are satisfied that he would not have wished it otherwise. Our sympathy goes out to his widow, who, sharing his humanitarian views as she did, gladly spared him for the work on which his heart was set.

The following well-known medical men have recently died: Dr. LAWRENCE JOSEPH RHEA, professor of pathology at McGill University Faculty of Medicine, aged 67; and Dr. FREDERIC ATWOOD BESLEY, a founder member of the American College of Surgeons, aged 76.

SOCIETY OF APOTHECARIES OF LONDON

At a recent meeting of the Court of Assistants, with Dr. J. P. Hedley, Master, presiding, an illuminated address was presented to Sir Stanley Woodward upon the completion of three years as Master of the Society. Surg. Rear-Adm. C. P. G. Wakeley delivered a lecture in the hall on "War Surgery in 1944" in place of Col. Elliott Cutler, who was unable to lecture owing to military duties.

The diploma of the Society was granted M. J. Blunt, D. A. Cox, D. I. F. Edwards, E. D. C. Jones, R. A. Leeming, I. A. Nazroo, and the diploma of Mastery of

Medical Notes in Parliament

Tuberculosis and Health Services in Nigeria

In a reply on Nov. 8 Col. STANLEY reported that detailed statistics of the incidence of tuberculosis in Nigeria as a whole were not available, but the position gave cause for concern. Facilities for the treatment of tuberculosis, and indeed medical facilities as a whole, obviously needed to be widely extended, but the expansion of the activities of the medical department had inevitably been limited during the war by the staff shortage. This had been accentuated by releases for military service, by invalidings, and by recruitment difficulties. In Nigeria as an essential preliminary towards preparing a comprehensive tuberculosis prevention scheme the Nigerian Government made provision for the establishment of a Tuberculosis Investigation and Survey Unit under the charge of a tuberculosis officer. The unit would include a mobile mass radiography section. The survey would start as soon as staff and equipment could be obtained. When these had been completed it would be possible to prepare for the needs of the country as a whole. Steps were also being taken to appoint a venereologist to take charge of a campaign against venereal disease. Venereal disease clinics would be opened in Lagos and elsewhere as soon as facilities were available. Meanwhile treatment for tuberculosis, venereal disease, and pneumonia was available to the public at existing hospitals and clinics. Expansion of general medical facilities would form an important part of the post-war development programme for Nigeria.

In one part of his reply Col. Stanley said that Government medical officers in Nigeria provided their own transport, but were eligible for assistance in the form of an advance of salary towards the purchase of motor vehicles. Maintenance and mileage allowances were paid. He was not aware of any difficulties.

Industrial Injury Insurance

Sir DAVID MAXWELL-FYFE resumed the debate on Nov. 9. He said there was an absence from the present system of provisions for medical and post-medical rehabilitation. All agreed that must be changed. The present scheme proposed grants for maintenance in hospitals, treatment, and constant attendance. Medical treatment and rehabilitation of the injured workman and post-war rehabilitation and training would be provided as part of the general medical and post-hospital rehabilitation services organized by the Ministry of Health and the Ministry of Labour. There would be a duty on the Ministry of Social Insurance to co-ordinate these activities with those of the Department, to assure free information, and to see the best services were provided for rehabilitation and training. The House had seen light work used as a method of stopping compensation. That was wrong and destroyed what work could do to restore and rehabilitate. The Government's proposals eliminated the idea of deciding how far a workman had recovered his earning capacity. They eliminated the grievance that an increase in earning capacity resulted in an automatic reduction in pension. Many M.P.s had seen the mental harm which that system caused in the past. The proposals also removed the suspicion that the workman would be pressed to undertake unsuitable work, with the result that he hesitated about rehabilitation and his recovery was retarded. The Government system gave a workman a right to his pension whatever work he did. It also met to some extent the complaint that there was no compensation for mutilation and disfigurement except in strict relation to earning capacity. By the system proposed, the workman would notify the pensions officer of the accident and would send the certificate of the doctor who had examined him for the injury. There would be confirmation from the employer, or, if there was a dispute, an appeal to the local appeal tribunal. When the Bill was drafted the Government would bear in mind the allocation of onus of proof. Clear working instructions would cover the vast majority of cases. When the change came from allowance to pension the question of disability would go to a medical board, against whose decision there could be an appeal to the local appeal tribunal, with the same chairman but with medical instead of ordinary members. That procedure would get rid of one-man decisions by a medical referee as was now done under Section 19 of the Act. He suggested that the words "arising out of and in the course of" employment should be retained when drafting the new Bill. Interpretation of those words had changed in favour of the workman.

Mr. BOWLES cited the case of a workman who had twice got dermatitis at a factory when unloading machinery which was oiled with oil. This man had great difficulty in

The Services

Cpts. L. J. Calvert, D. G. Cameron, C. B. Caswell, and R. C. Mellow, R.C.A.M.C., have been awarded the M.C., and Major (Temp. Lieut.-Col.) E. J. Selby, O.B.E., R.A.M.C., has been mentioned in dispatches in recognition of gallant and distinguished services in Italy.

Capt. S. Gopalakrishnan, Lieut. (Temp. Capt.) C. J. Pinto, Lieut. (Acting Capt.) C. S. Rao, and Subadar H. M. Yaqub, I.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Burma.

Capt. J. P. Irwin, R.A.M.C., has been mentioned in dispatches in recognition of gallant and distinguished services in the field.

The Efficiency Decoration of the Territorial Army has been conferred upon Col. R. I. Poston, Lieut.-Col. (Temp. Col.) J. P. J. Jenkins, Lieut.-Col. (Acting Col.) I. G. W. Hill, and Majors (Temp. Lieut.-Cols.) N. Capstaff, W. M. Evans, M.C., A. J. King, and H. S. Ward, O.B.E., R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed in Western Europe.—Lieut. David Michael de Reuda Winer, M.C., R.A.M.C.

Died.—War Subs. Capt. Ian William Barclay, R.A.M.C.

Died of wounds.—Capt. Philip Augustus Robinson, R.A.M.C.

Wounded.—War Subs. Capt. A. Anderson, T. G. Gray, D. R. Hughes, G. P. Mitchell, and H. B. S. Warren, R.A.M.C.

Wounded or injured.—Temp. Surg. Lieuts. R. C. Carr, J. P. W. Grant, B. H. Hand, and E. V. Mackay, R.N.V.R.

Missing, presumed killed.—Temp. Surg. Lieut. Horace Edward Dunning Gale, R.N.V.R.

Missing presumed lost from Japanese transport.—Capt. Matthew Joseph McNamara, A.A.M.C.

Reported missing, now prisoner of war.—Major T. R. B. Courtney, R.A.M.C.

Previously reported missing at Arnhem, now known to be a prisoner of war.—Capt. R. E. Bonham Carter, R.A.M.C.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there was a general increase in the notifications of infectious diseases. There were 925 more cases of measles than last week, 162 more of whooping-cough, 64 more of dysentery, and 63 more of acute pneumonia.

The rises in whooping-cough and acute pneumonia notifications were greatest in Lancashire, 88 and 35 respectively more than last week, and this county had the greatest fall—47 fewer cases—in scarlet fever. Notifications of diphtheria fell by 24 in Cheshire, and by 13 in Lancashire, but rose in Staffordshire by 12, and in Warwickshire by 14.

Measles is still rising in incidence in the north. Increases over last week's totals were as follows: Lancashire 450, Warwickshire 218, Staffordshire 92, Southampton 51; the only drop of any size was in Devonshire, where 73 fewer cases occurred. Lancashire had 36% of the measles notifications for the country. The 2,055 cases recorded made the largest weekly total in the country since the end of 1942, when 2,096 cases were notified, this number being only 14% of the total for the country.

The notifications of dysentery rose to 320. The principal centres of infection remain unchanged. The largest returns were London 64 (Wandsworth 29); Lancashire 57 (Prestwich M.B. 17, Prescott 15); Middlesex 27 (Sunbury-on-Thames U.D. 20); Glamorganshire 19 (Cardiff C.B. 17); Essex 17; Gloucestershire 14; Cheshire 12.

In *Scotland* notifications for acute primary pneumonia rose by 42, measles by 38, diphtheria by 29, and dysentery by 10. Glasgow had 11 more cases of dysentery than last week, and Aberdeen County 8.

In *Eire* the incidence of measles again fell, only 11 cases being reported. The incidence of diphtheria remained unchanged at the relatively high level of 123.

In *Northern Ireland* the most notable feature of the returns was the increase of 62 in the notifications of measles; 200 cases were reported in Belfast C.B. during the week.

Week Ending November 18

The returns of infectious diseases in *England and Wales* during the week included: scarlet fever 2,335, whooping-cough 1,410, diphtheria 619, measles 6,091, acute pneumonia 626, dysentery 320, typhoid 45, paratyphoid 18, typhoid

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 11.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

America for the Referee Board of the Council of Pharmacy and Chemistry of the American Medical Association. They found that large doses (0.75 to 1.5 g., or 12 to 20 gr., daily) occasionally produced hyperacidity and increased intestinal putrefaction. There were no such effects with small doses. It can, therefore, be safely used in ordinary amounts by patients with peptic ulcer. An antipyretic action is not described, but in large dose—e.g., 10 gr. (20 tablets)—it might well have one, judging by its composition.

Hepatic Cirrhosis

Q.—[Is there any treatment available along new lines for hepatic cirrhosis, such as are envisaged in your annotation of Sept. 9 (p. 346)? Dietary considerations in this case can, I believe, be solved in accordance with that annotation, but tell me which preparation "containing all the members of the vitamin B complex carefully balanced" is recommended? Is methionine available for clinical use?

A.—The analogy between cirrhosis of the liver in man and hepatic injury from dietary deficiencies in animals can be overstrained, and there is little evidence that cirrhosis in man is specifically improved by vitamins or food principles. The improvement is not greater than might be expected from good nutrition in any chronic disease. Yeast is probably the best-balanced source of the vitamin B complex, and it is possible to give as much as 3 oz. a day in the form of bakers' yeast, dried yeast, or food yeast. Unfortunately the total vitamin content is not very high. In any event no convincing results have been seen in a controlled therapeutic trial of yeast in hepatic cirrhosis (unpublished observations). More concentrated proprietary preparations of the B complex are available in the form of wheat germ, autolysed yeast, or extracts of rice polishings. Liver extract is also a very good source. Alternatively, the separate elements in the complex—aneurin, riboflavin, and nicotinic acid—may be given simultaneously in high dosage, but this means omitting elements of the B complex such as folic acid, and is likely to be extraordinarily costly. No report of any controlled trial of methionine in cirrhosis is available, but it is known that it has not had any noteworthy success in large-scale trials in infective hepatitis. A recent fine chemical manufacturer's catalogue quoted methionine at 7s. a gramme. The therapeutic dose is of the order of 5 g., or 35s. a day. There is reason to believe that stocks are not sufficient for clinical trial apart from officially sponsored research, nor are they likely to become available during the war in view of the high cost of production of methionine and the scant evidence of therapeutic effects in man.

Nephrotic Syndrome in Childhood

Q.—Has the work of Farr *et al.* in America on casein hydrolysate in the treatment of the nephrotic syndrome in children proved of any use in nephrotic crises, and if so, where could I get a suitable preparation?

A.—Farr believed that injections of casein hydrolysate were of special value in the treatment of infectious episodes in the nephrotic syndrome in childhood, but no confirmation of his work has been published. A theoretical disadvantage of protein hydrolysates in the treatment of hypoproteinaemia of renal origin is the fact that, if the material is given parenterally, large quantities of water and mineral salts are given at the same time. The final concentration of hydrolysate administered is usually 5% or less, so that 1,000 c.cm. of fluid must be given to inject 50 g. of protein. Amounts of this order would need to be given for many days, and in practice this difficulty seems greatly to have limited the application of parenteral treatment to children with oedema. Oral therapy is often difficult owing to loss of appetite or nausea. More hope is therefore being placed in the possibility of using purified serum albumin for injection in these cases, but this is still a project for the future. Several research groups are at present co-operating with British manufacturers on the preparation and use of protein hydrolysates, but the technique is still in the experimental stage, and there are apparently no preparations on the open market in this country.

Oxalated Blood for Cell Counts

Q.—Is the practice of sending blood (oxalated) by post for estimation of Hb, cell count, etc., likely to give true results? It is presumed that the sample reaches the laboratory within about 15 hours after withdrawal from a vein.

A.—While oxalated blood is adequate for rough haemoglobin estimations and red cell counts, an accurate complete blood count cannot be carried out by this method, and it should be discouraged.

B.M.R. Estimations and Thiouracil

Q.—Are B.M.R. estimations essential in treating a patient with thiouracil provided a watch is kept on the white cell count?

A.—No. B.M.R. estimations are certainly useful, but in experienced hands they are not necessary. The general condition of the patient, his nervous state and autonomic function, his pulse rate,

temperature chart, and skin temperature, are all important indications of progress. Probably the most important sign is his weight. It has been reported that the blood cholesterol (the absolute value of which is too variable to be useful) is valuable in a relative way, and that in any individual patient changes in blood cholesterol run parallel to changes in B.M.R. This statement has not been fully corroborated, but appears often to be true.

Treatment of Rodent Ulcer

Q.—What is the best line of treatment for a somewhat doubtful rodent ulcer, apart from excision?

A.—Provided that there are reasonable grounds for the diagnosis of rodent ulcer and that the situation is appropriate, intensive radiotherapy is called for, which can be carried out only by an expert. It is often desirable to remove a small portion for microscopical examination before the treatment is carried out.

Disturbed Sleep in a Child

Q.—Could you advise me on the treatment or causation of disturbed sleep in a boy of 3? After three to four hours' sleep the child begins rocking in the "knee-elbow" position, eventually waking up after the bedclothes have been thrown off. If laid on his side he quietsens for a quarter to half an hour, and then begins again. So far no treatment has been of any avail.

A.—Should there be any doubt of the child's intelligence not being normal, mental testing even at this age can be done by an educational psychologist at a child guidance clinic. In children of normal intellect in the first three years rhythmic movements in the state between sleep and wakefulness are common. The first essential is to reassure the parents that such movements, though annoying, are of no importance and will disappear. To hasten their departure and help to break the habit, a sedative for two or three weeks to provide deeper sleep is the only form of treatment necessary. For a child of 3 years luminal gr. 1/4, or, if well tolerated, even gr. 1/2, at bedtime is usually effective.

LETTERS, NOTES, ETC.

Mental Hospitals

Dr. OTHO FITZGERALD (Shenley Hospital, Herts) writes: It surprised me when reading the *Journal* of Oct. 28 to note the title or reference of "Asylum Doctors' Pay" applied to the letter which was signed "A.M.O." Apparently your attention has not been drawn to Section 20 of the 1930 Mental Treatment Act, which rules that the term "asylum" should be replaced by the term "mental hospital." I am sure you will admit the wisdom of that ruling, since institutions catering for the mentally disordered are no longer merely places of rest and detention but provide active and specific forms of treatment. "A.M.O." pleads that "niggardly remuneration is not likely to increase the repute of a branch of medicine which in the past has not enjoyed the prestige it deserves." It is surely very unkind of you, Sir, further to lash poor "A.M.O.'s" injured sense of prestige by insinuating that he is employed in institutions which are worthy only to be designated "asylums."

Flea Bites

Dr. THOMAS FENTON (Bushey, Herts) writes: I have read the note under the above heading (Oct. 14, p. 520). Unfortunately I am one of those who appear to attract fleas, and it may be of some comfort to others similarly attractive to think that may be one reason why others are immune. However, I found years ago that if I took a 5-grain tablet of sulphur, at first daily and then at longer intervals, the flea, though he might irritate by running about, would not bite. A few drops of chloroform, a sort of depth charge, in the neighbourhood of his walk but on the outside of the clothes, sufficed to put him out.

Arsenic in Malaria: Correction

Prof. D. B. BLACKLOCK writes: By an oversight on my part a phrase of some importance was omitted from the typescript of my letter published in your issue of Nov. 18. The fourth paragraph should read: "This evidence, so far as it goes, is against the probability of organic arsenic alone, in the form of neokharisivan and in the dosage suggested, proving curative. . . ." The phrase which was omitted is in italics.

Pure-tone Audiometer: Correction

Dr. MARY D. SHERIDAN writes: May I correct an inaccuracy in my article of Aug. 26, to which my attention has recently been drawn? The first pure-tone audiometer in this country was used by Dr. A. W. G. Ewing at Manchester University in 1927. Dr. Ewing's original paper on "High-frequency Deafness" was read before the Physical Society in London in 1930. His book *Aphasia in Children*, describing still earlier researches in this subject, was also published in 1930.

TREATMENT OF HYPERTHYROIDISM WITH THIOURACIL

BY

A. M. NUSSEY, M.D., M.R.C.P.

Physician to Selly Oak Hospital Birmingham

Until recently partial thyroidectomy was the treatment of choice for thyrotoxicosis. X rays and radium had their advocates, and some continued to pin their faith to iodine, either alone or in combination with various sedatives. It is true that in quite a number of mild cases of thyrotoxicosis the disease would abate spontaneously, but only too often, especially in severe instances the patient treated medically for too long would become a physical, sometimes a mental, wreck, or fall an easy prey to intercurrent infection. The advent of thiourea, and especially of thiouracil, bids fair to alter the position radically. These preparations may represent only a milestone in the approach to a problem the real key to which may be a substance acting through the pituitary, but at present, to say the least, they offer a serious challenge to the hitherto undisputed sway of surgery in the treatment of hyperthyroidism. The use of thiourea and thiouracil in thyrotoxicosis is an example of how seemingly unrelated research may sometimes, almost by accident be turned to advantage in treatment of disease. This research began when the Mackenzies and McCollum (1941), working on the effects of sulphaguanidine in rats, discovered that it had the property of inducing a hypothyroid state and enlargement of the thyroid gland in the experimental animals. At about the same time similar results were obtained by Richter and Chisby (1941, 1942), who used phenyl thiourea, and by Kennedy (1942) who used allyl thiourea which he isolated from rape seed. Later the Mackenzies (1943), and Astwood and his colleagues (1943), proved that, besides sulphaguanidine, other sulphonamide derivatives, and to a lesser degree sulphanilamide itself, also had the power to depress metabolism and cause hypertrophy of the thyroid gland in rats. In an endeavour to find a metabolic depressant suitable for clinical use these workers then tested a large number of compounds, and found that thiourea and thiouracil were the most effective and least toxic. These observations led to the first clinical trial by Astwood (1943).

The original workers and those who followed are all agreed that thiourea and thiouracil probably act by preventing the union of tyrosine and iodine into diiodotyrosine, which is a precursor of thyroxine. Once thyroxine is present in the body thiourea and its derivatives cannot stop its action. This explains the lag observed in clinical response of thyrotoxicosis to thiourea and thiouracil and is in keeping with the observation that desiccated thyroid gland is capable of counteracting the effects of these substances in experimental animals. Further light on the mode of action of thiourea is thrown by the paper of Campbell Landerebe, and Morgan (1944), who pointed out the great affinity of thiourea for iodine and have shown that thiourea given by mouth is quickly absorbed from the intestine, widely diffused through the tissue fluids, and very rapidly excreted unchanged in the urine. Williams and Bissell (1943), who successfully treated 9 cases of thyrotoxicosis with thiouracil, noted equally rapid absorption and excretion of this substance. They stated that blood analyses of 4 of their cases showed in each a fall of the protein bound iodine to a normal or subnormal level. More recently Williams and his

associates (1944a, 1944b) devised a method for the estimation of thiouracil in the blood, tissues, and urine, but whether such biochemical tests will prove a help in regulating the dose of the drug remains to be seen.

At present it is possible when treating patients, inadvertently to exceed the optimum dose and to cause an increase in the size of the thyroid gland and a condition resembling myxoedema. The reason for these complications is presumably the same as that put forward by the experimental workers—namely that when the supply of thyroxine falls below the needs of the body the pituitary gland is stimulated to excessive secretion of the thyrotrophic hormone, which in turn causes hyperplasia of the thyroid gland. This must have happened to the first patient described by Astwood (1943), to another given in detail by Himsworth (1943) in his first series of 6 cases treated with thiourea and to several patients in the present series. Other complications known at present are granulopenia, thrombocytopenia, enlargement of lymph glands and spleen, fever and skin eruptions, but these have been more frequently noted when thiourea was used (Newcomb and Deane, 1944; St Johnston 1944; and Astwood's first case 1943). Now that the more palatable and less toxic thiouracil is freely available there is no reason why thiourea should be employed any longer. It is true that using thiouracil, Gabrilove and Kert (1943) found that out of 9 cases they treated for thyrotoxicosis one developed fever, generalized enlargement of the lymph glands and dermatitis, another fever and dermatitis and a third moderate leucopenia, but their patients were all given rather heavy doses of the drug in addition to an unspecified quantity of barbiturates.

In a discussion on thiouracil at the Royal Society of Medicine, Himsworth (Himsworth *et al.* 1944) drew a distinction between idiosyncrasy to the drug, which is liable to occur early, and toxic effects which follow prolonged overdosage. Under manifestations of idiosyncrasy he listed the complications mentioned above, and the toxic effects of overdosage he described as superficially resembling myxoedema. Of those taking part in the discussion Drs H. P. Himsworth, E. P. Sharpey-Schafer, and H. Evans were favourably impressed with thiouracil. One of Himsworth's patients, who had rather large doses died of agranulocytosis, and two of his other patients, whose goitres increased unduly as a result of the treatment, had to be operated on. Mr C. Joll (Himsworth *et al.* 1944) who used thiourea and thiouracil in 20 to 30 cases, presented results in 9, in which, in his opinion the length of treatment justified making deductions. His failure to achieve success in 3 out of the 9 subjects was criticized at the discussion by Himsworth on the ground that in these iodine was used before thiouracil and that the latter was not given a sufficiently long trial. Himsworth stated that he found no difference in response to thiouracil in either primary or secondary thyrotoxicosis. The cases mentioned in the discussion at the R.S.M. bring up the number of those fully reported to over 100.

It is obvious that further and more prolonged observations will be required before the treatment of thyrotoxicosis with

thiouracil can be placed on a more satisfactory basis. As a contribution to the problem a presentation is made of the data obtained from personal observations on 27 patients treated at Selly Oak Hospital for periods varying from a year down to 3 weeks. The results are summarized briefly in the accompanying table

Discussion

The cases are classified into very severe, severe, moderate, and mild, partly on clinical grounds and partly on the basis of a routine preliminary B.M.R. estimation. The majority of

patients had general enlargement of the thyroid gland, others had a nodular goitre, and both types responded to thiouracil equally well—a point already noted by Himsworth. In every instance except in Nos. 8 and 12 the initial treatment was administered while in hospital, thus making possible day-to-day observation of progress. Periods varying from 2 to 11 weeks passed before satisfactory clinical response was noted. The average stay in hospital was about 3 weeks. During that time no other drug, not even a simple sedative, was allowed. Where iodine was found to have been given, it was discontinued

TABLE OF RESULTS

A	B	C	D	E	F	G	H	I	J	K
1	35 F	18 mths.	Moderate	+29%	23/10/43	23/11/43: +15 11/5/44: +2 25/8/44: +11	—	23/11/43: 6,200, 71% 11/12/43: 7,600, 61% 8/1/44: 5,800, 69% 26/2/44: 5,200, 66% 1/11/44: 5,800, 71%	23 lb.	Initial treatment with thiourea tolerated badly. Transient rash when changed to thiouracil. At one time considerable swelling of neck, which disappeared on reducing the dose. Possible to omit treatment for 4 mths., but it had to be resumed a month ago.
2	54 F	6 "	"	+27%	23/10/43	4/11/43: +19 17/11/43: +5 3/2/44: +21 9/8/44: +10	—	26/11/43: 6,055, 55% 19/1/44: 7,200, 41% 1/2/44: 7,800, 51% 2/5/44: 6,200, 58% 1/11/44: 5,600, 74% 19/11/43: 9,600, 71% 4/10/44: 9,200, 70%	10 lb.	Given 53 g of thiourea before change to thiouracil on 11/11/43. Tolerated both well. Now on 0.05 g. of thiouracil daily
3	40 F	12 "	"	+31%	25/10/43	8/11/43: +16 20/11/43: +12 3/5/44: +10	—	19/11/43: 9,600, 71% 4/10/44: 9,200, 70%	Nil	Had 25 g. of thiourea. Changed to thiouracil on 11/11/43. After end of Jan did not attend till May, 1944, when there was no evidence of relapse. Now recurrence of mild features of thyrotoxicosis and 0.2 g. thiouracil resumed on 4/10/44
4	28 F	15 "	Severe	+45%	22/11/43	7/12/43: +26 12/1/44: +8 19/6/44: +29	—	30/11/43: 5,000, 45% 10/1/44: 4,400, 62% 3/5/44: 4,200, 47% 8/7/44: 4,200, 47% 2/8/44: 3,600, 55%	6 lb.	Some days before treatment with thiouracil admitted with influenzal bronchopneumonia and given sulphathiazole. Has rheumatic mitral disease; her auricular fibrillation reverted to normal during treatment. At one time excessive increase in weight and enlargement of neck noted. This subsided when dose of thiouracil was reduced. Now on 0.05 g daily
5	53 M	12 "	Very severe	+67%	23/11/43	6/12/43: +41 20/12/43: +18 17/1/44: +20	—	25/11/43: 5,600, 62% 7/12/43: 8,600, 75% 3/2/44: 4,600, 66% 17/3/44: 4,000, 58% 14/6/44: 5,200, 36% 6/9/44: 10,600, 59% 4/10/44: 5,600, 64% 1/11/44: 6,800, 57% 4/12/43: 6,200, 48%	15 lb.	Temporary increase in size of goitre reversed by reduction in dose. Treatment omitted for 2 months, after drug given for 5 months, but had to be resumed; now on 0.1 g. daily. Able to do heavy work
6	65 F	18 yrs	Severe	+45%	25/11/43	13/12/43: +42	—		1 lb.	Partial thyroidectomy 18 years before. In-patient for 1 month. Died early in Jan. 1944, 3 weeks after leaving hospital
7	29 F	1 yr	Mild	+19%	11/12/43	22/12/43: +9 29/4/44: +25 7/7/44: +11	5,600; 79%	14/12/43: 6,300 13/1/44: 8,700, 75% 2/5/44: 7,600, 74% 19/6/44: 5,000, 53% 4/8/44: 7,000, 34% 10/1/44: 7,000, 84% 19/2/44: 10,000, 49% 17/4/44: 10,400, 59%	Nil	Tachycardia was an outstanding feature, pulse of 100-120 per min down to 90 after 8 months of treatment. Now on 0.05 g. thiouracil daily
8	40 F	18 mths	Moderate	+30%	20/12/43	13/1/44: +28 7/2/44: +2 21/6/44: Normal	7,600, 60%		14 lb.	Partial thyroidectomy on 2/2/43, followed by treatment on face, omitting treatment 24/5/44
9	40 F	1 yr	Severe	+52%	6/1/44	25/1/44: +17 21/6/44: +5	4,400; 45%	21/1/44: 6,200, 55% 1/2/44: 3,600, 48% 5/2/44: 4,800, 44% 14/6/44: 6,000, 52% 4/10/44: 4,700, 61% 2/2/44: 3,300, 43% 23/2/44: 4,200, 52% 2/3/44: 5,600, 51% 11/3/44: 14,200, 51%	22 lb.	Goitre increased for a time; went back to previous size on reducing the dose of thiouracil. No treatment since 4/10/44
10	32 F	4 mths.	"	+67%	14/2/44	8/2/44: +63 2/3/44: +10 5/7/44: +12 13/4/44: +7 28/3/44: +22 13/4/44: -7 25/7/44: +17	6,200; 32%		14 lb.	No treatment required since 5/7/44
11	21 F	3 "	"	+75%	1/3/44	16/3/44: +33 28/3/44: +22 13/4/44: -7 25/7/44: +17	11,100		6 lb.	At one time weight up by 23 lb; neck much increased in size, and mild myxoedema. Relieved by adjusting dose of thiouracil. No treatment since 1/9/44

for at least a month before thiouracil was administered. With the exception of Nos 3, 6, and 18, who were seriously ill at the beginning of their treatment, strict confinement to bed was not practised.

During the initial in-patient phase the dose of thiouracil was generally 0.2 g t.d.s. Three early cases also had thiouracil in doses of 1 g t.d.s. before thiouracil became available. Thus No 2 received 32 g of the substance and No 3 had 35 g No 1, after only 7 g of thiouracil, developed toxic symptoms resembling those described by St Johnston (1944), including extensive skin eruption, vomiting, headache and fever. She was subsequently given thiouracil, when a much milder maculopapular rash appeared on the parts of the skin exposed to light. The rash disappeared after the dose was reduced, and eventually she did exceptionally well. Skin rashes were caused by thiouracil in a few other instances. No 8 had a papular eruption on the face, lasting one week which cleared up of its own accord without having to modify the treatment. No 20 had a transient papular rash which disappeared after the dose of thiouracil was reduced. No 22 complained of occasional itching of the limbs at first without any actual skin changes. Later the parts exposed to light showed a scaly erythematous eruption, and it was interesting to note that as soon as she began to wear stockings the skin of the legs cleared rapidly, while the lesions of the hands and wrists disappeared much more slowly with a reduction in the dose of thiouracil. Only in No 22 was there a moderate degree of leucopenia while the rash was present.

Signs of improvement were usually apparent 10 to 14 days after starting treatment. Severe thyrotoxicosis frequently responded to thiouracil as quickly as the moderate type but in some of the former—e.g. Nos 5, 17 and 18—one sometimes had to persevere for several weeks before the patients began to show a change for the better. Restlessness was usually the first to go, and then the flushed and moist skin would become paler and drier. The staring expression and the shiny appearance of the eyes, which are such striking features of thyrotoxicosis, would fade. The weight would begin to go up and the tremor of the fingers would become less. Then the vascularity of the thyroid would diminish as shown by lessening or disappearance of the bruit over the gland and finally the tachycardia would subside. Oddly enough it was in the milder cases—e.g. Nos 7 and 14—that tachycardia tended to persist longest. In every instance, with the exception of No 6, the patient would admit to feeling better after a few weeks' treatment and all those gainfully employed previous to their illness were back at work long before it would have been possible had they had a partial thyroidectomy. Reduction of the B.M.R. was roughly parallel in each case with signs of clinical improvement. In nearly all patients the B.M.R. came down to within normal limits. Only in Nos 6 and 19 has this not been achieved. In No 6 the period available for treatment was probably too short while in No 19 it is almost certainly a matter of time before a normal basal metabolic rate is reached. Exophthalmos which was present in only a few of the patients was not appreciably influenced by treatment; neither did enlargement of the thyroid diminish to any extent. Four

instances of auricular fibrillation were noted, two of which—Nos 4 and 21—reverted to normal rhythm spontaneously in the course of the treatment and another—No 18—in whom this was achieved by means of quinidine. In the fourth—No 12—auricular fibrillation persists, and owing to the fact that it is probably of at least 5 years' standing no attempt at conversion to normal rhythm with quinidine was made. The gain in weight was negligible in a few, appreciable in the majority and in two it amounted to almost 2 st since starting treatment. Only No 3 lost weight. Excessive gain was sometimes accompanied by a bloated appearance, listlessness, and an increase in size of the thyroid gland. In contrast to the view held by Himsforth, I could see no difference at all between these manifestations and mild myxoedema. By a suitable reduction of the dose of the drug it was possible rapidly to reverse the pathological depression of metabolism, the excessive increase in weight and the enlargement of the neck. The size of the neck was recorded in each case and checked at regular intervals, this proving an additional guide to the dose of thiouracil required. In fact experience showed that the maintenance dose on which the pulse rate and general condition remained satisfactory varied from individual to individual, thus proving the value of periodic inspection. All patients were seen regularly after discharge—first at 2, then at 3 and finally at 4 weeks intervals. There was only one patient—No 3—who did not co-operate satisfactorily. She turned up only twice after discharge from hospital and ceased taking thiouracil of her own accord after 3 months. She was seen again in May 1944 when her condition was found to have remained satisfactory and the B.M.R. was +10. More recently this patient came up again with symptoms of a slight recurrence of thyrotoxicosis and her treatment was resumed.

As for the maintenance dose the patients were usually given 0.2 g of thiouracil b.d. for 2 to 4 weeks after leaving hospital. Later most of them were maintained on 0.2 g and some on 0.1 or 0.05 g daily. In a few instances it was found possible to omit treatment altogether—e.g. in No 8 since May 24 1944, No 10 since July 5, 1944, No 12 since Aug 2 1944, No 13 since Sept 5 1944, No 15 since Sept 9 1944 and No 16 since Oct 24 1944. In No 5 treatment had to be resumed because the man began to lose weight once more and the same had to be done in No 1 after omitting treatment for 3 months. Astwood (1943) mentions a patient in whom after a relatively short period of treatment he omitted thiouracil for a few weeks and had to resume it because of a recurrence of symptoms. Himsforth (1944) reported that in 3 mild cases he was able to leave off thiouracil for periods of from 7 weeks to 7 months.

Observations on the white cell count proved interesting. With the exception of Nos 1-6 and 12 a preliminary count was always made before treatment was started and low initial readings were not at all infrequent. These although sometimes borderline on frank leucopenia were not taken to be a bar to giving thiouracil and surprisingly in those the white cell count usually showed a rise as the treatment proceeded. In no case was there an alarming fall of the white cell or polymorph count. Consistently low figures were seen only in Nos 4 and 16. In this connexion it is worth noting the findings of

Goldsmith and associates (1944), that when liver extract is given to rats simultaneously with thiourea it protected them from neutropenia.

Three patients had operations of partial thyroidectomy before they came under the present review. No. 6, operated on 18 years before, had a nodular goitre, and a recurrence of symptoms 9 years after operation. About 12 months before coming to hospital she became short of breath, experienced nausea and vomiting, and when admitted her heart showed marked enlargement to the left and a systolic murmur at the apex. She showed no appreciable response after 4 weeks' treatment, and, unfortunately, although she was urged to stay, insisted on going home. It was reported later that she had died suddenly 3 weeks after leaving hospital. In No. 8, in which partial thyroidectomy failed to cure the condition, 5 months' treatment with thiouracil appeared to complete what surgery had left undone. Another milder recurrence, 8 years after partial thyroidectomy—No. 15—did equally well. No. 17, radium treatment of which 10 years before had been a complete failure, responded satisfactorily to thiouracil.

Conclusion

We have now in thiouracil a potent weapon for overcoming thyrotoxicosis. The drug, although not entirely devoid of risks, is much safer than operation. All patients suffering from thyrotoxicosis should therefore be given thiouracil. At some future date it may be possible to assess the initial and maintenance dosages on a more scientific basis, but at present, in the light of experience, a satisfactory working rule is to give 0.2 g. of thiouracil thrice daily for the first 3 to 5 weeks, after which the dose should be gradually reduced, and kept at the lowest possible level compatible with the patient's well-being. Slow response to treatment calls for patience, and not for increasing the dose beyond a safe limit. Leucopenia before the treatment should not be taken as a contraindication to the use of thiouracil. All patients treated with thiouracil should be kept under adequate supervision. Only more prolonged observations will tell whether thiouracil is capable of effecting a permanent cure within a measurable period.

Summary

A series of 27 unselected cases of thyrotoxicosis treated with thiouracil for periods varying from 3 weeks to 12 months are described.

Good response, with the exception of one long-standing instance, was noted in all.

The importance of continued supervision of the treatment is stressed.

It is submitted that the hitherto almost unrivalled surgical treatment of thyrotoxicosis may, in the light of further experience, have to give way to medical treatment.

Grateful thanks are due to both my medical and my surgical colleagues, who kindly passed on to me their patients with thyrotoxicosis, and thus made this series much larger than it would otherwise have been. Our biochemist, F. Morton, M.Sc., F.R.I.C., carried out the B.M.R. estimations, and Messrs. British Drug Houses generously supplied, free of charge, most of the thiouracil used in this investigation.

THE HAEMOGLOBIN LEVEL IN MUNICIPAL SCHOOL CHILDREN

EFFECT OF IRON THERAPY, SCHOOL DINNERS,

AND SEASON

BY

R. H. DOBBS, M.D., M.R.C.P.

Major, R.A.M.C.

AND

K. BINGHAM

Assistant, Pathological Department, Royal Free Hospital

The lack of knowledge of normal haemoglobin levels in school children, of the physiological rise with age, and of the effect of iron therapy, diet, and economic circumstances has recently aroused attention in this country. The present paper represents an effort, only partially successful, to increase our knowledge of this subject.

Clinical Material

Children at two municipal schools were examined. One—school B—was in a London suburb, where 127 children, aged 7 to 12 years, were examined in Oct., 1942. Many of the pupils' fathers were black-coated workers in moderately comfortable circumstances. The other—school A—was in a small town near London where the children had repeated haemoglobin examinations during a period of over a year, beginning early in 1942. The number of children examined at this school was 325. Here economic standards were more varied, but very few families were below the poverty line, as shown by the supply of free milk or free dinners. About half the fathers were industrial or transport workers (mechanics, skilled craftsmen, unspecified munition workers, railway workers, etc.); about 23% were in the armed Forces, and another 13% were clerical workers or shop-assistants. About 43% of the mothers did paid work, part- or full-time, outside their own homes.

Technique, and Some Sources of Error

Estimations were made with a Haldane standard by the three of us, and figures are given with the National Physical Laboratory B.S.I. corrections applied for colour tube and pipettes. Apart from the percentage correction for the dilution tubes (a correction required because the distance between the 20 and 140 marks, and hence the diameter, differed from the B.S.I. standard), the mean N.P.L. correction for the tubes was -0.3 at 80%. This correction was obviously negligible, and was omitted. The maximum correction thus omitted on any one dilution tube was -0.9 at 80%. The blood was taken from a prick in the thumb after soaking the hand in hot water. The earliest estimations were made during a period of extremely cold weather in January and early February of 1942. The children at the time nearly all had chilled extremities, and, in spite of soaking the hand in hot water, there were wide discrepancies in the results, presumably because of capillary changes and stasis. All readings taken during this period have been discarded as doubtful. It is probable that cold limbs, in spite of precautions to get a warm hand and a free flow of blood, produced inaccurate estimations at other periods, but it is difficult to see how this can be prevented under the conditions of field work. Another source of misleading results is, we believe, anxiety or apprehension on the part of the child: it was noticed that children showing anxiety often registered wide fluctuations in haemoglobin level.

Haemoglobin Level in Relation to Age and Sex

Table I shows that there was a fairly steady rise in haemoglobin level with age, though the numbers in the different subdivisions were not sufficient to even out chance fluctuations. Taking the mean haemoglobin level for the combined results at school A in Feb., 1942, and again in Feb. or March, 1943, together with school B in Oct., 1942, there was a rise from 87.8% at 7 years to 92.1% at 10 years—that is, a rise of 4.3 in three years, or an average rise of 1.4 per year of age; and each subdivision in Table I shows a rise with age of a similar order. The haemoglobin levels at school B were slightly

TABLE I.—Changes in Haemoglobin Level with Age

Average of means														

higher than at school A, which may be a reflection of a slightly higher economic status.

The average of the mean Hb levels of boys and girls aged over 7 and under 11 (all figures in Table I combined) was 89.3 and 89.7% respectively—that is, the means for the sexes were all but the same. In the small group of 26 boys aged 11 the haemoglobin level (89.5%, S.D. 6.24) was lower than in girls of the same age (94.1%, S.D. 4.7) and also slightly lower than in girls or boys aged 10. However, the difference between the sexes at 11 years of age is not statistically significant, and the lower mean level of the boys' haemoglobin is probably quite fortuitous and due to inadequate numbers. So that, like other investigators (Osgood and Baker, 1935; Murgage and Andresen, 1936), we have found no evidence of a difference in haemoglobin between the sexes at these ages.

Haemoglobin Level in Relation to Year and to Season

Children living in or near London and of similar economic class to those attending school A were examined by us in the second half of 1941 (Wills *et al.*, 1942). The average of the mean haemoglobin values for children aged 7, 8, 9, and 10 years respectively was in 1941 distinctly lower than that of the children of the same age examined in 1942 and 1943: the values were 83.4% in 1941, 88.9% in Feb., 1942, and 89.6% in Feb. and March, 1943. (The value for 1941 has

TABLE II.—Changes in Mean Haemoglobin Level during Year 1942-3 in a Group of Children at School A given No Iron

Date of Examination	No. of Children	Mean Hb	Change in Hb since Previous Examination	Change in Hb since Feb., 1942
1942: Feb.	50	89.8 ± 0.68	—	—
March	80	87.5 ± 0.40	-2.3 ± 0.84*	-2.3
April-May	76	89.1 ± 0.56	+1.6 ± 0.75*	-0.7
July	79	91.7 ± 0.47	+2.6 ± 0.73*	-1.9
Nov.	67	91.4 ± 0.55	-0.3 ± 0.72	-1.6
1943: Feb.-March	53	91.1 ± 0.62	-0.3 ± 0.83	-1.3

* The change in haemoglobin level is more than twice the standard error of the difference; in July it is more than 3½ times the standard error of the difference.

been corrected so as to conform to the same standard as these later estimations.) Thus at school A in Feb., 1942, and a year later in Feb., 1943, the mean haemoglobin level of children of corresponding age differed little (Table I). There was, however, a rise of haemoglobin level with age during this period of 1942-3. The mean haemoglobin level of our control group, who received no medicinal iron, was 89.8% in Feb., 1942, and 91.1% in Feb. and March, 1943, when the average age had increased by a year (see Table II). This is a rise of 1.3, which is just about equivalent to the mean increase in

haemoglobin level with each year of age shown in Table I. The year's increase in haemoglobin was not evenly spread over the year, but occurred between March and July. There was actually a fall in haemoglobin level between Feb. and March, 1942, a rise between March and July, 1942 (these changes being statistically significant), and thereafter no significant change up to the following Feb. and March, 1943.

Effect of Iron Therapy on Haemoglobin Level

Iron medication was given to about half the available children at school A from Feb. to July, 1942. The iron preparation used was fersolate (Glaxo), and each child in the iron group was ordered one pill daily, increasing in seven days to 4 pills daily for 5 days in the week, to be taken in the classroom with the school milk. Four pills provided 4 gr., or 260 mg. of iron (ferrous), 0.04 gr. of copper and 0.04 gr. of manganese. Most children took their dose regularly. In a few cases it probably gave rise to some abdominal discomfort or looseness of stools and was consequently stopped, or sometimes it was stopped for quite irrelevant reasons.

The head master's allocation of children to classes in this school was determined by age and the age groups were then subdivided according to ability. Thus nearly all the 11-year-olds would be in class 1A, 1B, or 1C—the brightest in class 1A and the least advanced in class 1C, and similarly for each age group.

The children were given iron medication by classes. For example, all children whose haemoglobin had been estimated in class 2A acted as controls; those in 2B and 2C received iron pills. In the next age group the allocation was reversed, and 3A children (the brightest of this age group) received the pills, and 3B and 3C acted as controls. It so happened that the children examined in the A divisions were often about equivalent in numbers to those in divisions B and C of the same age group. By this means it was hoped to prevent any possible confusion in iron administration and to keep the groups evenly balanced. Children on the iron list have been included in the tables as having iron irrespective of their absences from school (during which time iron medication ceased), as otherwise selection of both controls and iron cases would have been necessary. The effect of iron medication is shown in Table III. The children given fersolate showed an immediate rise in haemoglobin, which continued until July, when treatment was stopped, the mean total rise being 7.0%. The children not given iron showed a fall in haemoglobin till March, and then a rise; but measured from February the total rise of the control group was only 1.9% (Table II). However, as the initial haemoglobin level of the children given

TABLE III.—Effect of Iron Medication on Mean Haemoglobin Level of Children at School A

Date of Examination	Iron Group					Control Group

* The difference in haemoglobin level in these groups is about 2½ to 3½ times the standard error of the difference.

TABLE IV.—*Effect of Iron Medication on Mean Haemoglobin Level of Children at School A Examined in Feb. and also in March, 1942*

Date of Examination	Iron Group		Control Group	
	No. of Children	Mean Hb	No. of Children	Mean Hb
1942: Feb. ..	41	87.0	48	89.9
March ..		89.9		87.6

ferrisolate, was lower than that of their controls, the difference in haemoglobin level between the controls and iron-treated cases in July was only 2.1%. Even so, the iron group had significantly higher haemoglobin values than the controls from March till July. In July iron medication was stopped, and by November the haemoglobin level of the iron cases had dropped and was within 1% of the mean for the controls but 3.8% above their own mean before iron medication was begun 9 months previously. The difference in the trend of haemoglobin values between iron cases and controls over this period is confirmed by examining subdivisions of the main groups, for in each age group in the iron series the mean haemoglobin value showed a rise between Feb. and March, 1942, whereas in each age group in the controls the mean haemoglobin fell over the same period; moreover, if the comparison is limited to children who supplied observations in both February and March (see Table IV) the result is practically the same as for the whole group shown in Table III. Hence we can safely assume that iron medication prevented a fall in haemoglobin and produced instead a fairly steady rise, continuing till medication was stopped in July, but that once medication was stopped there was a fall in haemoglobin to about the level of the controls.

Iron medication over this period of five months did not reduce the absentee rate. Between February and July (i.e., during two terms) the mean attendances of control cases and iron cases were almost identical; each child in the iron group averaged 237.9 attendances, while each child in the iron group averaged 237.3.

Effect of School Dinners on Haemoglobin Level

The effect of school dinners on haemoglobin level was investigated (see Table V). At school A the midday meal

TABLE V.—*Effect of School Dinners on Mean Haemoglobin Level of Children who had had School Dinners for Over 3 Months*

Age in Years	School A, Feb. or March, 1943				School B, October, 1942				Schools A and B Combined			
	Dinner Children		Controls		Dinner Children		Controls		Dinner Children		Controls	
	No.	Hb	No.	Hb	No.	Hb	No.	Hb	No.	Hb	No.	Hb

11	13	94.0	21	90.9	2	94.3	3	84.5	20	94.0	24	90.1
7-12	112	90.5	100	90.9	36	91.5	80	90.4	148	90.7	180	90.2

when first instituted was the so-called Oslo, or modified Oslo, meal, which proved unpopular. From June, 1942, an ordinary hot dinner was provided, usually consisting of meat and two vegetables and a sweet course. This at first was not quite adequate in quantity for the older children, but by the end of 1942 the calorie value seemed ample. A similar meal was provided at school B. Table V shows the mean haemoglobin level of children who had had school dinners of this type for not less than three calendar months, many for much longer periods. At school B, in 1942, the children having school dinners had a mean haemoglobin level approximately 1% higher than the controls; but this slight superiority was not constant in the subdivisions, and was presumably the result of chance. At school A the difference between the haemoglobin of "dinner children" and controls was less than 0.5%, the controls being slightly higher this time. Thus these figures provide no evidence that school dinners had any influence on haemoglobin level. The suggestion we previously made that school dinners caused a slight but significant rise in haemoglobin level in school A in the summer of 1942 (Mackay *et al.*, 1942) is not supported by the present findings.

Effect of Home Circumstances on Haemoglobin Level

It has already been stated that many of the children's mothers did paid work outside their homes. Of 235 mothers of children examined in Feb. or March, 1943, 57% were housewives working only in their own homes; about 28% did part-time and 15% did full-time work outside their own homes. Over a half of those earning wages were engaged in some form of paid domestic work. As one might expect, mothers were more likely to go out to work when their children were older; thus 10% of mothers of 7- and 8-year-old children, and 18% of mothers of 9- to 12-year-old children, did full-time paid work. In Table VI the mean haemoglobin levels of children

TABLE VI.—*Effect of Home Circumstances on Haemoglobin Level of Children examined at School A in Feb. or March, 1943*

	Mother's Occupation			Three or More Earners	No. of Non-earning Children in Household			
	Housewife Only	Part-time Earner	Full-time Earner		1-2 Children not Earning	1	2	3 or More
No. of children ..	134	65	36	18	73	87	47	19
Actual mean Hb. .	89.5	90.8	90.9	92.0	90.4	90.1	89.7	88.5
Expected Hb for age ..	89.8	90.4	90.4	90.3	90.0	89.8	90.4	90.2
Actual less expected Hb	-0.3	+0.4	+0.5	+1.7	+0.4	+0.3	-0.7	-1.7

are shown according to whether or not the mother went out to work. In each of the three subdivisions the mean haemoglobin level is within 0.5% of the expected figure according to age. Hence haemoglobin levels in this series of children were not affected by the mother working outside her home. We have no information as to the relative financial status of these three groups, but there is little doubt that economic causes play a large part in determining whether a mother shall go out to work and that paid work considerably enhances her means.

The next five groups shown in Table VI suggest that economic factors were influencing haemoglobin level, though, unfortunately, numbers are too small to provide proof. In these five groups the highest mean haemoglobin level was in households with three or more wage-earners and not more than two non-earning children, and the mean haemoglobin level of these children—namely, 92.0%—was 1.7% above the expected level for age. The lowest mean was in households with four or more non-earning children, and their mean haemoglobin level was 1.7% below the expected figure. The mean haemoglobin level of children in households with one, two, or three children was intermediate, and showed a progressive fall, the figures being 90.4, 90.1, 89.7, and 88.5%. It was thought that children of men in the Forces might, for economic reasons, have a lower haemoglobin level than the children of civilians, but the difference was negligible—only 0.4%: children of men in the Forces, 89.7%; children of civilians, 90.1%. Further investigations on the effect of home circumstances on the haemoglobin level were planned, but have fallen through for the time being owing to the evacuation of school-children.

Discussion

The children examined at school A in the present investigation were of similar economic status to the small group of school-children included in our 1941-2 investigation. We found a rise in mean haemoglobin level between the second half of 1941 and early in 1942, but little change between early 1942 and early 1943. On the other hand, our 1941 values are similar to Davidson's values for municipal-school children in Edinburgh in the next year—i.e., 1942—and he observed a rise between 1942 and 1943 (Davidson *et al.*, 1943). Our 1942 values for municipal-school children are nearly as high as Davidson's 1942 values for private-school children (Davidson *et al.*, 1943). The causes for the changes in haemoglobin level are probably to be found in the food available to the children. It seems probable that the haemoglobin levels of school-children were lowered by food shortages accentuated by uneven distribution in 1940-1. Possibly food supplies improved more quickly for the children examined by us, or perhaps, as they lived

in a small town with many gardens, there was more opportunity for augmenting their diet from home-grown produce than existed for the Edinburgh children, and this may have accounted for the higher levels in our group in 1942. The following official account of food available in the United Kingdom before our 1941 investigation is taken from *Food Consumption Levels in the United States, Canada and the United Kingdom* (Combined Food Board Committee, 1944): "In the United Kingdom there was a sharp fall in food supplies in 1940 and 1941, particularly of meat, visible fats, sugar, and fruit, which greatly reduced the palatability as well as the nutritional value of the diet. At the period of greatest shortage in the first half of 1941 calorie supplies fell to 2,680, animal protein to 33 g., and fat to 105 g. per head per day, and there were indications that the diet was inadequate." It is a curious fact that the haemoglobin of children showed little increment between the ages of 5 and 11 years in our earlier series (last six months of 1941) or in Davidson's 1942 series, yet in Feb., 1942, in Oct. 1942, and in Feb. and March, 1943, in our present investigation, there is a steady increase in haemoglobin with age. A possible explanation is that our earlier investigation included small batches of children in a number of different schools and immunization clinics in different seasons, and that the rise with age was masked in this more heterogeneous group. Whether the same holds for the Edinburgh children we do not know.

It is well known that school-children's rate of growth in height and weight is not even throughout the year. Widdowson and McCance (1944) for example, have recently demonstrated that boys at two public schools grew much more rapidly in height and weight in holidays than in term-time. Our figures suggest that the rise in haemoglobin level with age also shows fluctuations during the course of the year. The main increment in haemoglobin level in our series occurred between March and July. We have no evidence as to whether variations in the physiological rise in haemoglobin level were directly due to seasonal differences in the incidence of droplet or other infections, or were associated with changes in the diet or were dependent on a variety of factors. Vitamin C has been thought to influence the absorption or utilization of iron, and a sharp summer rise in the level of blood ascorbic acid has been demonstrated in this country during the war years, the rise occurring as a result of the consumption of new potatoes. This change in ascorbic acid intake, however, could not account for the rise in haemoglobin level as the increase in haemoglobin occurred too early in the year.

Though the group of children given iron at school A had haemoglobin levels only 2.8% lower than Davidson's private-school children, iron medication produced a mean rise of 7% in 1942. Iron produced a rise within a month and at a time when the haemoglobin level of controls was falling, but in the spring and summer the haemoglobin level of controls also rose, and the difference in level between treated cases and controls in July, 1942, before medication was stopped, was only 2.1. Though this small difference in level was statistically significant, the absentee rate of controls and treated cases did not differ. With so small a difference in haemoglobin level perhaps an increased resistance to infection in the treated group could scarcely be expected in this period. The superiority of the treated cases in haemoglobin level was not maintained after treatment was stopped. A similar rise in the haemoglobin level of Edinburgh municipal-school children given iron therapy was shown by Davidson and Donaldson in 1944.

There is at present little or no evidence to show whether or not children having dinners in school commonly get in addition a large share in their own rations at home. If they do, their diet should, of course, be better than that of children who have only their home rations and no school dinners. Our investigation shows no improvement in haemoglobin level as a result of school dinners, though children in better economic circumstances may have somewhat higher haemoglobin levels even under our system of rationing (Wills and Bingham, not yet published).

The fact that a mean rise of 7% was produced in the group receiving iron medication and that the haemoglobin level in our municipal-school children was lower than that of children of higher economic status certainly suggests that there were

many children in our group with subnormal levels, but does not establish what the normal level should be. A few children had persistently high haemoglobin levels; for example, a boy aged 9 years who received no iron treatment had the following values in the course of a year: 100.7, 101.1, 100.0, 97.9, 100.0, 101.1, and 99.1. But such a case was an exception; most children even those with several consecutive high readings, showed fluctuations in the course of a year. Some fluctuations were no doubt due to errors in technique, others to illness of the child but it is probable that physiological changes due to exercise differences in temperature and emotion also caused fluctuations.

Summary

The haemoglobin levels of children at two municipal schools were estimated with the Haldane haemoglobinometer. At school B 127 children were examined in Oct., 1942, at school A haemoglobin estimations were repeated at intervals for over a year in 1942-3 and 125 children in all were examined. The mean haemoglobin level at 7 years was about 88%, and there was an increase with age to approximately 92% at 10 years. The mean haemoglobin level for each age was approximately the same in Feb., 1942, as in Feb. or March 1943. The age increment for this twelve-months period occurred between March and July, after a drop in haemoglobin level between February and March. Iron therapy for five months in 1942 produced a mean rise of 7.0%, but when treatment was stopped the haemoglobin fell to approximately the level of the controls. Dinners provided in school had no effect on the haemoglobin level. Children who had eaten a midday dinner in school for three months and upwards had a mean haemoglobin level within 0.5% of controls who had no school dinners. Results suggest that in families where there are three or more children not earning wages the haemoglobin levels are likely to be lower than the average, but numbers were too small to be more than suggestive. The haemoglobin levels in 1942 and in 1943 were higher than they were in the latter half of 1941 for children of similar economic status examined by us.

Our sincere thanks are due to the medical officers of health and their staff for their help. The head masters and their teaching staffs assisted us most generously in spite of all the extra work thrown upon them and we are glad to express our gratitude. We are much indebted to Dr W. J. Martin for certain statistical analyses.

[POSTSCRIPT.—Since this paper was written there has appeared in the *Journal* (1944, 2, 334) an interesting paper by Davidson and his co-workers on haemoglobin levels in 1944 as compared with 1942 and 1943. In this two-year period they found a mean rise in haemoglobin of about 4½% at one municipal school in Edinburgh and about 13% at another. Allowing (as found by us) for a rise with age of 2.8% in two years this means an increment of about 2% and 10% respectively between 1942 and 1944. We, on the other hand, found a rise at an earlier date, children examined early in 1942 had a haemoglobin level 5½% higher than similar children examined in the second half of 1941, and between 1942 and 1943 we found little change. The Edinburgh workers conclude that the compulsory use in bread of 85% extraction flour and a consequent increase in iron intake "has been the chief factor responsible for the raised haemoglobin levels." The use of flour of 85% extraction was made compulsory all over Great Britain from March 23, 1942, and very little such flour was used anywhere in the country before that date, hence this cannot have been responsible for the rise in haemoglobin observed by us by Feb. 1942. Moreover, the use of this flour had little, if any, effect on the haemoglobin level in our group between Feb., 1942, and Feb. and March, 1943, since the levels at these dates differed by only 0.7%. Their haemoglobin level was, however, responsive to iron, for iron given in large doses produced a rise of 7%. The addition of calcium carbonate to the national bread was started gradually from April, 1942, so presumably much of the bread consumed by the children under our observation between April, 1942, and Feb. and March, 1943, contained this addition. Our observation therefore makes us hesitate to accept the view that the rise in haemoglobin level observed in Edinburgh school-children was attributable to changes in the composition of bread, although, like Prof. Davidson, we feel certain it was due to an improvement in the diet.]

THE DIETARY CONTROL OF ALLOXAN DIABETES IN RATS

BY

J. H. BURN, M.D., F.R.S.

Professor of Pharmacology

T. H. C. LEWIS

AND

F. D. KELSEY

(From the Department of Pharmacology, Oxford)

The importance of fat in lessening the severity of diabetes has long been known, but still receives little emphasis. Recently it has been underlined by observations in dogs made diabetic by the daily injection of anterior pituitary extracts. Marks and Young (1939) have found that when these dogs are given a diet which is almost exclusively fat the glycosuria and the ketonuria are greatly diminished. It seems as if on a fat diet the metabolism of these dogs ceases to be abnormal. Recently we have studied the production of diabetes in rats by the injection of alloxan, and have taken the opportunity to observe the effect of dietary changes, in particular of a high-fat diet, upon the glycosuria so produced. Our first experiments showed that the abrupt substitution of a high-fat diet for a normal diet caused a disappearance of glycosuria which was accompanied by some ketonuria. Although this ketonuria was transitory, we endeavoured to avoid it altogether by introducing fat in the diet in stages. In our first attempt to do this we used an unpalatable diet, and the results served only to demonstrate that a reduced calorie intake reduces glycosuria. In other experiments we successfully demonstrated the inhibitory effect of fat on glycosuria when the calorie intake was maintained.

Alloxan has the formula shown, and is closely related to the purines chemically. It is a substance which may arise in the natural course of metabolic processes in the body, and may be one actual cause of diabetes in man.

the purines chemically. It is a substance which may arise in the natural course of metabolic processes in the body, and may be one actual cause of diabetes in man.

Shaw Dunn and McLetchie (1943) produced permanent glycosuria in rats by injecting a succession of doses of varying size at varying intervals. Working in April, we observed that two doses given subcutaneously on two successive days, each 16 mg/100 g., produced glycosuria in 8 rats of about 200 g. weight. In two of these the glycosuria disappeared after 4 days, but in 6 rats it persisted. Alloxan seems to be inactive by mouth, for, in 3 rats, four times the above dose on four successive days, followed by eight times the dose on two days, did not cause glycosuria.

Effect of Diet on Glycosuria

In the accompanying Chart is shown the onset of glycosuria in two rats which were kept in the same cage. On the 2nd day, after the injection of the second dose of alloxan, the dextrose excretion rose to 5 g. in 24 hours, and on the 7th day to 7.7 g. The average excretion for the first 13 days was 5.5 g. in 24 hours. During this time the rats received a mixed diet, the composition of which was as follows: 19% ground wheat, 19% bran, 19% oats, 9% ground maize, 9% ground barley, 5% fish meal, 10% meat and bone meal (this being 50% protein), 10% skimmed-milk powder, plus yeast, cod-liver oil, and salt. The calorie value was estimated to be 3.8 cal. per gramme. On the 13th day the diet was changed to a high-fat diet of 90% margarine and 10% casein, plus a salt mixture. As the Chart shows, the glycosuria dropped to 0.5 g. on the first day and disappeared thereafter. In two other pairs of rats the same prompt disappearance of glycosuria was seen on changing from the normal diet to one consisting of 20% casein and 80% margarine. In one pair the dextrose excretion on the normal diet rose during 9 days to 10.9 g. per 24 hours, the mean figure being 7.0 g. On the high-fat diet it fell at once to 0.3 g., 0.2 g., and 0.2 g. on three successive days. On restoration of the normal diet it rose again to a mean figure of 7.6 g. for the next four days. In another pair of rats the normal diet was given for 30 days before it was changed, to observe whether any spontaneous arrest of glycosuria

occurred. The mean dextrose excretion was 3.5 g. daily during this period, and showed no sign of declining. When the diet was changed to a high-fat diet, glycosuria disappeared in the first 24 hours and, save for traces on four occasions, remained absent for 6 weeks, until the rats were again given the normal

Chart showing the daily excretion of dextrose (ordinate) in the urine of three pairs of rats. In the first pair the onset of glycosuria is shown after two injections of alloxan. On the 13th day a high-fat diet was given. In the second pair the effect of 3 days of high-fat diet is shown. In the third pair the effect of high-fat diet is shown after 31 days of normal diet. The high-fat diet abolished the glycosuria in all three pairs.

diet. These observations show clearly that the substitution of a high-fat diet for a normal diet abolishes the glycosuria in rats as found by Marks and Young in the dog.

Fat Diet and Ketonuria

The sudden change to a high-fat diet produced ketonuria in varying degree, as shown in Table I. The ketonuria was

TABLE I.—Ketonuria on High-fat Diet. (Mg. Acetone per Day.)

Rats	Fat in Diet	Days of Fat Diet				
		1	2	3	4	5
1st pair ..	90%	2	12	132	49	24
2nd " ..	80%	2	9	4		
3rd " ..	80%	0	6	15	0	0

determined by the gravimetric method of van Slyke (1917). Table I shows that the ketonuria in the rats given 90% of fat reached the high figure of 132 mg. on the 3rd day, thereafter declining; it was, however, much less in the two pairs which were given 80% fat.

Gradual Change to Fat Diet.—The rat is an animal which develops ketonuria less readily than man, and, indeed, outside the spring months can eat a diet wholly fat for a week or more with little or no ketonuria (Burn and Ling, 1928). An attempt was therefore made to introduce fat in the diet gradually in order to avoid the occurrence of ketonuria: if ketonuria could not be avoided in the rat it certainly could not be avoided in man.

Importance of Total Calorie Intake

The first experiments were made by changing from the normal diet to a diet of casein, margarine, starch, and a salt mixture. The proportion of casein was kept constant at 20%, while the proportions of carbohydrate and fat were altered: diet of any, one composition was continued for a period of not less than 5 days, for which the food consumed was measured and the calorie value calculated. The results in a pair of rats are given in Table II. In the column headed "Diet" the letter S indicates the diet of casein, margarine, and starch, as distinct from N, the normal diet. The figure following S is the percentage of fat in the diet. For each period the mean daily calorie intake and the mean daily dextrose excretion are recorded, and, finally, the body weight of the two rats at the end of each period is shown.

At first, with a diet containing only 40% of fat, the food intake was reasonably good and the dextrose excretion high. On raising the fat percentage to 60 the dextrose excretion dropped very low, but coincidentally with this change the rats ate much less food and the calorie intake fell to little more than half. That the main cause of the diminution of glycosuria was the drop in calories rather than the increased fat was shown by the fact that when the fat percentage was decreased

TABLE II

Diet	No. of Days	Mean Daily Cal. res.	Mean Daily Dextrose Excretion (g.)	Body Weight at End (g.)
S 40	5	143	3.0	364
60	5	70	0.2	333
60	5	52	0.02	308
60	5	70	0.2	293
60	5	85	0.1	253
60	11	125	2.2	373
60	12	190	5.55	420
60	6	75	0.6	342

in stages to 50, 40 and 30% glycosuria remained very slight. The low calorie intake was reflected in a serious fall in body weight, for at the end of the fifth period the rats had together lost more than 100 g. They were then given the normal diet, 40 g. per day. They ate all of this and dextrose excretion rose to a mean figure of 2.2 g. In the next period the normal diet was increased, and the calorie intake rose to 190, as a result the dextrose excretion more than doubled. At the end of this period the body weight was fully restored. A final demonstration of the importance of calorie intake on the amount of dextrose excreted in the urine was provided by reducing the diet to 20 g. per day. The dextrose excretion again fell to a low figure.

Effect of Fat on Dextrose Excretion

The attempt to demonstrate the importance of fat had so far failed because the mixture of casein, starch, and margarine was not liked by the rats and they ate very little. In another pair of rats the experiment was performed by adding fat to the normal diet. The result is shown in Table III. During

the first period the rats were eating the unpalatable mixture and were then given the normal diet (N). Although the diet was of approximately the same composition the calorie intake rose to about three times the previous value, the body weight increased, and the dextrose excretion rose from 0.3 to 4.9 g. per day. Margarine was then incorporated in the normal diet—first 20%, then 30%, until, finally, 70% was included.

As the percentage of fat rose the mean daily excretion of dextrose steadily fell. With 60% of added margarine the dextrose was as little as 0.3 g. per day, and with 70% the urine became completely sugar-free. While this occurred the calorie intake fell only a little. On the normal diet without added fat the calorie intake was 202 g. per day at a time when the dextrose excretion was 4.9 g. When the diet contained 70% added fat the calorie intake was 165—that is to say, about 80% of the previous intake—and since 5 g. dextrose, representing 20 calories, was no longer lost in the urine, the calorie usage was 90% of that on the normal diet. The maintenance of the calorie intake was reflected in the maintenance of the body weight, which remained near 490 g. on the diets containing 30, 40, 50, 60, and 70% of added fat. After each change in the diet the urine was examined for acetone bodies on three or more successive days. Ketonuria occurred on only one day of the whole period, which was approximately 8 weeks. It amounted to 19 mg. acetone, and occurred after the rats had

been given 50% of added fat. Strangely enough, there was no ketonuria when the added fat amounted to 60 or 70%. Thus in this experiment glycosuria was abolished by a high fat diet which did not reduce the calorie intake sufficiently to affect the body weight.

Permanence of the Diabetes

When these diabetic rats were given alternate periods of a normal diet and a high fat diet it was found that the glycosuria recorded when they were eating the normal diet gradually diminished in successive periods. Figures illustrating this change in one pair of rats are given in Table IV. It is

TABLE IV

Period when Diet Normal	Mean Dextrose Excretion in 24 Hours (g.)
2nd 13th day	5.5
3rd-42nd	4.4
10th 137th	2.3
161st 171st	1.6

The first day was the day on which glycosuria first appeared.

uncertain at present whether this decrease in dextrose excretion was due to intervening periods of high fat diet or not. Perhaps diabetes produced in rats by alloxan diminishes in course of time even on a normal diet. Further work is in progress to determine whether a high fat diet not only prevents glycosuria but also restores functional islet tissue in rats.

Discussion

These experiments show how convenient a tool alloxan is for the study of diabetes in groups of animals. Most experimental studies hitherto made have been carried out in dogs or in cats made diabetic either by removal of the pancreas or by Young's method of repeated injections of anterior pituitary extract which has the great advantage that the pancreas remains. Even so, the production of diabetes takes a considerable time and requires much anterior lobe material. Two injections of alloxan are enough to produce diabetes in the rat, so that diabetes can be studied in groups of animals with ease. We have been able to demonstrate that glycosuria is eliminated by diets of high fat content. Allen (1917) recommended high fat diets for the treatment of human diabetes, as did Newburgh and Marsh (1920), and Petren (1925). Later Haist, Campbell, and Best (1940) from their studies of the insulin content of the pancreas conclude that fasting, fat-feeding and the injection of insulin are three factors which allow the pancreatic islets to rest. As already stated, Marks and Young (1939) found that a diet of beef suet diminished both glycosuria and ketonuria in dogs made diabetic by anterior lobe extracts, and Dohan and Lukens (1939) have confirmed this. A diet exclusively fat could not, of course, be given indefinitely. While we have not found it possible to make a sudden transition to a high-fat diet without increasing ketonuria we have found that by a gradual increase in the fat content of the diet it is possible to abolish glycosuria without producing ketonuria and at the same time to provide a diet containing enough calories to maintain body weight reasonably well. Thus we have been able to demonstrate that alloxan diabetes in the rat can be brought under complete control by diet.

The difficulty in applying these results to man is that most people do not believe that man (in particular, a diabetic patient) can eat a high fat diet without developing ketonuria and exposing himself to the risk of coma. Our knowledge of the mechanism of ketonuria is still small. Petren (1925) stated that a diet of butter diminished acidosis, whereas a protein diet increased it. Marks and Young (1939) also say: "The results of our investigations have shown that the ketonuria is at a maximum when a meat diet is given and is lowest with the prolonged feeding of fat." It seems clear that further progress in the dietary control of human diabetes must await a clearer understanding of ketonuria.

Summary

Rats have been made diabetic by the injection of alloxan. When a high fat diet was substituted for the normal diet the glycosuria disappeared and remained absent until the normal diet was resumed. This abrupt change to a high fat diet was accompanied by some

per ml. had survived in 2-aminophenol and only 300 in proflavine. After 24 hours both compounds had killed all the organisms. In a control tube consisting of a similar suspension of organisms in water slight multiplication occurred.

Antibacterial Action in Blood in Slide Cells.—As Fleming (1930-1) has shown, most of the antibacterial agents used before the discovery of sulphonamide destroy leucocytic function in dilutions which have no effect on bacterial growth. Many bacteriostatic compounds are also inactivated by blood or serum. The following experiment was carried out to determine whether either of these statements applied to 2-aminophenol. Two series were set up in parallel; in one case fresh defibrinated blood was used, and in the other blood 1:1000 liquid. It was assumed that 1:1000 liquid would destroy all leucocytes. Serial dilutions of 2-aminophenol and proflavine were made in isotonic saline, mixed with equal quantities of blood, and a suitable inoculum of streptococci added. Controls consisting of saline, blood, and organisms only were included. The mixtures were transferred to slide cells, which were sealed and incubated for 24 hours. Table III gives a typical result with a small inoculum of *Str. pyogenes* consisting of approximately 30 viable organisms per slide cell. These figures show that 2-aminophenol has a considerable antibacterial activity in the presence of 50% blood, and the compound does not interfere appreciably with phagocytosis in greater dilutions than it is bacteriostatic.

Action of 2-aminophenol on Penicillin.—The effects of mixtures of penicillin and 2-aminophenol on *Staph. aureus* were studied. A large inoculum of staphylococci will grow in a concentration of 1:8000 2-aminophenol, although much greater dilutions are inhibitory to smaller inocula. Serial dilutions of penicillin were made in plain broth and in broth containing a final concentration of 1:10,000 and 1:100,000 2-aminophenol. An inoculum of approximately 4 million staphylococci was then added to each tube. The results are shown in Table IV. It will be seen that even a dilution of 1:100,000 2-aminophenol increases the antibacterial activity of penicillin.

TABLE IV.—Effect of Penicillin + 2-aminophenol on *Staph. aureus* when an Inoculum of Approximately 4 Million Organisms was used

Penicillin, Units per ml. (approx.)	Plain Broth	1 : 100,000 2-aminophenol in Broth	1 : 10,000 2-aminophenol in Broth
None	++	++	++
1/4	0	0	0
1/8	0	0	0
1/16	0	0	0
1/32	0	0	0
1/64	0	0	0
1/128	0	0	0
1/256	0	++	0
1/512	0	++	0
1/1000	0	++	0

Plus signs indicate degree of growth as observed by turbidity. 0 = No growth.

Toxicity.—(1) *Skin sensitivity*:—This was tested on 6 human volunteers. A 1:500 solution of 2-aminophenol in water was rubbed into the same area of skin every day for a week. No reactions of any kind were observed and no irritation was felt. (2) *In mice*:—A series of 18 mice were given varying doses of 1% solutions of 2-aminophenol and proflavine respectively by subcutaneous injection. Doses of 0.4 g. 2-aminophenol per kg. of body weight were tolerated, but 0.5 g. or more per kg. was fatal. Proflavine was fatal in doses of 0.2 g. per kg.

Activity of Allied Compounds.—The antibacterial activity of 2- and 4-aminophenol (I, II) suggested a further investigation designed to determine the effects of molecular substitution in these

(I) Activity among the substituted 2-amino- (o-amino-) phenols (I) was limited almost entirely to substances of the class (II), but was absent where R was $-\text{COOH}$, $-\text{COOCH}_3$, $-\text{COOC}_2\text{H}_5$, $-\text{COOCH}(\text{CH}_3)_2$, or $-\text{NO}_2$. The most active substituted 2-aminophenol was 4-methyl-2-aminophenol (3-amino-*p*-cresol, III; R = $-\text{CH}_3$), and the activity of this substance was of the same order as that of 2-aminophenol itself.

So far we have not discovered a substance in which substitution has enhanced the activity of 2- or 4-aminophenol. Compounds of formula III, however, should be worth further investigation, and this is being undertaken.

Discussion

The mode of action on bacteria of 2-aminophenol is not known. Like the sulphonamides, the compound is mainly bacteriostatic in action, and is very much more effective *in vitro* against a small number of bacteria than it is against a large number. 2-aminophenol in strong solutions, however, is slowly bactericidal. 4-aminophenol (*p*-aminophenol) has been shown by Bernheim *et al.* (1937) to have a considerable effect on tissue oxidations. These workers found that this compound, compared with a large number of similar substances, was the most active in inhibiting the oxygen uptake of liver suspensions.

Williams (1938, 1943) has studied the fate of 2-, 3-, and 4-aminophenol in the body. He has shown that 2-aminophenol when fed to rabbits by stomach-tube is excreted in conjugation with both sulphuric acid and glucuronic acid. No free aminophenol was excreted. He gave 1-g. doses of 2-aminophenol to 6 rabbits of 2.5 kg., apparently without toxic effect. He also showed (Williams, 1943) that 2- and 4-aminophenol glucuronides were methaemoglobin-formers *in vitro*.

Further observations on this group of compounds are required, but its low toxicity and its bacteriostatic activity against the Gram-negative bacilli suggest that 2-aminophenol may be of value as a local antiseptic.

We are glad to acknowledge the help of J. D. Oriel, of Guy's Hospital Medical School, in the preparation of substituted aminophenols.

MEDIASTINAL TERATOMA SUCCESSFULLY REMOVED BY OPERATION

BY

A. W. FAWCETT, M.B., F.R.C.S.
 Honorary Surgeon, Royal Infirmary, Sheffield

The following rare case is of interest, being that of a teratoma in a child aged 7, which was successfully removed.

Case History

In Jan., 1944, the patient was referred to me by Prof. E. J. Wayne and Dr. Thompson. The history was somewhat scanty, but the child had complained of shortness of breath while playing and on going uphill, and the mother, wondering if her heart was at fault, brought her to the Children's Hospital, Sheffield. Examination of the chest showed that the cardiac area of dullness was considerably increased to the right, and a radiograph disclosed that there was a tumour which occupied a large part of the right hemithorax. Further investigation revealed that it was roughly oval and lying in the anterior mediastinum. Scrutiny of the film showed that the shadow was not of homogeneous consistency, but was an irregular fine one which was very suggestive of bone. A diagnosis of mediastinal teratoma was made. The child was transferred to the Royal Infirmary, Sheffield, and was about to be operated upon when she developed scarlet fever and had to be sent to the local fever hospital.

She was readmitted on March 13, and the operation took place on March 21. The anaesthetic was ether-oxygen administered by an Oxford vaporizer. The chest was opened by an incision running parallel to the second rib, then down the margin of the sternum

substances. The following compounds were therefore prepared and tested for antibacterial activity: 2- and 3-methyl-4-aminophenol, 5-methyl-2-isopropyl-4-aminophenol (6-aminothymol), 2-methoxy-4-aminophenol (5-aminoguaiacol), 2-aminoanisole (o-anisidine), N-acetyl-2-aminophenol, 3-, 4-, 5-, and 6-methyl-2-aminophenol, 4-carboxy-2-aminophenol and its methyl-, ethyl-, and *iso*-propyl esters, 4-phenyl-2-aminophenol, and 4-nitro-2-aminophenol (sodium salt, B.D.H.).

As a result of this work, the conclusions reached were: (1) The 4-amino- (*p*-amino-) phenols (II) are generally so unstable that their use as therapeutic agents would be seriously limited. Work on them was not pursued, although 4-aminophenol as well as 2- and 3-methyl-4-aminophenol showed antibacterial activity of the order of that of 2-aminophenol itself. The remaining substituted 4-aminophenols were inactive.

and outwards along the sixth rib. The costal cartilages were cut on the bevel to prevent overlapping when the chest was closed. The right pleural sac was stripped away and a window raised of

bulk by removing a series of wedges of tissue until it had reached reasonable proportions. It was finally removed by further digital dissection. As the upper pole seemed to be the most likely place for a blood supply, since none had been encountered, a clamp was placed across the last piece of tissue which held the tumour. To avoid infection the window in the chest was closed without drainage and the air aspirated out of the cavity to prevent surgical emphysema. Sero-sanguinous fluid collected during the next few days, which I aspirated on one occasion, but, as is so common in all chest operations, could not find any fluid on a subsequent attempt. The fragments of tumour when collected were found to weigh 12 oz.

My colleague, Dr. L. C. D. Hermitte, undertook the examination of the specimen, and his report is as follows:

"Sections from various parts of the tumour show the structure of a multipotential teratoma. The following structures are present: (1) fatty areolar tissue; (2) cartilage; (3) ossifying cartilage; (4) bone marrow; (5) thymus gland tissue complete with epithelial pearls; (6) branching tubules lined by semi-stratified ciliated epithelium with plain muscle, cartilage, and numerous glands in the walls suggestive of bronchial epithelium; (7) tubular collections of melanin pigment; (8) cystic spaces lined by cubical epithelium forming papillary processes, the nature of which is not clear; they resemble the pink-celled cyst of the breast; (9) areas of connective tissue containing calcospheres."

The child made an uninterrupted recovery, and was discharged on April 6.

A radiograph taken three months after operation showed a perfectly normal chest. There appeared to be a tendency to form keloid in the scar, so x-ray therapy was instituted.

In a review by Lloyd Rusby (1944) of dermoid cysts and teratomata of the mediastinum based on a study of the world's literature, it is stated that only

some 245 cases, exclusive of six original cases, had been published between 1827 and 1939.

chest wall. This revealed a large yellowish-white tumour, which was found to be relatively free on blunt dissection below, but was more firmly attached towards the upper pole. Owing to its large size it would have been necessary to enlarge the opening in the chest, so, to overcome this difficulty, the tumour was reduced in

Medical Memoranda

The Incomplete Antibody in Rh Immunization

The recognition of an Rh antibody which combines with homologous red cells *in vitro* but does not agglutinate them as announced independently in June of this year by Wiener and by one of us.

The "blocking" antibody (Wiener, 1944) or "incomplete" antibody (Race, 1944) is specific for one part of the antigen complex of Rh positive cells. If this antibody could agglutinate it would be of the type which has been variously called anti-Rh standard anti-Rh 85%, anti-Rh₀, Δ, and rho. It reacts with the antigen common to the genes Rh₁, Rh₂, Rh₀, and the rare Rh₁. However, the complexities of antigenic components, genes, antibodies, and nomenclatures need not be gone into here.

Wiener has pointed out that this "blocking" antibody can be detected in some cases in which immunization is suspected and the mother or recipient is Rh-negative, but in which no antibody can be found by the ordinary means. The purpose of this note is to draw attention to this latest method of detecting immunization of an Rh-negative person and particularly to Wiener's technique which is more sensitive than that described by Race. The following is Wiener's description of the test.

"The technique of the test is simple. First, one drop of a 2% suspension of Rh-positive cells and a drop of the patient's serum are mixed in a small test-tube and allowed to react in a water bath at 38°C for 30 to 60 minutes. Then a drop of a suitable dilution of an active anti-Rh serum is added, and after an additional incubation period of 30 to 60 minutes the reactions are read. If blocking antibodies are present no agglutination will occur, or the clumping will be markedly weakened.

The example given of a suitable dilution of an anti-Rh serum is 1:5, when the original titre was 60.

We have tried Wiener's technique on a number of sera collected from Rh-negative women over about two years and stored at minus 20°C. Whereas Wiener placed the tubes in a water bath we used an incubator at 37°C., re-suspending the sedimented cells when adding the active anti-Rh serum after the first period of incubation. Of 19 cases in which the history sounded typical of haemolytic disease and yet in which no anti-Rh had been detected the incomplete antibody was found in 6. Of 26 cases in which a trace of anti-Rh had been detected the incomplete antibody was found in 19.

These results confirm the importance of testing for the presence of the incomplete antibody in any serum from an Rh-negative woman in which no anti-Rh can be found. The less sensitive the technique for detecting anti-Rh agglutinin the more useful will be the test for the incomplete antibody. In some cases it will yield the only evidence of immunization, and in others will strengthen that given by the finding of only a trace of agglutinin.

A fairly extensive search involving more than 100 mothers with histories suggesting haemolytic disease has failed to give any evidence of incomplete forms of the other three types of anti-Rh agglutinins.

Reviews

EXPERIMENTAL BASIS FOR NEUROTIC BEHAVIOUR

Experimental Basis for Neurotic Behaviour: Origin and Development of Abnormal and Deviant Behaviour in Dogs. By W. Horsley Ganitt, M.D., Assistant Physician and Head of the Pavlovian Laboratory, Johns Hopkins University. (Pp. 211, 54s.) New York and London: Paul B. Hoeber, Inc.

The full title of this volume conveys almost as much as can be put into a brief review. The book deals very largely with observations on one dog, Dick, which was under observation for 12 years and has been in a state of nervous imbalance for a decade. Considerable additions have been made to the original observations of the Pavlov school particularly in the study of aberrations of sexual function. The author claims that, in animals, the origin and spread of nervous imbalance can be detected before it is properly expressed, can be traced in its development and followed as it extends to the various physiological systems. Social and personal relationships can also be studied.

The book is stimulating and conveys a challenge, and probably marks the beginning of an epoch of productive work in this important new field. For, as the author rightly points out, in such a periodically recurring chaotic world state of affairs any approach to the question of emotional imbalance is important. Although the most detailed observations have been made on one animal, Dr. Horsley Ganitt lays special stress on the fact that individual variations are very great. We feel irresistibly drawn to his conclusion that there is in these experiments much that is applicable to the problems of tortured mankind. We congratulate the author on a work full of interest.

DRUGS AND THEIR ACTIONS

A Concise Pharmacology and Therapeutics of the More Important Drugs together with an Introduction to the Art of Prescribing. By F. G. Hobart, Ph.D. and G. Meacham, M.R.C.P. Second edition. (Pp. 168, 12s. 6d.) London: Little, Hill Ltd. 1944.

The title of this book is misleading, for pharmacology is an experimental science which is not expounded by giving a list of drugs and saying a little about the action of each. While it is a useful work for the doctor in practice who wants a book of reference handier than the *Eviva Pharmacopoeia*, yet because it is called "Pharmacology" it is unlikely to be bought by the qualified man, and its main sale is likely to be to the student for whom it is much less suited. The actions of the substances dealt with are almost always well described, and the information is reasonably up to date. But this is not a book on which the student should rely, because no space is given to mechanism of action, with which a work on pharmacology should be primarily concerned. For example, it is not enough to say that "ephedrine delays the destruction of adrenaline in the tissues and so prolongs its action." As an explanation of the mechanism of ephedrine action this is wholly inadequate.

There are a number of points where the best information is not given. Thus it is stated as was formerly believed, that sulphaguandine is only slightly absorbed from the alimentary tract. It is now known that though it is absorbed slowly much sulphaguandine is absorbed, unlike sulphasuxidine which remains in the intestine. Acridine is said not to affect phagocytosis, this again is erroneous for antiseptic concentrations kill polymorphonuclear leucocytes.

A SURGEON'S PHILOSOPHY

Meaning and Purpose. By Kenneth Walker. (Pp. 170, 7s. 6d.) London: Jonathan Cape.

This book represents another rung on the ladder by which Mr. Kenneth Walker is climbing, from the contemplation of the genito-urinary system of the human being to a philosophy of the universe, and a very interesting rung it is. It is written with all the clearness and lucidity of style we have come to

expect from Mr. Walker. In this book he reviews the various doctrines which he has accepted with greater or less enthusiasm during his life and for the most part found wanting. It he has not yet reached a complete satisfying philosophy to put in their place how shall we blame him?

He points out that in spite of close observation, scientific knowledge is necessarily indirect and that Western civilization has not made a sufficient attempt to improve the faculties of reasoning and reflection. Science firmly rejected metaphysics when it began to make real advances but now we find that physicists have been compelled to become philosophers. After all, Plotinus said that intuition transcends experiment and reason and this was accepted till the nineteenth century, when the real fight between science and religion began with the efforts of science to explain everything in terms of materialism, then of vitalism then of mechanism. But all these approaches were one-sided because they forgot or ignored mind and epistemology (knowledge). With Darwin the scientists thought they had won battles and the *Origin of Species* became for a time as authoritative and uncriticized as was the Bible for the richard religions. With the growth of exact genetics, and the discovery of mutations the majority of which did not persist Darwinism became difficult to accept, in fact it could not be accepted unless some form of central purpose in the evolution of the universe was admitted. The next step was the rise of the various psychologies based on (a) biology—the observation of animal behaviour (b) physiology—the conditioned reflex of Pavlov and the behaviourism of Watson, and (c) medicine—Freud and those who followed him. All these are incomplete though all contain truth. In spite of what the scientists have said meaning, purpose, and intelligence do exist and these are concerned with the "why" of evolution whereas science is concerned with the "how". Attempts to answer this why were made by Bergson with his *élan vital* and by Ouspensky with his "Great Laboratory." Man is conscious of a purpose and this is the province of religion which he cannot do without. Faith is essential to man and the solution may be through the mystics and the affective realization that God is Love.

Mr. Kenneth Walker then goes on to discuss the three religions of modern times. First humanism—the worship of man with the corollary of the emergence of a superman. This may be hastened by the second religion, the worship of race—the herrenvolk. But the psychology of the crowd is always at a lower level than that of the individual and is bound to produce war. The causes of war are economic circumstances, man's social state and his acquisition of wealth. The third religion is that of communism—aiming at an aristocracy of power rather than of wealth which may also lead to war. The promise of the future does not lie in these or in science which alone cannot achieve truth, yet modern physics makes possible a liaison between science and philosophy and an integration of philosophy into something higher than has yet been reached is necessary to avoid war and lay the foundations of a brighter world order.

MEDICAL LEXICOGRAPHY

The American Illustrated Medical Dictionary. By W. A. Newman Dorland, M.D., F.A.C.S. Twentieth edition, revised and enlarged. (Pp. 1665, with 450 illustrations including 700 pictures. Price 10s. 4s. 6d. (hardbound), 4s. 6d. (Philadelphia and London: W. B. Saunders Company) 1944.

The ever useful Dorland's *Medical Dictionary* appears in its twentieth edition on thoroughly revised and brought up to date. All departments of medicine and surgery have been covered and hundreds of fresh terms used in the fields of biochemistry, chemotherapy, allergy, specific therapy, endocrinology, vitamin research, tropical and parasitic diseases and mycology have been incorporated together with the names of a host of new synthetic and medical preparations. The vocabulary of war medicine and surgery, too, has received special attention. It is to be noted that the terminology employed is that of the *Standard Nomenclature of Diseases and Operations* published by the American Medical Association, and edited by Dr. Edwin O. Jordan.

A close study of Dorland's dictionary seems to indicate that there are broadly two kinds of definition, one supplied by experts in the particular branch of medicine represented by

the word defined, and the other supplied by men with lexicographical talent but no expert medical knowledge. For example, the word "enteric" is defined as "pertaining to the intestines," but no reference is made in this entry to the common use of this word in "enteric fever": "enteric fever" does appear under the general entry "fever," as a synonym for typhoid fever, but not in the entry for "typhoid fever." Some definitions are tantalizing because they are incomplete. "Vitapathy," for example, is defined as "a modern system of quack medicine," but the definition does not tell us what the system is; as it is probably of limited interest, it seems unnecessary to give a separate entry: "vitapathic," with the definition "pertaining to vitapathy." In these days medical terms spring up like mushrooms in the night, and one of the great merits of Dorland's dictionary is the speed with which new words are incorporated in successive editions. At the same time we feel that this excellent work could be made still more serviceable if some of the dead wood were cut away, and if words not strictly medical were omitted. There would seem, for example, to be no point in including the word "voluptuous," well defined in any English-language dictionary, and still less reason for including the delightful but unusual word "volupty," the meaning of which is defined as "sensual enjoyment"—less bashfully defined in Webster's dictionary as "sexual enjoyment." Among the relatively new terms we note the word "geriatrics"—"that department of medicine which treats of the clinical problems of senescence and senility, geriatric medicine." There is, incidentally, no separate entry for the word "geriatric," but there is one for "geratic." Pursuing other cognate words, we note "geratology" and "gereology," both of which mean "the science which deals with old age and its phenomena." Then there is the word "gerontology"—"the scientific study of the ageing process, its phenomena, diseases, etc." The compilers of the dictionary are to some extent bound to follow the current usage of words among medical writers. But that editorial pruning hook—the blue pencil—might perhaps have been used more ruthlessly; and, too, the word "geratology" was some time ago given a definition which would seem worth preserving. The *Shorter Oxford* defines it as "the science of the phenomena of decadence, esp. in a species of animals approaching extinction." Those who share the reviewer's taste for dipping into dictionaries will find they get as much pleasure out of a medical dictionary as out of any other, and may even share his delight at discovering the word "gephyrophobia," which means "fear of walking on a bridge, river bank, or other structure near the water."

Notes on Books

Prof ARNOLD SORSBY's thoughtful and stimulating book *Medicine and Mankind* was reviewed in these columns on Dec. 13, 1941. An abridgment from the fuller work has now been published by Watts and Co. as No. 104 of their series, the Thinker's Library, at 2s. 6d. This will ensure a wider public for the author's account of the meaning and mechanism of health and disease, and of the conceptions and aims of medicine.

The pamphlet by Lord HORDER (in collaboration with the Empire Rheumatism Council) entitled "Rheumatism. Notes on its Causes, its Incidence, and its Prevention; with a Plan for National Action" was first published in March, 1941. A fourth edition, the text practically unchanged but with a new preface, makes the total printing 7,000 copies. It is published by H. K. Lewis and Co. at 2s.

Three pamphlets by Dr EDWARD F. GRIFFITH (H. K. Lewis and Co.; 1s. 6d. each) are the lectures which form the second part of his book *The Road to Maturity*, reviewed in these columns on June 3 (p. 754). They are useful guides in sex education, though it is not desirable that lectures on such subjects should be stereotyped, since their form and substance must vary with both the audience and the lecturer. *Facts in Development* is a biological account of reproductive function from the amoeba to man. *Emotional Development* deals with the mental side of sex and touches on masturbation, homosexuality, and the guilt feelings which are liable to arise from them and the emotional differences between the sexes. *Towards Maturity* deals with the problems of preparation for marriage, family limitation, premarital relationship, prostitution, and other related questions.

Preparations and Appliances

CONTINUOUS PENTOTHAL ADMINISTRATION

Dr. W. G. MCKINNEY (Londonderry) writes:

I have found the actual giving of continuous pentothal solution simplicity itself by means of the apparatus illustrated. There is nothing very original about it except the little tap mount, in which the 20-c.cm. syringe securely fits. The introduction of the tap into the apparatus is obvious, as allowing the syringe to be detached for refilling during the course of a prolonged operation, especially if 2½% solution is being used. By the agency of the tap the whole system can be left charged with pentothal solution during detachment of the syringe; and clotting definitely does not take place, either in the needle or in the tubing.

The tubing used is of very fine bore, and is most easily obtainable as an infant's catheter cut into suitable lengths or portions. It is advisable to have some four inches of tubing between the window and the tap to allow for free and unhampered use of the syringe, which may be held comfortably in hand or, if desired, fixed to some simple rack fitting. The window is of the type used frequently as a syringe attachment for the injection of varicose veins, and serves admirably as a visual guide to the true intravenous position of the needle.

Of the needles which I have used, size 12 intravenous, made by Allen and Hanburys, is without doubt the best and most satisfactory. When properly in position it is securely fixed to the arm by means of a piece of narrow strapping passing over the mount. Another piece of strapping at the lower end of the window gives extra stability and freedom from worry about drag on the needle-point. The syringe may be either eccentric or concentric nozzled: it makes no difference. The patient's arm is supported on an arm-rest and firmly fixed thereto by means of a wrist-strap or bandage.

Using this simple and readily procurable apparatus I have given pentothal continuously on numerous occasions and have had no trouble with needle blockage, leakage, or air bubble.

UNDER-CARRIAGE FOR SLEDGE STRETCHER TRANSPORT

Lieut.-Col. D. G. DUFF, F.R.C.S.Ed., writes: The advantages to be got from sledge stretcher transport in minimizing shock to the patient and hard labour to the bearers are undeniable. A practical test against any other stretcher assembly (especially in hill country) will quickly convince anyone. The incorporation of sledge runners, especially in a tubular metal stretcher, need not add much to the weight. It adds greatly to the utility, while preserving all the traditional usages (*Lancet*,

Sledge-wheel under-carriage for standard stretchers

June 17, 1944). Since, however, there may be reluctance to scrap existing stretchers, an under-carriage has been designed and made to fit the standard wooden stretcher. It weighs about 9 lb., but will save many foot-pounds of energy expenditure. With a central wheel applied, it will take practically all the strain off stretcher-bearers. On occasion it will allow the wheel-barrow *modus operandi*, so that one bearer can carry his patient with less exertion than is required from either of the normal two bearers. The accompanying photograph shows the wheel-barrow position. The central position with vertical wheel-forks is better, as it takes all the weight from the two bearers.

'KEPLER'

COD LIVER OIL WITH MALT EXTRACT

**Helping to build
the men and women of tomorrow**

'Kepler' provides valuable supplementary Vitamins A and D together with readily assimilable fat and carbohydrate.

There is no finer product of its kind. The high standards of quality for which more than one generation of medical men has esteemed 'Kepler' have in no way been lowered because of wartime difficulties.

'Kepler' Cod Liver Oil with Malt Extract contains Cod Liver Oil 23% w/v with Malt Extract; each tablespoonful provides not less than 3000 International Units of Vitamin A and 300 International Units of Vitamin D.

BURROUGHS WELLCOME & CO.

(The Wellcome Foundation Ltd.)

LONDON

ORAL TREATMENT OF ANAEMIA

with

HEPAMINO

(Proteolysed Liver)

Clinical trials have demonstrated the value of Hepamino in the oral treatment of pernicious and other megalocytic anaemias even when these have proved refractory to the established forms of liver therapy.

Developed and introduced by The Evans Biological Institute, Hepamino contains the enzyme digested constituents of whole ox liver in a dried, soluble and readily assimilable form.

Every effort is being made to allocate the increasing supplies where they are most needed

Issued in

Bottles of 5 oz. (approx.) 15/- each

Subject to the usual discounts

DIENŒSTROL B.D.H.

The non-toxic highly-active œstrogen

Dienœstrol is the most potent synthetic œstrogen yet discovered. It possesses the advantage of being non-toxic, no untoward effects having been reported following its oral administration even in high dosage. Dienœstrol may be prescribed freely, therefore, for patients who are intolerant to stilbœstrol, particularly when large doses are necessary as in carcinoma of the prostate. It is being widely prescribed also for all those gynœcological conditions in which an œstrogen is required and when there is any suspicion that toxic reactions may be followed by the administration of stilbœstrol.

Dienœstrol B.D.H. is available in tablets of 0.1 mg. and 0.3 mg. in bottles of 25 and 100. Tablets of higher strengths are available if required for special clinical purposes.

Details of dosage and other relevant information on request

THE GERMINAL EPITHELIUM AND THE PROSTATE

A hormone secreted by the germinal tissue of the testicles has often been postulated but never hitherto proved. The question is one of more than academic importance, for one hypothesis advanced by Lower¹ to explain senile prostatic enlargement involved the assumption of such an internal secretion. Lower and his colleagues assumed that with advancing years this secretion decreased, and that the anterior pituitary was thus induced to increase its output of gonadotrophin, just as in the menopausal woman the output of gonadotrophin is increased by ovarian failure. The gonadotrophin acting on the still functional interstitial cells of the testicles gave rise in their hypothesis to an increased output of testosterone, which caused enlargement of the prostate. Unfortunately for this neat hypothesis, it is impossible to produce by the administration of testosterone a condition resembling benign enlargement as it occurs in man. The prostate hypertrophies but remains histologically normal. A second hypothesis is diametrically opposed to that of Lower. It takes no account of an internal secretion of the germinal epithelium, and is based on the fact that the normal man secretes both androgenic and oestrogenic hormones, the former from testicles and adrenals and the latter from some tissue or tissues hitherto unknown. That the oestrogen-producing tissue also is within the testicle is made probable by the observations that animal testicles contain an oestrogen and that the testicles and urine of stallions are very rich sources of oestrogens. It assumes that with advancing years the secretion of testosterone diminishes with no corresponding decrease in oestrogen and that the unopposed oestrogen is responsible for the prostatic enlargement. That oestrogen does in fact cause prostatic enlargement was independently shown by Lacassagne, by de Jongh, and by Burrows and Kennaway. The hypothesis was given still further experimental support by the work of Zuckerman and his colleagues, who showed that the changes induced were due largely to the sensitivity of the prostatic utricle and its bed (the "middle lobe" of the surgeon) to oestrogenic stimulation; that in the dog there occurs spontaneous prostatic enlargement indistinguishable from that induced by oestrogens; and that the effects of oestrogens can be prevented by the simultaneous administration of androgens, especially testosterone propionate. The changes induced in animal prostates by oestrogens bear some resemblance to benign enlargement in men, and the dissimilarity may possibly be explained by species differences in the embryology of the uterus masculinus. Treatment based on this hypothesis has unfortunately not proved wholly satisfac-

tory, and such "successes" as have been reported have been uncontrolled.

Whether or not either hypothesis represents part of the truth, it is obviously of the greatest importance to elucidate further the endocrine function of the testicles. Törnblom¹ has described a series of beautifully planned experiments with this in view. He showed that giving testosterone to young castrate rats in such quantity that the weight of the prostate and seminal vesicles exceeded somewhat the weight of these organs in whole animals did not prevent the increase in weight of the pituitary which occurs after castration. It follows that some other hormone must be normally formed in the testicles the effect of which on the pituitary is greater than its effect on the prostate and seminal vesicles. By treating the testicles of rats with x rays it is possible to cause atrophy of the germinal tissue without affecting the interstitial cells. In such animals the weights of the prostate and seminal vesicles are unaffected, but the weight of the pituitary is increased. It follows from this that the hormone the absence of which causes the increase in weight of the pituitary is formed in the germinal epithelium. Moreover, when the difference in radiosensitivity of the two testicular tissues was increased by stopping the testicular circulation during treatment, a weight increase occurred in both the pituitary and the accessory sex organs. This may possibly be explained on the supposition that the inhibition of secretion in the germinal epithelium causes overactivity of the pituitary and thus of the interstitial cells, with the resulting enhanced androgenic effect upon the prostate and seminal vesicles. In his next series of experiments Törnblom succeeded in isolating a fraction from testicular tissue which prevented the increase in weight of the pituitary in castrate rats without influencing the weight of the accessory sex organs. It therefore possessed the postulated properties of the germinal-tissue hormone. When isolated it was found to possess all the biological properties of oestradiol, and all its actions could be exactly reproduced by oestradiol. No evidence of any non-oestrogenic substance having the postulated properties of germinal-tissue hormone could be found.

An attempt was next made to show directly an increase in gonadotrophic hormone by a new experimental method. An increased formation of gonadotrophin causes the ripening of follicles in infantile ovaries implanted into the kidneys and a secondary oestrous reaction in pieces of vagina implanted in muscle. By this method the enhanced production of gonadotrophin after castration can be demonstrated. Unfortunately no such increase could be demonstrated after inhibition of the germinal-tissue secretion only. This is the only gap in the experimental proof of Törnblom's thesis, but it is not a very serious one, for, as he points out, the production of pituitary gonadotrophin is inhibited by both testicular hormones, and it is naturally not so stimulated by the absence of one as by the absence of both.

It is only in his last chapter that Törnblom leaves the straight path of close reasoning which he has clearly set himself. Having established that the cessation of the

¹ *Uppsala Läkartidning*, 1942, Häft 1, och 2, p. 1.

internal secretion of the germinal tissue causes an increased secretion by the interstitial tissue, he asks the question: "Is hypertrophy of the human prostate due to a corresponding functional disturbance?" To answer this question he treated dogs with testosterone propionate, choosing dogs because they are the only animals known to suffer from spontaneous prostatic enlargement. He confirmed the work of previous investigators who have shown that it is possible by such means to cause prostatic enlargement and even urinary obstruction. Histologically the enlargement was found to be due to a diffuse homogeneous hyperplasia. It resembled one type of spontaneous enlargement seen in dogs, but it did not resemble human benign enlargement. Zuckerman and Groome have already pointed out that in most instances the spontaneous prostatic enlargement of dogs is not histologically abnormal and have suggested that it may well be due to excess of male hormone. They described, however, a case in which the enlargement was histologically abnormal and similar to that which can be experimentally induced by oestrogens. They point out, also, that, on the assumption that the common type is due to excess of testicular androgen and the less common type to excess of testicular oestrogen, Hobday's successful treatment by castration is readily understandable in both conditions. Without committing himself to a definite statement, Cornblom appears to suggest that his proof that the germinal epithelium of the testicles of rats elaborates oestradiol supports the hypothesis of Lower that human prostatic enlargement is due to excessive androgenic stimulation. It may equally well be taken as supporting the contrary proposition. It is clear that no final decision can be reached until more is known about the effects on the human prostate of administered androgens and oestrogens.

EGGS AND SALMONELLA INFECTIONS

Knowledge of the reservoirs of *Salmonella* infections in different animals is steadily growing, and explains both their wide distribution as a cause of animal diseases and the various ways in which the causative bacteria can obtain access to man. Ducks' eggs were known as a source of *Salmonella* food-poisoning as far back as 1926, but their significance was not realized in this country until the publication of an important paper by the late Dr. W. M. Scott¹ in this *Journal* in 1930. Since that date more facts have come to light. It is now known that ducks may suffer from epidemics of *Salmonella* infections, and that, while the bacilli may be extraneous organisms passing from contaminated material through the porous egg-shell, others are present in the egg yolk and are derived from specific infections of the ducks themselves. Certain varieties of ducks seem to be especially liable. While outbreaks are commonest in some Continental countries, particularly Holland and Germany, they are not unknown in Great Britain. J. S. Garside and R. F. Gordon² described an extensive outbreak in 1938-9 in which *B. enteritidis* and *B. typhi murium* were recovered from 44 ducks whose blood contained *Salmonella* agglutinins; but *Salmonella* strains were not recovered from the eggs of the infected birds. This was not the experience in other outbreaks, and several strains have been isolated; by far the most prevalent are *B. enteritidis* (variety Essen) and *B. typhi murium*. In Holland the duck industry is an important

one, and in 1940 C. F. Van Oigen³ described the extensive investigations undertaken by the Netherlands Egg Control Bureau to stop the spread of *Salmonella* infections. Their report shows that there is no one ready remedy which is satisfactory, but that by blood agglutinin tests, segregation, and examination of eggs the number of infected eggs can be reduced to small proportions. The use of pasteurized frozen eggs is quite satisfactory.

The egg of the hen has a much cleaner record. There have been at the most only one or two food-poisoning outbreaks which might be ascribed to the use of infected eggs (excluding dried eggs). While infections with *Salmonella* strains in hens have been fairly numerous—and expensive to breeder and owner—almost always the source of infection has been *S. pullorum* or *S. gallinarum*, strains not pathogenic to man. Recent work shows, however, that more toxic strains may be present. For example, W. L. Mallmann, J. F. Ryff, and E. Matthews⁴ isolated a variety of *Salmonella* strains from diseased hens sent to them from various parts of Michigan, U.S.A., including such types as *S. oranienburg* known to have caused human food-poisoning. None of them, however, produced any symptoms when fed in large doses to monkeys. With a true bill against the duck and something of a "non-proven" verdict against the hen, the question of infection from dried eggs and egg powders has to be considered. N. E. Gibbons and R. L. Moore⁵ have recently given some important information on the subject. They examined for *Salmonella* types 380 lots of Canadian egg powder produced from November, 1942, to December, 1943. Organisms were found in 28 samples (7.4%): 9 different types were isolated—*S. bareilly* (11 lots), *S. pullorum* (5), *S. oranienburg* (4), *S. typhi murium* (3), *S. thompson* (2), *S. minnesota* (2), *S. newport* (1), *S. potsdam* (1), and *S. manhattan* (1). Except *S. pullorum* all strains are potentially pathogenic to man. In the samples for which numerical estimations were made the actual number of *Salmonella* organisms present was low, mostly less than 1-10 per gramme, but one sample contained 54 per gramme. Their presence was not related to general contamination as judged by coliform estimations. No information was available as to how these *Salmonella* strains gained access to the egg powder. In a second paper⁶ the authors investigated the effect of drying, storage, and cooking on the *Salmonella* content. They found that over 99% of the organisms in heavily inoculated liquid egg were killed on drying in an experimental spray drier, and concluded that similar results would be obtained in commercial driers. Storage also is inimical to their survival, and they rapidly diminish in number, surviving the longer the lower the temperature. In cooking experiments with reconstituted eggs heavily inoculated with *Salmonella* organisms they found that the bacilli were all destroyed in egg powder cooked as scrambled eggs and omelettes, and in sponge cakes, custards, and muffins. They therefore consider it is debatable whether the contamination of egg powder with *Salmonella* organisms can be regarded as a health hazard. But F. Sieke⁷ found that

² *J. comp. Path.*, 1940, 53, 80.

boiling ducks' eggs in the shell for shorter than 8 minutes would not make an infected egg harmless.

The present position would seem to be that we cannot entirely exonerate dried eggs from the possibility of acting as a vehicle for the spread of *Salmonella* poisoning, although the risk is probably small. The actual outbreaks in this country of *Salmonella* food poisoning associated with dried eggs are not unusual during the present war, although none has apparently been the subject of a scientific paper.

THIOCYANATES AND THIOURACIL

Sodium and potassium thiocyanate have been used for the treatment of hypertension since Pauli in 1903 discovered the property of lowering blood pressure. While many doubt their efficacy, others are certain that some patients derive benefit. The mode of action of thiocyanates does not appear to have been defined, but the recent evidence concerning substances like thiouracil which affect the thyroid gland probably throws some light upon it. Astwood¹ has shown that when thiouracil is given to rats an enlargement of the thyroid gland follows. From the work of the Mackenzies² and of Astwood and his colleagues it is known that this effect occurs only when the pituitary gland is present, and that it is accompanied by a fall in the basal metabolic rate. Thiouracil, it is concluded, depresses the formation of the thyroid hormone in the thyroid gland, and because of the consequent fall of thyroxine in the blood, the anterior pituitary stimulates the thyroid gland so that this becomes hyperplastic. Thiouracil is now used in thyrotoxicosis because it diminishes the formation of thyroxine and therefore causes the B.M.R. to fall.

Among the substances which Astwood found to cause hyperplasia of the thyroid gland of rats was potassium thiocyanate. It is evident, then, that if patients receive potassium thiocyanate for long periods of time for the relief of hypertension the same symptoms will probably appear in them as have been observed in rats. Foulger and Rose³ describe precisely this occurrence in one patient, and Rawson, Hertz, and Means⁴ describe it in two others, citing more from the literature. In Foulger and Rose's case—that of a woman treated with 0.3 g. potassium thiocyanate daily from March, 1938, to July, 1939—the blood pressure fell from 210/110 mm. to 175/110 mm. In September, 1940, when she was still receiving thiocyanate, she had diffuse enlargement of the thyroid, the B.M.R. was -11%, and there were general symptoms of hypothyroidism; she was therefore given thyroid together with the thiocyanate, with the result that the symptoms cleared up. Later the thyroid was stopped and the symptoms then reappeared. It was finally recognized that the thiocyanate was responsible for the hypothyroidism, and when thiocyanate was stopped the puffiness of the face, the swelling of the gland, and the low B.M.R. disappeared. It is clear from this and other cases that so far as their effect on the thyroid gland is concerned thiocyanates, thiourea, and thiouracil are identical.

The question remains why thiocyanates benefit hypertension. Is it because of this action on the thyroid gland? Does the blood pressure fall because the B.M.R. falls? Rawson, Hertz, and Means⁴ apparently do not think so, at least they state that "thiocyanate could be relieved by the administration of thyroid even when thiocyanate

administration for hypertension is continued." Perhaps they have not considered the point in the form in which it is now presented. It is to be remembered, however, that Blumgart, Levine, and Berlin introduced total thyroidectomy as a treatment for angina pectoris, a condition not unconnected with hypertension. If thyroidectomy benefits patients with angina pectoris, and if thiocyanates, which diminish thyroid function, benefit patients with hypertension there is some likelihood that thiocyanates act in hypertension by diminishing thyroid function. If so, thiouracil should also be of value in hypertension, and might suitably be tried. Astwood, to whom we owe the introduction of thiouracil for thyrotoxicosis, chose it in preference to thiocyanates and other substances because of its lower toxicity.

SUPPLY OF MEDICAL BOOKS

As fellow-sufferers under the rationing of paper and the shortage of skilled labour we sympathize with medical publishers in their wartime plight. A memorandum on the inadequacy of the supply of medical books in relation to present and future needs has been drawn up by the Medical Group of the Publishers Association (28, Little Russell Street, W.C.1). This explains the present serious situation with regard to the supply of books on medicine and its basic sciences, nursing, pharmaceuticals, veterinary science, etc. It urges that adequate measures should be taken to remedy the acuteness of the long existing shortage of such books. No improvement can occur until the Government makes more paper and labour in the printing and binding trades available for educational books. Medical publishers are responsible for maintaining the supply of textbooks, works of reference, and monographs for doctors, research and laboratory workers, medical and dental students, nurses, pharmacists, veterinarians, and all classes of medical auxiliaries. The growth in the numbers of students and practitioners has greatly increased the demands of the medical profession, and the same is true of nurses, pupil midwives, and students of first aid. Meanwhile the requirements of the overseas market are at least twice as great as in pre-war years, for the Empire very largely depends for its supplies on publishers in Great Britain. Various economies have been, and are being, achieved in book production by medical publishers, but these cannot effect a substantial saving. Some medical books are out of print solely because the paper for them is lacking, this applies to textbooks of major importance, and particularly to nursing textbooks. The need for providing reprints and revised editions on the limited paper quota has diminished the production of new medical works, more particularly books on war medicine and surgery wanted urgently for the higher professional education of medical officers in the Forces and the E.M.S. Having already made the point that a distinction should be drawn between "medical books" as understood by us and popular books on medical matters for the general public, the memorandum shows how the shortage of medical books is due to a diversity of causes. Early release of key men to the printing, engraving, and binding trades would have a profound influence if coupled with a less meagre supply of paper. We are at one with the Medical Group of the Publishers Association in urging that the special problems connected with the production of medical books and journals demand full and early consideration. Medicine cannot advance without books and reputable periodicals. Even if the existing difficulties were remedied to-day the demand would long continue to outrun productive capacity. There is bound to be an increasing call both for books that have gone out of print during the war and for new books designed to meet the needs of the

changing curricula of the medical and nursing professions; moreover, the activities of the British Council are stimulating the market for British medical books abroad.

LOGIC AND MEDICAL RESEARCH

Of some men it can be said that whatever they write is valuable, whether the conclusions reached are right or wrong. Nobody doubts now that *The Conduct of the Allies* was bitterly partisan and that *Reflections on the Revolution in France* was coloured by prejudice and violent emotion; but nobody could read either without pleasure and intellectual profit, because Swift's power of lucid and telling argument commands admiration and Burke cannot write a page without some flash of beauty or of insight into human nature. The writings of a third great Irishman, Sir Almroth Wright, have the same effect. Like Swift and Burke, he has been engaged in many controversies and, like them, he has not always been just to points of view with which he has no sympathy; but whatever he has written bears the hall mark of genius. His reprinted paper on Induction¹ contains some passages which a reader familiar with the statistical methods despised by laboratory workers, and indeed in their early childhood a generation ago, but now almost universally adopted, must think inexact; but even statisticians can learn something of value from the censures. There is a danger—not threatening statisticians alone—that some men will believe that Nature's secrets can be wrested from her by anybody who has learned a sufficiently elaborate technique. "Pray, what do you mix your colours with, Mr. Opie?" "With brains, Mam." Brains are as important in the art of medical research as in that of painting; in both technique is important too, but secondary. The Wrights, like the Opies, are contemptuous of mass-produced research. Blackmore, better known as a versifier than as a physician, was a pupil of Sydenham, and when he asked his master what he should read was told to read *Don Quixote*. Dr. Johnson reproved Sydenham for jesting, but perhaps the great man intended to convey to his pupil the truth that it is not by reading books one becomes a physician. One cannot learn from books how to become a great researcher. Something can be learned by study of masterpieces, although even then there is the difficulty familiar to students of the noble game of chess. One need not be an adept to be thrilled by the way in which a Morphy or a Lasker destroys his antagonist in a few moves, by, shall we say, a crucial experiment. But the student—unless himself a Morphy—only learns a little, a very little, of the process which enabled Morphy to make the crucial experiment, and will not learn it from treatises on "openings." That is one of Sir Almroth's lessons: the amount of pains, imagination, and hard thought which prepare the way to a crucial or decisive experiment. It is possible to help a beginner by a logical analysis of methods of discovery. Here again the humble analogy of a mere game is serviceable. A famous teacher of chess of the last generation, James Mason, once said that a careful study of a few of the stock methods of beginning a game was of much more value than trying to learn the tricks of this or that gambit. Sir Almroth helps the student by contrasting the various senses or connotations of the term "induction" and the shades of meaning of "control" as used in clinical or laboratory research. He proposes a new terminology which seems to us good, although the modern prejudice against "dead"

languages may hinder its adoption. He makes good play with the dangers of under- or over-simplification in experiment; in his terminology, hypoclastration and hyperclastration. The former he illustrates by the conclusion of the Victorian physiologists that nutrition was explicable on quite simple physical analogies; the experimenters had not realized adequately that there was a difference between supplying calories and giving foodstuffs. The latter he illustrates by the remark that to test the value of antiseptics by successive dilution with water fallaciously omitted albuminous substances which operate as quenching and buffering advepts whenever antiseptics are employed in local treatment or are administered internally.

Few readers will agree with all Sir Almroth's conclusions; still fewer will not profit by a careful study of the essay on Induction. The word "research" has propagandist value now; it is good that young people should learn that it is not much easier to enter the kingdom of genuine research than the kingdom of heaven.

WAR AND MENTAL HEALTH

For reasons of paper economy the annual reports of the Board of Control are not being printed or put on public sale during the war. Its example might well have been followed more widely. Summing up the effect of war on mental health, the Board finds no evidence that the war has brought about any increase in serious cases of mental breakdown. Though admissions to mental hospitals do not by themselves give a complete picture of the incidence of psychosis and neuropsychosis, they indicate the general trend. Even in the "blitz" areas there are relatively few cases in which the mental breakdown can be attributed with certainty to the effects of war and more particularly of air raids. Where breakdown appears to have been caused or accelerated by air raids it is generally found that the patients' past history suggests that they might have developed mental trouble in any event, though possibly at a later date. A recent neurosis survey carried out by the Ministry of Health did not show any alarming increase in neurosis, particularly when allowance was made for the fact that the war had forced into industry, often in unfamiliar and trying conditions, many who previously led sheltered lives and whose breakdown under unaccustomed strain might have been thought inevitable. "Looking at the situation as a whole, we feel that it may fairly be claimed that the war has demonstrated the mental stability of the nation." The Board, at the request of the War Office, has organized a scheme of after-care for Service patients discharged from special hospitals and E.M.S. centres on account of psychiatric disability or mental abnormality. The aim is to secure that patients will, on discharge, know where to look for skilled treatment and advice. In co-operation with the Ministry of Health the Board has also undertaken a follow-up of ex-Service cases of this kind. Such inquiries will be purely fact-finding and will not overlap the after-care scheme; they will cover cases discharged from the Army through E.M.S. neurosis centres. The Board is also assisting the War Office in a follow-up of cases discharged from military mental units; wartime difficulties of staff, however, will not permit detailed inquiries now, but when the investigation can be completed "it should throw valuable light on the success of modern methods of treatment." At the end of 1943—the year covered by the Board's 30th report—the number of persons suffering from mental disorder notified as under care in England and Wales was 147,557 (63,054 men and 84,503 women), and over 86% of them were being treated in mental hospitals provided by local authorities.

PREAMBLE TO POST-WAR FOOD EDUCATION

BY

I. LE GROS CLARK, M.A.

We have made during the war a far more systematic attempt than ever before to influence the public in the choice and preparation of their food. The scope and plan of the wartime campaign will be briefly examined below. The question that naturally arises at the present stage in our affairs is this: What are our prospects of continuing this wholesome work in more normal times and what are the conditions for its success?

But first how far will this leaven of teaching and persuasion be necessary after the war? We can argue for it in this wise. A sound dietary is part of the broad basis of social stamina and good health, and we may assume that a fair proportion of our annual expenditure on ill health is indirectly attributable to poor feeding. The exact proportion could scarcely be demonstrated, but the evidence is sufficiently good to make it worth our while to see whether we can effect a saving. This, however, is still a matter of persuading the public to eat the right food even where wage-levels and prices are so adjusted as to allow a reasonable standard of consumption, the food may be available, but it does not follow that it will be consumed. The truth is that when a civilized community has a very wide choice of foods there is nothing in Nature to prevent it from adopting the most lamentable pattern of food habits and within that pattern of food habits it will live and die for all time unless some effort is made to change the pattern. It is useless to hope that tastes and habits of this kind possess some internal power of effecting their own improvement. Man is an omnivorous animal, a fact to which no doubt, he in some measure owes his survival, but he is ill supplied with instincts in the choice of food, and he has to pay for his survival by gradually shifting the choice of his foods on to a rational level. He will otherwise, since he is obviously not protected by instinct, be subject merely to a mass of whims, traditions, customs, and cravings.

In that case the work might as well be undertaken. There is no chance that a brief campaign will have any effect whatever, this is a job for a lifetime. It is one, moreover, that needs strict scientific method and an appreciation of the anthropological material with which we are dealing. The technique is that of the leaven and not that of the textbook. Provided we understand this and admit the premises, there seems good reason for continuing our campaign of food education even if we have to adapt our style and our methods to the conditions of peace.

Food Advice Centre

The structure assumed by the present campaign is somewhat after this manner. Most of the work is fostered by the Ministry of Food, in the sense that considerable funds are required and that the Ministry is naturally felt by a people at war to be the well head of sound advice in the matter of food. The other Departments and the voluntary organizations, that all have their part in the work, acquire a peculiar virtue in the mind of the public through their association with the Ministry. The Ministry of Food may properly deny that it is more than an equal partner in this campaign with the Ministries of Education and Health, but the fact is that "food" to the public means the Ministry of Food.

The immediate contact the Ministry has with the public lies of course, through the Press, the radio, the leaflet, and the poster. Its more pervasive influence is exerted through two special devices—that of the "food advice centres" and that of the "food leaders' schemes." These are perhaps the most interesting aspects of the whole campaign. All else that the Ministry has done by providing itself with experimental and practical kitchens and developing an effective news-letter and bulletin service is merely what any serious organization of the kind would do if it had the funds.

The method of the food advice centre is that of renting a shop in a good thoroughfare, equipping it for cookery demonstrations, and staffing it with two or three qualified

women. Centres of this nature were first opened by the Ministry in 1940, and there are now some 40 of them. It is, of course, obvious that the direct influence they can have reaches a very small percentage of the public. As often in cases of this kind a centre or a shop window may vaguely affect the public mind by its mere existence, it impresses upon the shopping women of an area that food and cooking are matters of national interest, even if no more than 10% of them enter the premises or pause to study the window display. But it would be almost impossible to assess the extent of this influence. As time went on, the centre became rather the office of the organizer, from which she might arrange for the delivering of lectures or demonstrations in factories, village halls, and so forth. The ability of two or three qualified women to permeate a large area was really the factor that counted, and the technique of the travelling van, of the news-letter, of the shop display, and of the poster have all been tried.

Food Leaders' Scheme

But by 1942 it was evident that a very large proportion of housewives were still uninfluenced to any calculable extent. Some new device was needed for the dissemination of elementary teaching. The earliest of the food leaders' schemes was initiated in Birmingham, and they have since spread rather unevenly through the West Midlands and the Home Counties, with a gradual but perceptible growth elsewhere. It must be noted that here the Ministry of Food assumes no direct responsibility, though in practice a fair amount of the basic work has usually to be undertaken by the food advice organizers. The idea of street or village "food leaders," who would transmit advice and information to their neighbours, was soon realized to be insufficient unless it were associated with some kind of elementary classes for the prospective leaders. This not only brought the schemes within the sphere of what is known as "adult education" but it might imply that premises would at times be needed for the holding of classes. Now, it is the Ministry of Education that is responsible for adult education, and, so far as the Ministry of Food is concerned, almost the only available premises in any area are the schools. In practice, however, what has often happened is that the women's organizations prompted by the Ministry of Food, have gone ahead with the selection of their prospective food leaders and on making formal application to their local education authority, found it too short staffed to undertake more than a fraction of the lectures that were needed. But the Ministry of Education remains ultimately the responsible department, and in theory the education authority of each area transmits to the local food advice organizer most of its functions in the training of the food leaders.

There was probably a further doubt that for a time affected the judgment of the Ministry of Food. The schemes had not been originated by the Ministry of Food, but by an education authority. The women they were intended to organize were almost entirely unqualified lay women, whose advice and counsel would presumably be sought and absorbed by an indeterminate mass of housewives. If there were in the recesses of the Ministry a few tolerant minds prepared to take the risk of something going wrong, several of the practising dietitians were more dubious. It was accepted, of course, that the food leaders were not to teach or lecture, they were to be no more than a leaven of right thinking in the urban streets and in the countryside. But the distinction could not readily be drawn, no one could forbid them to lay down the laws of correct feeding. In effect, the trained dietitians have not always been enthusiastic in their dealings with the local food leaders, even if they have done their duty by them: the two modes of teaching and persuasion have never quite fused into a single instrument.

Style of Wartime Food Education

But when we come to examine the literature of the movement, embodied in its pamphlets and news letters, it occurs to us at once that, however enduring may be the knowledge imparted, the form and style of the teaching have almost invariably a wartime flavour. The reason given for the proffered advice is the scarcity of many foods, and the appeal is for housewives to play their part in maintaining the fitness

of a people at war. The assumption behind it all is that there will come a time when these motives will no longer operate. It is, in brief, a wartime movement only, and there can be no unbroken transition from the forms of war to those of peace. The fact is that the campaign is devised to catch the largest and least-organized section of our adult population, the housewives, and to draw it functionally into the total war economy. In its "food leader" aspect it meets a need, in that it attempts to resolve the self-contained lives of an increasing number of housewives into the common effort; it gives them the *raison d'être* for their many discomforts and supplies them with the first requisite of every trade or calling—a specialized and easily accessible literature. There is no question that the news-letters and pamphlets distributed from the local centres of instruction have a very unifying and stabilizing effect upon the communities they reach.

After the war we shall have a different and a somewhat more complex problem to face. Much of the way in which we re-orientate our campaign will depend upon the extent of the final rupture between war and peace. If all the forms and phrases of war lapse with the transition, the process of re-orientation will be far more tedious and debatable. Because of the prestige it has earned, and the common admission that if anyone has a right to talk about food it is a Ministry of Food, the survival of the Ministry even in a very modified form is a matter of some importance to us. It is an elementary fact that the teaching of other Ministries on the subject of food is suspect to many members of the public, and they would be well advised, perhaps, to leave most of it either to a reconstituted Ministry of Food or to some body contrived for the purpose, that will have to earn its reputation by its work.

No small part of the relative success of the Ministry of Food has been due to the fact that it has never announced any intention of *educating* the public; it has merely "advised" and "informed." We must recognize that the average adult woman in this country has no wish to be further *educated*, least of all in matters of diet; but she is quite prepared to assimilate learning about subjects that seem to her interesting or useful. If we want the post-war woman to absorb into her daily life the knowledge of food values we must make our matter both digestible and palatable. One lesson from our wartime experience seems clear; and that is that probably 90% of housewives will not come to formal classes and demonstrations. They may be led to do so in the future; for the moment they do not. The only obvious method of reaching them is through the technique of the social leaven, the stall in the market-place, the village expert, the informal parlour gossip, the flower-show quiz. We shall have to take our chance that from time to time some curious doctrine or twisted interpretation will gain credence; the risk has always to be taken by those who set themselves the slow task of changing the daily habits and the ingrained patterns of taste of a population. But we must recognize from the start the distinction made in the public mind between *health* teaching on such matters as venereal disease, diphtheria immunization, or dental treatment, and *food* teaching that has reference to a positive and daily satisfaction. The clinics, the medical practitioners, and the societies established for health propaganda can all play their part; but if the movement is to be effective it must mean by food precisely what the public means by food—that is, far more than a physiological basis for sound metabolism.

Changed Conditions of Peace

To what extent, then, may we assume that our wartime methods will have to be modified to meet the requirements of peace? Our main public is the community of housewives; and much will depend on our ability to maintain in the mind of the average housewife the sense of her social function. There is a risk that this sense will be lost when the close of hostilities relaxes the cohesive bonds that unite us in some measure towards a common task. It seems likely that the joint consultative committees of the women's organizations that have emerged in the course of the war will survive it and will provide a starting-point for the period of new construction. They account between them, it is true, for only a relatively small proportion of the housewives of the country; but they

are a pervasive influence, and a joint committee of this nature can often take on a vitality of its own that transcends influence the sum of its component parts.

What we have to seek is some method of creating a firm of change in the views and practices of women in the kitchen. The concept of "food leaders" is the most-satisfactory one that has so far emerged from our wartime experience. I there are two or three comments that must be made on the scheme as it might in theory be applied in a post-war economy. (1) We shall have, in my opinion, to discard the phrase "food leaders" and contrive a more suitable one. The term accepted in war, when a nation takes on the semblance of an army; but it is only just accepted. There are even now some doubts whether the title and the badge may not arouse more resistance than respect among a woman's neighbours. (2) The flow of news-letters seems an essential feature of such a movement: it is both its pulse-beat and its organic unity. (3) The movement will have to be associated, both in the mind of the average housewife and in that of the dispersed body of women who have to do the work, with a source of authority that enjoys high prestige. What that source will be it is not for me to suggest: the practice in this country is often to establish a council with a certain degree of independence which is known to possess the confidence of a State Department. (4) If there are a number of qualified women employed in the campaign, as at present, they will have to be selected not merely for their dietetic training but for their appreciation of the techniques that will be in use.

There are, no doubt, many among them who begin to comprehend their business as a branch of applied anthropology; but the merging of expert and inexpert functions should be more complete and durable than it has so far proved.

Basis of Post-war Food Education

There are two further aspects of a post-war campaign on which we may comment. It is a principle of educational theory that teaching in mature life is best associated with a practical job that concerns the learner; the confusion lies in our tendency to label this kind of teaching as merely *technical*, where it implies no more than that the job is the obvious point upon which we should concentrate. Now, a housewife's job is the buying, storage, and final preparation of the food; and the kitchen is her workshop. If the Ministry of Food survives the war in some form it might do worse than present itself to the public as essentially the housewives' Ministry; and the basic substance of our story should be the shopping basket and the kitchen stove. But we must by all means avoid concentrating our teaching either at the extreme of the "food values" kind of discourse or at the extreme of the "cooking and bottling demonstration." They both have their place; but they must be related to our central duty of realizing housewifery as a social function with its tools of work, its raw materials, and its body of consumers.

The other aspect that is worth mention is this. A movement of this nature should have its local habitation, the permanent sign of its existence, the source from which its influence is diffused. It might be suggested briefly that there are three types of establishment we could use for our purpose. One is the obvious shop premises adapted as now for the "food advice centre" service. On the assumption that some of these centres are maintained after the war, it will be necessary to review their work and decide how far they are really worth the cost. The second is the school kitchen, with which a large proportion of our primary schools are apparently to be provided; these kitchens are the concern of the mothers whose children will be fed from them, and they may well become the natural gathering-place, on selected evenings, of many of the housewives of a neighbourhood. The third establishment we might seek to use is the grocer's shop and the dairy. It is true that some educationists would prefer to have their food-teaching uncontaminated by the flavours of commercially retailed bacon and butter. But shops are still a part of our national life; and they are a significant part of the experience of every housewife. If we are to influence popular tastes we must some time begin with the distributive trades, for it is obvious that if we do not draw them into collaboration we may find ourselves competing with them.

Some such course as this will have to be adopted if the wartime experiment in dietetic teaching is not to lapse when the phase of reconstruction is upon us. We have suggested a few reasons for maintaining it in a suitably modified form; and these reasons could theoretically be expressed in financial terms, even though it might be impossible precisely to weigh the saving in hospitalization against the expenditure on public teaching. It is not the business of this essay to decide who shall meet the bill or what the annual dimensions of the bill might be. We are for the moment solely concerned with the conditions necessary for a successful peacetime campaign, for if we do not determine the right conditions before we start we shall spend whatever money we spend to no useful purpose.

A NATIONAL DENTAL SERVICE

TEVIOT COMMITTEE'S RECOMMENDATIONS

The White Paper on a National Health Service said that there must be some temporary exceptions to the comprehensiveness of the service, and dentistry was mentioned as the first of these, owing to the insufficient numbers of dentists to serve the whole population. The Interdepartmental Committee on Dentistry, which has been dealing with the question of adequacy among other matters, has now issued an interim report.¹ The committee was set up in the early part of 1943 under the chairmanship of Lord Teviot, and consists of twenty members, one-half of whom hold a dental qualification. Its outstanding recommendations are:

- (1) The setting up of a comprehensive dental service to form an integral part of, and to operate simultaneously with, the National Health Service
- (2) A general dental practitioner service analogous to the proposed general medical practitioner service in the Government scheme.
- (3) Experimental dental health centres in suitable areas.
- (4) A special effort to improve the teeth of expectant and nursing mothers, children, and adolescents.

Dental Man-power

Some 15,000 dentists are at present on the *Register*, but owing to the large admission of bona-fide dentists at the time of the Act of 1921 the *Register* is at present heavily over-weighted in the higher age groups, and during the next few years there will be a rapid loss of names by retirement. The average annual admission to the profession in recent pre-war years was 340, but during the war years the annual student entry has fallen to below 300, and 10% of students, for one reason or another, do not become dentists. These figures are not nearly sufficient to maintain the *Register* even at its present strength. An actuarial table is appended to the report showing that if the number entering the profession annually were raised to 400 in the years immediately ahead, and later to 425, it would still be 30 years before the present effective total number of the profession would be increased. "This," says the committee, "is an alarming forecast."

At present the career of dentistry is relatively unattractive to young people in comparison with other professions, especially medicine. The work is apt to appear unpleasant and its scope restricted, at all events until the scientific interest of it begins to be appreciated, and there is not much opportunity for specialization. There are five dental schools in London, seven in the English Provinces, three in Scotland, one in Northern Ireland, and four in Eire. Some of the schools, like the English provincial ones, are closely associated with universities; others, like the London schools, with hospitals.

Dental Needs and the Present Services

The report says bluntly that "the state of dental health of our population is bad, and its effect on their general health is bad." An average of 90% of the male recruits to the Army in the present war needed dental treatment on enlistment. Of a group of 10,000 Scottish five-year-old children, only 1,000 were found free from dental caries. One approved society in one year found that 12.2% of young persons between 16 and 19 who applied for treatment needed full upper and lower dentures. In the last pre-war year about 3½ million elementary-school children in England and Wales were dentally inspected; some

2½ million were recorded as requiring treatment, and about 1,600,000 had some treatment. The majority of local authorities, as part of their maternity and child welfare services, make some provision—in most cases meagre—for dental attention. Dentistry is an additional benefit under National Health Insurance, and roughly two-thirds of insured persons are entitled to it, but only 800,000 (less than 7%) claim it on the average each year. "It is a common experience in insurance dentistry that people do not resort to treatment until a stage when the teeth are unserviceable, and then there is gross oral sepsis."

The broad picture of the present position is of a number of public dental services not closely related, and each with shortcomings, and of a public ill educated and apathetic in regard to the care of the teeth. The committee believes that fear of pain and lack of understanding of the importance of dental health are more effective deterrents than the economic factor.

Steps towards an Adequate Service

In making its recommendations the Teviot Committee distinguishes between the *need* for treatment and the *demand* for treatment. If the demand for treatment rose to somewhere near equality with the need there would obviously be a shortage of dentists. It must be the object of policy to increase demand in this way, but the whole question of the shortage of dentists turns upon the probable pace of increase in demand and supply.

"If, for example, a total annual demand rate of the order of 10% to 20% were the experience in the next few years, and if vigorous measures were taken to make the career of dentistry attractive, we foresee no substantial shortage. If, on the other hand, the annual demand rate rose rapidly to 40% or 50% and the numbers of the profession showed no rapid increase, the shortage would be very serious."

The committee urges the acceptance of the principle of a comprehensive service, one which, while not wholly adequate, will be equally available to all who demand it, and will be paid for by the community as a whole. It regards dentistry as an integral part of the comprehensive health service, a fact which in itself, with the prospect of plenty of work, adequate pay, good conditions of service, and the knowledge that dentistry was making an essential contribution to national health, would encourage the recruitment of young men and women to the profession.

The sharpest point in the mobilization of dental forces should be the dental care of expectant and nursing mothers, children, and adolescents. The committee looks for a large expansion of dental services available to school-children (under Section 48 of the new Education Act) as one of the essential foundations of a comprehensive service. It also hopes that employers will give their workers, particularly adolescents, time off without loss of pay for dental treatment.

Fundamental points in any new comprehensive public dental service will include the following:

- (1) No compulsion on any dentist to enter the public service.
- (2) Any dentist should be free to engage, either whole-time or part-time, in the service or any branch of it in which there is opportunity to serve.
- (3) A patient must have free choice of dentist and liberty to alter his choice if he so desires.
- (4) The proposals are not intended to interfere with the free right of everybody to seek dental advice and care through private arrangements and by private fee.

Family Dentists: Health Centres

The idea of a general dental practitioner service, analogous to the general medical practitioner service, available to all who wish to use it, and set up on the basis of the family, is put forward in the report. The idea of the family dentist is as yet unfamiliar to a large part of the population; the committee thinks it should be developed and encouraged.

The setting up in suitable localities of dental health centres, providing facilities for team work, is recommended. These centres should be experimental, and the profession should be consulted as to their development, size, siting, internal arrangement, design, and equipment. There must be no compulsion on dentists to work in such centres or on patients to receive their dental treatment in them.

Finally, there are some recommendations on dental health education. The most important factor in such education will be the quality of the treatment given. The dental health centre

would offer, by means of lectures, films, and the like, opportunities for enlightening the public. "We do not wish to separate dental from general health education; the one is a sentence on the page of the other. But we are anxious that the sentence should not be crowded out; rather than that, we would have it given a page to itself."

Recommendations for securing an increased entry into the profession will be dealt with in the final report. Here the committee urges only the encouragement of ex-Service men and women to offer themselves for dentistry, and the early release of dental teachers from the Forces to resume their work in the schools.

SEVENTH ADDENDUM TO THE BRITISH PHARMACOPOEIA

The General Medical Council will publish on Feb. 1, 1945, a Seventh Addendum to the *British Pharmacopoeia*, 1932, in which new monographs, and modifications of existing monographs, will be included. Arrangements have been made for a limited number of advance proofs to be available, on application, to manufacturers of the preparations described therein, in order that facilities may be provided for the supply of substances in accordance with the new specifications, as soon as they become official.

The following new monographs will be included:

Amethocainae Hydrochloridum	Sulphacetamidum
Amphetamina	Sulphacetamidum Solubile
Amphetaminae Sulphas	Sulphadiazina
Cyclopropanum	Sulphadiazina Solubilis
Dextrosium Hydratum	Sulphaguanidina
Injectio Insulini Protaminati cum Zinco	Sulphapyridina
Liquor Sodii Citratis Anticoagulans	Sulphapyridina Solubilis
Liquor Sodii Citratis cum Dextroso	Sulphathiazolum
Oestradioli Monobenzoas	Sulphathiazolum Solubile
Oestronum	
Potobarbitonum Solubile	
Potassii Sulphas	
Progesteronum	
Strophanthinum-G	

There will also be a general monograph on tablets (including general processes, standards for uniformity of weight, and a disintegration test) and 34 monographs on individual tablets.

The Addendum will contain, in addition, amendments to the *British Pharmacopoeia*, 1932, which have been made official by notice in the London, Edinburgh, Belfast, and Dublin *Gazettes*.

All the official ointments have been reviewed, and a number of revised monographs for ointments are contained in the Seventh Addendum.

The Addendum will contain also new or revised appendices relevant to the monographs in question, and a cumulative index. It must be understood that no additional monograph, or emendation of a monograph, is official until the Seventh Addendum has been published.

SOCIAL BIOLOGY AND THE POPULATION PROBLEM

In a valedictory address from the presidential chair of the British Social Hygiene Council Sir WALTER LANGDON-BROWN discussed social biology in its relation to the population problem.

The family, he said, was the biological unit, and he regarded with grave suspicion the efforts of planners to dethrone the family and to hand children over to the State. The fact that some family life was far from what it ought to be was no reason for destroying something which, in the vast majority, was good. The birth rate had fallen fairly steadily since 1920, and during the same period the infant death rate had decreased and the expectation of life had lengthened. It had been rashly assumed that the level of fertility remained the same, but there were many evidences that the fertility rate decreased with improvement in the chances of survival. The conclusions of a special subcommittee appointed by the British Social Hygiene Council were that one-tenth of all marriages remained childless, though not deliberately so. The great majority of the population did not intend by contraceptive measures to procure permanent barrenness. The subcommittee did not report whether such measures contributed to sterility, and on that question he himself would be non-committal. Medical evidence was accumulating that the one-sided view that if there was barrenness it was the woman who was generally responsible was wrong. From a study of 2,000 marriages it appeared that the defect was on the man's side in 60%, and in general the average male fecundity was much lower than was usually assumed. Couples accepted their fate without generally

asking for medical help, though such help was now more effective than formerly, owing to new knowledge.

Turning to other factors operating against the family Sir Walter Langdon-Brown said that he was impressed by the rise in rents which had taken place since the turn of the century. The Victorian rule was that not more than one-sixth of income should be spent on rent, and that at a time when rates were low and income tax negligible. The proportion of total income which went in rent and rates in these days was alarming in its repercussion on family life and on infant mortality, for money was spent on housing which should go on food. The aggregation of urban populations led to the increase of flats, which were an unsuitable environment for children. Decentralization of industry offered some solution, but the real trouble was that building costs had increased so greatly that it was impossible for suitable houses to be made available at an economic rent. Thus there was resort to subsidies, the limit of which might be approaching. The Victorian principle was that everything should be self-supporting so far as possible, but there was danger also in the modern view that nothing need be self-supporting. Family allowances were proposed as an extension of social service, but he could not believe that a standard flat rate would prove satisfactory. It would be of small value except to those at the lowest income level, while those at a higher level would be more heavily taxed in consequence, and therefore might be inclined to limit their families still further. The social changes which compelled later marriages must be recognized. Celibacy was enforced for longer or shorter periods upon our young people. The position was difficult and the difficulties would increase as a result of the toll taken by war. There was scope here for study by the social biologist and for the spread of helpful information. Family life in a good home was the best foundation on which to build the new world.

Dr. Otto May proposed and Dr. Letitia Fairfield seconded a vote of thanks to Sir Walter Langdon-Brown, and the meeting proceeded to elect Prof. F. A. E. Crew of Edinburgh as the incoming president. Warm tributes were paid to Mrs. Neville-Rolfe for her many years of service as secretary-general, from which she is retiring, and she was made a vice-president. The annual report of the council was adopted on the motion of Sir George Elliston, seconded by Mr. McAdam Eccles.

Reports of Societies

TREATMENT OF DUODENAL ULCER

At a meeting of the Section of Surgery of the R.S.M. on Nov. 1 Sir JAMES WALTON, the president, opened a discussion on the treatment of duodenal ulcer by saying there was some danger to-day of going back to the mediaeval concept of authority and accepting the written word instead of the Hunterian notion of research and experiment. The young surgeon, while making himself familiar with Continental literature, should beware of thinking that what was stated there about duodenal ulcer, for example, necessarily applied to cases seen in this country. There was only one indication for surgical treatment—namely, failure of medical treatment; but this varied with the social condition of the patient. A well-to-do man, living a sheltered life and able to diet carefully, was obviously different from the labourer in respect to treatment. In this country the operative procedure for duodenal ulcer had varied between posterior gastro-enterostomy and partial gastrectomy. He still regarded the former as the ideal operation, and reserved the latter for cases which had developed gastro-jejunal ulcer, trying to judge beforehand in which this was likely to arise. For partial gastrectomy his present choice was Billroth I, which he thought less apt to cause immediate disturbance to the patient. To-day the use of the drainage tube was being decried; he had never known it to cause trouble.

Mr. C. JENNINGS MARSHALL said that duodenal ulcer was primarily a condition for medical treatment; surgery was indicated only in certain cases. But the number of medical regimes—all successful, in most cases, until the next time—should lead one to the common factor—rest in bed. Medicines and diets were directed to reducing the "acid in the stomach," but hydrochloric acid digested nothing, and any excess above 0.08% resulted in no increase of peptic activation. If it were conceded that the gastric secretion was, in part at any rate, responsible for the ulceration, at least it was to be urged that for prognosis and diagnosis a coefficient of

peptic activity should be noted, not of HCl. While there was some rough parallelism, yet some of the largest gastric ulcers might be associated with a low HCl secretion, even with achlorhydria, but apart from that there was reason for regarding high secretory activity as secondary to peptic ulceration, not causative.

With or without treatment 80 to 85% of cases of duodenal ulcer did not need surgery, and roughly one-sixth developed either imperative indications or progressed slowly to chronic invalidism or economic crippling. Perforation called for surgery, and so did recurrent massive haemorrhage; but apart from these cases there were others which from the first relapsed rapidly after the most stringent medical treatment, and there were the chronic slowly progressive ulcers which produced increasing economic invalidism. As for choice and results of operation, in 250 resections for duodenal ulcer there had been 7 deaths. In 35 resections for gastro-jejunal ulceration there had been 4 deaths. Of 350 gastro-enterostomies, done largely in the pre-gastrectomy era, about half the cases had been traced or reported, and two-thirds of these were free from serious symptoms. He had seen no serious case of anaemia follow resection.

Medical Treatment

Dr. HORACE EVANS said that in most cases the diagnosis of duodenal ulcer was fairly easy. The history was typical and x-ray confirmation made the diagnosis complete. But sometimes the history was difficult, particularly in women. One point was the frequency with which complications such as haemorrhage, perforation, and even stenosis might occur with minimal dyspeptic symptoms. In the more acute superficial ulcers, very shortly after the haemorrhage, no trace of the ulcer might be demonstrable radiologically. Much time and labour were wasted on test meals—of real value only in cases of obscure anaemias, some cases of carcinoma of the stomach, and cases of chronic gastritis.

The speaker had been impressed by certain aspects of medical treatment. Satisfactory healing was unusual if the patient was ambulant. There should be a minimum period of six weeks' rest in bed, followed by a further six weeks' quiet period. Mental relaxation was as important as physical, and sedatives were more important in the healing of the ulcer than alkalis. To suppose that alkalis formed a soothing lining in the stomach and duodenum and maintained a lower acid content was fantastic. In the feeding of the patient the nature of the feeds mattered little as compared with their frequency. Sometimes harm was done by too strict a dietetic regime. In hospital the results of treatment of these patients in special gastric wards with a proper regime and exclusion of unsuitable foods had justified itself. If the need for surgery did arise, certain often neglected points should be stressed. Pre-operatively the state of the lungs should be ascertained, not only by clinical but by x-ray examination, and the question whether the patient was anaemic or not was also important.

Sir HENRY TIDY felt that peptic ulcer on the Continent was not the same as in this country. Indeed, geography was a factor in all assessment. The incidence of gastric and duodenal ulcer—both total incidence and the incidence of the one as compared with the other—was entirely different in Scotland from what it was in London, both being far commoner in Scotland. Duodenal ulcer was extremely common in South India but almost unknown in North. He suggested that most gastric ulcers which began in early life were cured, disappeared, and did not recur. Duodenal ulcers followed a different pattern. Gastric ulcer increased enormously all over England between 1920 and 1930, but the incidence of duodenal ulcer during the same period actually fell. Both surgeons and physicians agreed on the necessity for rest in bed—and that was the first thing the surgeon ensured by his operation. Medical treatment was much easier to repeat than surgical treatment, and with it there were better results the second time the patient was treated than the first.

Types of Duodenal Ulcer

Major-Gen. W. H. OGILVIE confessed himself "distressed" to hear Mr. Jennings Marshall allude to "peptic ulcer." He thought that the distinction between gastric and duodenal ulcer was an established one. They were two distinct diseases. It

might almost be said that in duodenal ulcer they were dealing not with one disease but with one of three—duodenal ulcer A, B, and C. Duodenal ulcer A should be left to the physician so far as possible. It was associated with rapid emptying and high acidity. The patient was likely to be a "go-getter," of worrying temperament, and a cigarette smoker. Duodenal ulcer B was the ulcer which perforated and was practically never chronic (chronic ulcer did not perforate). The patient might be a healthy workman in full work and perfectly well until 48 hours beforehand. Many of these cases showed no further trouble. Duodenal ulcer C was an ulcer which bled—meaning by bleeding, catastrophic haemorrhage. The history was a silent one, not a duodenal ulcer history. This was a disease of "better-off" and of rather older people. Such an ulcer was an indication for surgery. The mortality after one attack was about 8 to 10%, and if the group were followed up the eventual mortality might be found to be very much higher.

Prof. C. A. PANNETT contested Major-Gen. Ogilvie's statement that duodenal ulcer A was a medical disease. There were numbers of patients treated medically whose life was a misery from constant pain. He did not think a treatment was worth anything if it had to be carried on for the rest of the patient's life. Undoubtedly medical treatment cured a number of ulcers permanently, but he did not think a man who had to take alkalis rapidly and continuously could be said to be cured of his ulcer. Yet in such cases surgery would bring about an absolute cure. His own standard of cure was that a man should go away and at least within three months be able to eat anything and within a year to eat normal-sized meals without having to think about them.

Mr. HERMON TAYLOR spoke of the man who got steadily worse after having conservative treatment for many years. What was the surgeon to do? The choice between partial gastrectomy and gastro-enterostomy was one on which there was a division of responsible opinion. He had set to work on some of the intractable cases of dyspepsia in which the operation of gastro-enterostomy had failed. All patients with duodenal ulcer had a marked excess of folding in the gastric mucosa. The late Sir Arthur Hurst had pointed out that the degree of rugosity in the stomach was a congenital characteristic. This seemed to him a rational explanation of the varying response of patients with duodenal ulcer to gastro-enterostomy. It appeared that gastro-enterostomy was sufficient to cure a duodenal ulcer provided there was not too great an excess of gastric secreting area, but if there was a gross excess then the patient was worse off than before and got a gastro-jejunal ulcer. In cases in which there was an excess of folding a partial gastrectomy should be done. No severe operation was justifiable if a less hazardous one would cure the patient. There was no comparison between the risk of gastro-enterostomy and of partial gastrectomy, and the latter should never be done unless it was "the only way."

Mr. G. W. BERESFORD said that apart from rest there was nothing one could do which could be called medical treatment. The most satisfactory operation for chronic duodenal ulcer was a subtotal gastrectomy. He repeatedly saw cases in which gastro-enterostomy had been done which not only developed gastro-jejunal ulcer but years afterwards got recurrent duodenal ulcer. Dr. J. I. SPIRA mentioned the treatment of chronic peptic ulcer on a low-fat diet. Mr. HAROLD DODD said that in the few cases in which he had carried Somerville's operation out the functional result was good, though the fractional test-meal showed no difference. He had not found from his follow-up that any more patients developed anaemia after partial gastrectomy than after gastro-enterostomy.

At a special general meeting of the Royal Academy of Medicine in Ireland, held in the Hall of the Royal College of Physicians of Ireland on Nov. 24, Mr. A. A. McConnell, F.R.C.S.I., was elected President of the Academy.

E. P. Scott and A. B. Ormer (Amer. J. Dis. Child., 1944, 68, 118) report a case of typhoid fever in a boy aged 11 years who survived successive multiple intestinal perforations. They appear to be a "record."

Correspondence

Time of Ovulation

SIR,—I appreciated the admirable annotation on ovulation and fertilization which appeared in your issue of Oct. 21 (p. 537). The facts as stated in this note have been substantiated by the majority of embryologists working on early human development. The letter by Prof. F. Davies of Sheffield, which appeared in your issue of Nov. 18 (p. 671), calls for some comment. The menstrual history of the patient, from whom the 9-10-day embryo was secured, is apparently the crucial point on which he bases his conclusions as to the time of ovulation. Even, however, on the assumption that ovulation occurred on the ninth or tenth day of this cycle, there is no evidence that the cycle, if uninterrupted by pregnancy, would have been a 28-day one. In fact, Prof. Davies, in his article with Harding (*J. Obstet. Gynaec. Brit. Emp.*, 1944, 51, 225), states:

"It is noteworthy that the histological structure of the endometrium on the 20th day of the cycle in the present case is closely similar to that of the endometrium on the 24th or 25th day of a 28-day cycle in a number of specimens examined by the present authors, and it is certainly much more advanced in the secretory phase than many 20-day specimens examined from women with 28-day cycles; in these cases ovulation probably occurred about the 14th day."

These changes in the endometrium, which are in agreement with the findings of Rock and Hertig (*Amer. J. Obstet. Gynec.*, 1942, 44, 973; 1944, 47, 343), point clearly, in my opinion, to the conclusion that the relevant cycle of the case described by Prof. Davies, had it been completed, would have been of about 24 days. This, of course, would mean that ovulation occurred at the time indicated by the writer of your annotation. Prof. Davies, in support of his thesis, then refers to five ova, described by Miller, Engel, and Reimann (*Growth*, 1938, 2, 381) and Reimann and Miller (*Arch. Pathol.*, 1939, 27, 412), and states: "All five of these ova indicated that ovulation occurred 15 to 17 days before the onset of the next menses in these 28-day-cycle cases. . . ."

The facts concerning three ova of this series, on which data are presented, are as follows: The first specimen was recovered on the fifteenth day of a cycle the length of which is not stated. In one ovary there was a fresh corpus haemorrhagicum "which on section proved to be a very young corpus haemorrhagicum in which no lutein cells had as yet been differentiated." The second specimen was recovered on the sixteenth day of the cycle; the previous cycles of this patient were of the 28-day type. This ovum was thought to be one day older than the first specimen. The third specimen was recovered on the fifteenth day after the onset of the last period; the previous cycles were of an average 28-day type. Section of the corpus haemorrhagicum showed a considerable amount of blood and a few differentiated lutein cells. For their investigations Miller *et al.* used 24 operative specimens. These authors state:

"Judging from the experience with these 24 specimens, excluding the 21-day ovum, the periods of the cycle during which the best chances are present of finding an ovum in the tube are between the fourteenth and the sixteenth day after the onset of the previous menses. The ovum recovered on the twenty-first day was degenerated and apparently had been withheld in the tube, since the tube was tortuous and offered resistance to the passage of the wash fluid. We believe the ova entered the tube on the fourteenth day after the last menses, assuming that ovulation took place at the same time in all three individuals. This is the obvious conclusion for two reasons. Specimens removed on the thirteenth day failed to yield ova. . . ."

It is true, however, that in the summary of their paper in *Growth* these authors state:

"Judging from the days during which these and other ova were recovered the ovulatory period is between the eleventh and thirteenth day after the onset of the previous menses in 28-day-cycle cases." In my opinion this statement is not borne out by their own findings. Finally they state:

"Probably the earliest day that the ovum can be found in the Fallopian tubes is the fourteenth day after the onset of the last menses." This of course would mean that the ovum takes several days to reach the tube after ovulation—which seems most unlikely.

It may be of interest to add that I have recently recovered two further ova: one, at the pro-nuclear stage, on the

seventeenth day of a cycle of the 28-day type; the other, an abnormally segmented egg, on the eighteenth day of a cycle of the 28-day type. It is probable that the first specimen is about 48 hours and the second specimen is about 72 hours old. —I am, etc.,

Anatomy Department, St. Bartholomew's
Hospital Medical College.

W. J. HAMILTON.

The Nursing of Tuberculosis

SIR,—Your annotation on the nursing of tuberculosis (Oct. 28, p. 569) calls for comment. Quoting the combined report of the Joint Tuberculosis Council and the Tuberculosis Association, you state that the risk to sanatorium nurses of acquiring tuberculosis is no higher than that to which general hospital nurses are subject. The important recently published work of Daniels, the Prophit scholar (*Lancet*, Aug. 5 and 12), on primary tuberculous infection in general hospital nurses shows that this risk is not inconsiderable, and he makes the specific recommendation that Mantoux-negative nurses are not to be allowed to work in tuberculosis wards. He shows that of 42 nurses initially Mantoux-negative, 33 developed tuberculosis, as compared with 2,120 Mantoux-positive, among whom 43 developed tuberculosis.

In view of this much higher observed incidence of tuberculosis in Mantoux-negative nurses in general hospitals it would seem probable that the same finding is likely to apply in sanatoria. A small series of figures from the tuberculosis hospital with which I am associated tends to support this view. During the past few years some 30 probationer nurses have been received for three months' training in tuberculosis. Of approximately 189 Mantoux-positive on arrival, 1 has subsequently developed tuberculosis, and of 32 negative, 4 have developed tuberculosis demanding institutional treatment. In addition, of the 32 approximately 25 became Mantoux-positive during their three-months stay. (I write from memory as I have not at the moment access to the figures, which are, however, substantially correct.) These figures, which are admittedly too small to be of statistical value, are, at any rate, suggestive, and I have as a result terminated the experiment and no longer allow Mantoux-negative nurses in tuberculosis wards.

Admittedly sanatoria have and usually exercise their facilities for Mantoux testing, radiographing, and "keeping nurses under observation," but none of these procedures will prevent the nurse from being infected during her work. To know that a nurse is Mantoux-negative is valueless unless that knowledge is applied by removing her from the tuberculous environment. The report as quoted by you states that a nurse of 18 runs no more risk of acquiring tuberculosis than one of 21; agreed, but only if she is Mantoux-positive, which is rather less probable.

In short, it is unfair to the individual Mantoux-negative nurse to expose her to the risk of acquiring tuberculosis; nor will the admittedly difficult problem of staffing tuberculosis institutions be solved by converting with certainty a proportion of Mantoux-negative nurses into tuberculous patients. —I am, etc.,

Abergele, N. Wales.

W. E. SNELL.

Endotracheal Connexions

SIR,—At a thyroidectomy recently I was administering nitrous oxide and oxygen through an orotracheal tube when the Magill connexion became detached from the tube. The patient's face was covered with a sterile square, and it was a few moments before I discovered what had happened. In these few seconds the tube had worked itself down quite a few inches, in spite of a pharyngeal pack, and was astonishingly near the glottis before I rescued it. Since then I have had a small hole bored through each side of all my Magill and Rowbotham connexions, and after inserting the connexion in the tube I put a safety-pin through the tube and through the holes, transfixing both tube and connexion. This makes the union quite secure. The hole must not be too small, or it will be difficult to find when it is hidden inside the tube. From experience I have found that if the holes are about 2 mm. in diameter and are placed about 1 cm. from the distal end of the connexion no difficulty is likely to occur in transfixing them.

I have found this very useful in the case of the new vinyl-plastic tubes, which do not hold a metal connexion very securely when they are soft after boiling. Apropos the vinyl-plastic tubes, I find them delightful for oral intubation, and I think they are kinder to the tissues than the rubber ones. I have found, for instance, that after the operation is over and the tube is withdrawn the end which has been in the trachea is quite soft and flabby with the heat of the body, and I believe it will be less likely to cause tracheal irritation than the harder rubber tube. For nasal intubation it seems less useful. It is a little hard and rigid unless boiled immediately before use, and then it becomes too soft and loses its curve. It certainly passes through the tube very easily then, but blind intubation is less likely to be successful. I hope the makers will be able to produce one with rigid walls for nasal use—I am, etc.,

A. McCALLUM MILLAR

Artificial Respiration

SIR.—Surely the first essential in the treatment of respiratory arrest is to ensure that the resultant anoxia is counteracted without delay. Normally the chief function of respiration is the oxygenation of the blood, if the patient stops breathing for himself the obvious and most imperative remedy is for someone else to do it for him.

The first thing to be done is to make sure that the airway is clear, this point is often forgotten, not only in the resuscitation of the apparently drowned but even in the ideal conditions of the operating theatre. Next a well-fitting mask, with the expiratory valve closed, should be applied to the patient's face and connected with a breathing bag full of oxygen. If now the airway is kept clear and the bag is squeezed oxygen must be forced into the patient's lungs, and the chest will in fact be seen to expand. Release the pressure on the bag and the recoil of the thorax will cause expiration to take place. Continue the rhythmic contraction and expansion of the rebreathing bag, and so long as the airway is unobstructed and the circulation is adequate, the blood will be completely oxygenated and the patient will suffer no harmful effects of anoxia.

This is the simplest and most effective method of artificial respiration. It is without danger, whereas ribs can easily be broken—and frequently are—by over-energetic measures applied directly to the chest wall, and it has the added attraction that it is considerably less tiring. Then, when all this is done, and then only, should any recourse be had to drugs.

Dr. Bartley (Nov. 11, p. 643) apparently regards artificial respiration as tedious and useless exertion. In the absence of an unobstructed airway, of which he makes no mention, any such exertion is completely useless and therefore bound to be attended by the anxiety which colours his picture. The drugs he mentions will lose none of their power, and will, in fact, probably not be needed if no time is lost in relieving the anoxia first in the simple way I have described.

While discussing analeptic drugs may I correct a false impression from my views on this subject which I find has resulted from the wording of Dr. Thacker Neville's letter (Sept. 23, p. 415)? In this letter he says: "As regards Dr. Roberts's criticism on the use of picrotoxin, in future I shall accept his criticism and use leptazol, which is as active as picrotoxin if given in larger doses than picrotoxin, and is certainly more potent than coramine," thereby creating the impression, as I have discovered in conversation with many scattered readers of the *Journal*, that I recommended the use of leptazol in preference to picrotoxin. Actually in my letter (July 29, p. 161) I made no mention of leptazol: my main contention on that occasion was the same as in this letter—namely, that it is better to ensure that the apnoeic patient is not anoxaemic by the simple method of introducing oxygen to the lungs via an unobstructed airway than to put one's faith in any reputed cardiac or respiratory stimulant drug—I am, etc.,

F. W. ROBERTS.

London, W.1.

Anaesthesia and Shock

SIR.—I have read with interest the article in the *Journal* of Nov. 25 on general anaesthesia in shock by Crooke, Morris, and Bowler. Their conclusion that variations in blood pressure

during anaesthesia do not indicate any significant change in the plasma volume or haemoglobin concentration is important, and is an interesting contribution to our knowledge of the conditions associated with operative shock.

I do, however, find myself in disagreement with some of the statements made about anaesthesia. I would deny that the anaesthetic is the most important single factor concerned in the high mortality associated with operations on seriously shocked patients. I think that the anaesthetic matters much less than the way it is given. To get the best results in these cases it is essential that the anaesthetist should be experienced in this type of work, and not only in the administration of anaesthetics but in the uses and abuses of resuscitation and in the judgment of optimum time for surgical intervention. He should have followed his cases through their re-suscitation, operation and recovery, or otherwise in the wards, making full use of his blood-pressure apparatus and notebook. The question of the particular anaesthetic agent which he favours is a minor one. Experience has shown that the skill in the proper use of intravenous therapy is often the determining factor in serious cases. Many a patient has suffered from overdose of fluids, morphine, or heat.

I cannot understand the statement that blood-pressure changes were not found to be related to any particular operative manipulation by the surgeon. My experience is that blood-pressure changes are commonly caused even by a gentle surgeon, particularly in shocked cases. Traction on the parietal peritoneum of the upper abdomen, whether direct or through some other organ, causes an initial fall followed by a smaller rise. Exposure of a large length of bowel outside the abdomen will lower blood pressure. Raising of the kidney bridge or gall-bladder bridge will sometimes influence blood pressure. Heavy retraction of limb muscles will lower blood pressure in the seriously ill patient. I agree that these effects are not so obvious when regional or local analgesia has been used.

In my view resuscitation should not be regarded merely as leading up to surgical operation. The process of resuscitation may be a long one, extending over several days, and the operation and anaesthesia should be a part of the resuscitative process. If operative intervention is well timed it will usually be found that the condition of the patient is better after operation than it was before.

The authors conclude that the chief factors in anaesthetizing shocked patients seem to be: first, the use of a minimal amount of anaesthetic; secondly, the choice of an anaesthetic which stimulates rather than depresses the cardiovascular system; and, thirdly, an adequate amount of oxygen. My chief three factors in anaesthetizing shocked patients would be: first, anaesthetizing them at the right moment in the progress of resuscitation; secondly, maintaining an airway which is absolutely above suspicion; thirdly, in suiting the plane of anaesthesia from minute to minute exactly to the surgical procedure.

I agree that good oxygenation is important, but CO₂ retention, which may be present in spite of good oxygenation, is equally important as a cause of post-operative collapse. Finally, of all the five cases of shock quoted none suffered from injuries of the abdomen, thorax, or airway. It is in these cases where the choice of anaesthetic and technique provides the more interesting problems.—I am, etc.,

Colchester

DOUGLAS CLENDON.

Spinal Anaesthesia in Penetrating Abdominal Wounds

SIR.—In Major T. Moore's article on underwater blast injuries of the abdomen (Nov. 11, p. 627) there is a statement that cannot be allowed to pass without comment. He writes: "The other death occurred, just as the operation was about to be started, in a short-necked emphysematous patient. A spinal anaesthetic had unfortunately been administered by the Etherington-Wilson technique. It was undoubtedly the cause of death." Since the beginning of the war I have anaesthetized over 350 persons suffering from penetrating wounds of the abdomen, a condition in many ways comparable with that described by Major Moore. My experience confirms the wisdom of the usual advice that spinal anaesthesia should not in general be used in these cases. It is more than probable that it was the choice of spinal anaesthesia and not the choice

of the Etherington-Wilson technique that was the cause of death in the case described by Major Moore.

It would be a pity if statements such as that quoted were to bring into disrepute a technique of spinal analgesia that was most carefully evolved by the originator, possesses many advantages, and, when the indications for spinal analgesia are observed, has proved both safe and reliable in many different hands in many thousands of cases.—I am, etc.,

Major, R.A.M.C.

Sign for Acute Retrocaecal Appendicitis

SIR.—In the *Medical Annual*, 1944, under the heading "A New Sign in Appendicitis," R. Capurro of Montevideo is quoted as maintaining that whether the inflamed appendix is normally placed, pelvic, or retrocaecal, tenderness can be elicited by deep pressure at a point just internal to and above the anterior superior iliac spine. This sign is not new. I read of it first some twelve years ago as a sign for acute retrocaecal appendicitis. It was attributed to a French surgeon, whose name I have unfortunately forgotten. I have used it since then in some hundreds of cases, and I can vouch for its value in cases of acute retrocaecal appendicitis. In these cases the maximum tenderness will be found just internal to the anterior superior iliac spine; this does not hold for other positions of the appendix. The sign is best elicited by sitting facing the patient, placing the four fingers of each hand over the iliac bones, with the thumbs resting just internal to the anterior superior spines. Gentle pressure with the left thumb will give marked pain in cases of acute retrocaecal appendicitis. In such cases I always use the Rutherford Morison incision, which gives ample exposure. I am sure the sign has a definite value, more especially as the acute retrocaecal appendix is so often missed in its early stages.—I am, etc.,

Warrington.

J. J. MANNING.

Treatment by Movement

SIR.—I read with interest Dr. James Cyriax's article in the *Journal* of Sept. 2 (p. 303), and should like to be associated with him in stressing some of the points, at the same time criticizing others. His article deals with:

1. Treatment by movement as soon as possible and choice of type of therapeutic movement, which varies from tissue to tissue, with the nature, position, and extent of lesion, with the integrity or not of such structures as nerve or bone, and with the presence or absence of bacterial infection
2. Modern methods in the treatment of fractures.
3. The need for deep massage in certain strains of ligaments and muscle attachments working over bone, and in cases of tenosynovitis.
4. The use of passive movement in addition to active movements to maintain or restore full joint movement.
5. The use of faradism only in initial stages.

One of the most difficult problems in treatment of injuries of all types is to know what degree of graduated movement is the right amount for each injury at the stage of recovery in which it is examined. The different types of graduated active movement pass through a sequence of movement from complete rest through gentle movements without weight-lifting to every form of vigorous violent movement. There is no doubt that the A.I. soldier requires to be as fit as an international footballer for the duties of modern warfare, and it is not surprising to find that many injured soldiers break down in their training, as their joints are so damaged by the original injury that they are unable to withstand the strain to which they are subjected.

The presence of circulating toxin from some distant focus will naturally interfere with recovery, and in joint injuries, where this is the case, attention may be drawn to it, apart from general and local signs and symptoms, by the following points: (1) The amount of synovitis is out of all proportion to the injury force. (2) The synovium is thickened and spongy. (3) The controlling muscles stutter and twitch on attempting active movement, or when stimulated with faradism. (4) The blood sedimentation rate is raised in some cases, as well as the white cell count. (5) The joint shows failure to respond to exercises and physical treatment by the appearance of recurrent synovitis.

The degree and amount of active movement should vary with each case of injury and should depend on: (1) The amount of traumatic effusion present. (2) The relation of the area of cross-section of the injured structure to the total cross-section of the limb involved. Thus a ligamentous injury taking up a small area of cross-section can be supported, and active movement with weight-bearing or strain started at once, in contrast to a badly sprained joint in which a large portion of the cross-section is involved and in which (3) there is a secreting membrane made sensitive by the injury.

To understand the stages in recovery it is essential to realize that the amount of traumatic effusion can be out of all proportion to the injury, especially if a small vessel is ruptured with the formation sometimes of an enormous haematoma. The natural absorption of haematoma is taking place all the time, but its spread is governed by the following: (1) The forces of gravity either in an upward or downward direction, according to the position of the limb. (2) By the action of the muscles squeezing it towards either their origin or their insertion with the aid of gravity. (3) The direction of fascial planes helped by gravity and muscular action. (4) The direction of venous and lymphatic flow.

I am convinced that, apart from the accurate setting and stabilization of fractures by screws and plates, the excellent results obtained in the early full movement of the neighbouring joints is partly due to evacuation of the haematoma at the time of operation. It would appear to me as a criticism that in cases where screws or plates are employed insufficient understanding in the use of external fixation by plaster was still prevalent. Where a fracture of the tibia and fibula is fixed by a substantial plate and transfixing screws no plaster is necessary. But where screws alone are used in tibial or humeral fractures, or a femur is plated, it is essential for a time to use external fixation by plaster.

I had the opportunity of seeing the results of a few cases of fracture of the femur and tibia treated by the Germans with a long intramedullary hollow metal nail. At the end of 6 to 9 months there was some periosteal bone formation, but naturally little endosteal callus; on removing the nails, however, and applying a spica or long leg plaster, the fracture ends soon consolidated. The nail is introduced through the inner side of the greater trochanter and pushed down the medullary cavity. Another small incision over the fracture allows it to be threaded through the distal fragment, and at the same time fracture haematoma is allowed to escape. By this manoeuvre and early knee movement stiff knees were prevented. I consider there may be a definite place for this method in the future treatment of certain fractures of the femur—viz.: (1) introduction of nails; (2) treatment of overlying muscles and neighbouring joints; (3) weight-bearing after 6 weeks; (4) removal of pin at 3 months; (5) plaster-of-Paris walking spica for 2 months.

At the end of six months the femur is firmly united with no knee stiffness. I have been using a method of treating all fractures or injuries with extensive effusion in which open reduction is not indicated by making small longitudinal incisions and thrusting in pointed scissors down to the swelling and allowing drainage or expression of haematoma. Naturally absolute asepsis must be practised, but the results in severe external rotation fracture of the ankle-joint, severe Colles's fracture, and dislocated elbows justify this procedure. It is also combined whenever possible with the cutting of suitable windows for the daily application of faradism, which naturally is combined with active exercises. A more detailed communication on this method is to follow.

I am glad that Dr. Cyriax drew attention to the need for deep massage in certain cases, as the teaching is so much against massage in general that it is often denied to cases in which it should be the main treatment. I would like to add to his list of suitable cases enlargements of infrapatellar pads of fat and collections of organizing haematoma in places where there are no muscles, so-called "dead areas." I am certain that Dr. Cyriax would be first to agree that other forms of physical treatment, such as anodal galvanism, diathermy, heat, and faradism, are a great adjunct to massage.

I am surprised that he uses the phrase "passive movement," and I agree with Watson-Jones that the term should be used only in cases of paralysed muscles. Dr. Mennell has stressed the importance of the range of involuntary movements possessed by each individual joint and how important these movements are for free painless active movement.

Gray's *Anatomy* describes them as accessory movements and divides them into two types: (1) Certain movements which cannot be performed voluntarily, but only when resistance to active movement is encountered, as in imparting spin to a cricket ball with the fingers, thus causing a rotation at the metacarpo-phalangeal joint.

(2) Movements with complete relaxation of the muscles, as in the play between articular ends of the bones forming a joint.

It is evident then that every mobile joint has a range of (1) active voluntary movement; (2) involuntary movement. These involuntary movements allow for gliding of one bone on the other, rotary movements, and side bending. If after a simple sprain of a joint there are pain and limitation of movement at the end of two months, most orthopaedic surgeons would recommend a manipulation of the joint under anaesthesia but if gentle manipulative movements are carried out as part of the other treatment, such as exercises, massage, contrast baths, and fluidism, it is seldom that there is not a return to full range of joint movement in any sprained joint at the end of three weeks. Therefore I suggest that it would be better to delete the phrase "passive movement" and substitute "gentle manipulative movements." Apart from that, the methods of applying the manipulative movements are quite different, and, as Dr. Mennell points out, passive movements themselves are the cause of inflammatory reactions and increased stiffness, which gentle manipulative movements never produce.

Another important distinction in active movement, which I did not consider he brought out, is the difference between isometric and isotonic movements. With an injured limb in plaster movements will be isometric—i.e., the muscle contracts and broadens, but does not lengthen. As the joint has been placed in the optimum position of rest, movements of this type will prevent wasting of muscles and overstretching of the antagonistic muscles, and at the same time hasten the absorption of traumatic effusion. In isotonic movements, although the tone in individual muscle fibres is equal, stretching and alteration in the length of the muscle take place. This may lead to overstretching of one group of muscles with contraction of their antagonistic group. A good wrist-joint and ankle-joint plaster should allow both types of movement, so that the muscles acting on the joint can only move isometrically, whereas, with the wrist and ankle fixed the fingers and toes can move isotonically. While in plaster the patient must be told that not only must he carry out walking exercises, but he must do each individual movement against the resistance of the plaster so as to bring into use each group of muscles.

Faradism given properly throughout aids and encourages active movement, and allows each muscle of a group to be actively stimulated individually, so that one muscle works on the other, preventing intermuscular adhesions. This is not allowed by active group movement alone, and one only has to see cases treated by exercises plus faradism compared with those treated by exercises alone, to appreciate the difference in recovery time.—I am, etc.,

Major, R.A.M.C.,
Orthopaedic Specialist

Incidence of Peptic Ulcer

SIR,—In your leading article (Nov. 18, p. 665) you refer to the need for statistics of the total incidence of peptic ulcer in our population. May I suggest that this war has provided a simple means of obtaining such figures? I refer, of course, to the fact that the Ministry of Food has decreed that every sufferer from peptic ulcer is entitled to priority milk and eggs. Every food office in the country must be aware of the number of priority forms it has received bearing the figures "1d" (milk) and "1" (eggs) all such forms must indicate patients with peptic ulcers. Surely it would be possible, through the Ministry of Food, to collect such figures and thus determine the total number of peptic-ulcer patients at any given time.

I can think of two possible fallacies: first, that some people who have ulcers have not bothered to obtain their extra milk and eggs (in my experience such a class must be extremely small); secondly, that some doctors may have given to patients without ulcers the necessary forms. Again, I think this must be very rare.

In any case, a very good idea could be obtained of the number of persons in this country who have peptic ulcers sufficiently troublesome to warrant their consulting a doctor.

—I am, etc.,

Outwood, near Wakefield

J. D. BOTTOMLEY, M.B.

Sodium Bicarbonate and Peptic Ulcer

SIR,—In view of present-day opinion on the action of sod. bicarb. in stimulating the secretion of HCl, and thus conducing to the formation of peptic ulcer, would it not be wise to omit this ingredient from the tablets magnesium carbonate compound of the *National War Formulary*?—I am, etc.,

Maiden Newton, Dorset.

C. LL. LANDER.

Latent Mastoiditis in Infancy

SIR,—May I, as the otologist to the North-Western Hospital, where the possibility of mastoiditis in infants with gastro-enteritis always receives full consideration, make some answer to Mr. Leathart (Nov. 11, p. 637) and some otological comment on Drs. Patterson and Stewart Smith (Nov. 18, p. 659).

In the first place there can be no possible clinical doubt that mastoiditis can play a very important part in the syndrome which we call acute gastro-enteritis of infants. I am not as yet quite sure whether I agree with Mr. Leathart that the disease is a primary mastoiditis, or, more accurately, a primary upper respiratory infection with a secondary gastro-enteritis; or whether there is primarily a virus-produced gastro-enteritis, which, as a result of lowered resistance, allows organisms already present in the upper respiratory tract to become extremely pathogenic. Personally, I incline to the latter theory, but at the moment we have not sufficient evidence to decide one way or another. One can, however, say quite definitely that in a large number of these infants there is a clinically demonstrable upper respiratory infection which most often shows itself as an otitis media, which may or may not proceed to a clinical mastoiditis.

Drs. Patterson and Stewart Smith consider that the diversity of organisms found in the mastoid is a proof that the infection is not a primary condition. That is certainly not a tenable hypothesis. No matter what one's age the organisms found in an acute mastoid can be most varied and can vary in the two ears in the same patient.

Mr. Leathart has done great service in pointing out the three types of bone infection that can be met. My own experience agrees with this, and I have often seen operation on the purely mucoid type followed by an immediate and dramatic improvement. One might add that many a mastoid is passed as uninfected at post-mortem because it only contained mucus and not frank pus. Presumably the mucoid type is only the early stage of an acute infection, brought to the otologist's notice because of our old friends—the virulence of the organism and the resistance of the patient.

I cannot agree that posterior-triangle glands are always an indication for operation. They certainly indicate an otitis media, but I have seen many cases with glands which have recovered without operation. I do not, either, pay much attention to head-rolling, etc.; I prefer to go by the condition and progress of the child taken in conjunction with the aural findings. And it cannot be too strongly emphasized that a gross infection of the mastoid can exist with no more demonstrable lesion of the ear than a loss of the light reflex and a dulling of the tympanic membrane. Hence the necessity for careful and repeated examination of the ears. The appearance of the ears can change completely in a few hours, and the first clinical sign may be sudden dehydration in a child that had previously to all appearances been doing well. It is our rule that no gastro-enteritic baby should be allowed to die—there being no obvious cause for its death—without having its mastoids explored. As I always operate with local analgesia the process is as quick and devoid of risk as possible.

There are some points in the Manchester article which cannot be passed over without comment, as they are definitely misleading. The authors state that under the age of 2 years the mastoids are undeveloped. This is quite untrue. I have seen many completely cellular mastoids at the age of 4 or 5 months, and I am very much inclined to think that an acellular structure at that age is more often an indication of a past infection than of a normal structure.

Subperiosteal abscess is not a common complication in gastro-enteritis; I have never seen it, nor should I have said it occurs commonly in any infantile mastoiditis. Similarly, meningitis is rare. Drs. Patterson and Stewart Smith have rather confused the issue by discussing all infantile post-mortems which showed mastoiditis, whereas Drs. Eiser and Alexander, and Mr. Leathart, have been discussing gastro-enteritis. In this disease the common complications, apart from mastoiditis, are septicaemia (which is usually overlooked), bronchopneumonia, secondary anaemia, and toxic hepatitis. More than one of these conditions can coexist—a fact that has always to be borne in mind. It would seem that all Drs. Patterson and Stewart Smith have shown is the frequency

with which a lethal condition can exist in infants and escape notice. Admittedly, the condition can be most difficult to diagnose. All the more reason, therefore, for it never to be forgotten. The operation table should be the place for infantile mastoiditis and not the post-mortem table.—I am, etc.,

London, W.1.

WINIFRED HALL.

Episiotomy

SIR,—Mr. J. D. S. Flew, in his excellent paper on episiotomy (*Journal*, Nov. 11), which deserves widest circulation and attention, suggests calling slight descent of the anterior or posterior vaginal wall "vaginal hernia" or "prolapse of the vaginal wall." In my modest opinion this would add another misnomer. Why not call it rightly "descent," and that "anterior vaginal wall descent" and "posterior vaginal wall descent" respectively (*descensus vaginae*). More advanced cases should be nominated "*descensus vaginae et vesicae*," whereas still more advanced cases should be called "cystocele" if it is according to the anatomical findings. Applied to the posterior wall the respective names would be "*descensus vaginae et recti*" and "rectocele." Those cases in which the portio uteri appears in the vulva should then be labelled "*descensus uteri*," and the name "prolapse" left for those cases in which the uterus (or a part of it) is really prolapsed—i.e., fallen out (of the body)—and forms the contents of a bag of the inverted vagina (with or without a part of the bladder).—I am, etc.,

A. W. B.

Artificial Insemination

SIR,—Obviously this new procedure belongs to the same category as birth control and masturbation, both now condoned, even advocated, "in their place." The sexual appetite exists in all or most people; why then, the argument runs, should it not be assuaged "when it becomes too strong to resist"—so long, that is, as any resulting inconveniences to "the community" are fully insured against? Similarly, a woman wants to gratify her "maternal instincts" and have a baby (and the population needs to be increased in view of the ravages of war, of road motor traffic, and so on). Why, then, should she not have a baby if the thing can be done with a minimum of trouble to herself and her husband, he being perhaps incapable or, in any case, uninterested? There are in abundance maternity homes, anaesthetics, crèches, and so forth, and when once her infant, begotten by inoculation, begins to show signs of having a will and personality of its own, and so giving her trouble, the State will take it over and "direct" it into the right paths, while she, the mother, will be relieved of all further responsibility.

As against this facile reasoning, however, comes the awkward fact of the home and the family. This happens to be, in the nature of things, the basis of social stability and coherence—opposite pole from anarchy and chaos. (And alas that our educational authorities themselves nowadays fail to grasp the elementary fact that the home and its surroundings, form the young child's natural primary school!)

To say that artificial insemination is justified because it has restored family harmony in such and such a case is exactly like advocating the extended use of opium or alcohol for all the troubles that beset the mind.

Our profession is already suffering badly from competition by the faith healers, patent-medicine makers, and so on. Let it beware lest it lose caste still further by subscribing to this latest doctrine and practice of social disintegration. Man, as distinct from the animals, is provided with brains and an imagination, through which he can transmute his impulses to fine gold.—I am, etc.,

North Queensferry, Fife.

A. J. BROCK.

SIR,—Dr. Joan Malleon chides us who condemn artificial in-
mination for our lack of objectivity and for our appeal to emotion. With respect I suggest that the boot is on the other leg. Dr. Malleon's appeal is on behalf of the woman married to the sterile or impotent husband. In other words, it is a citation of the hard case which notoriously makes bad law, and is essentially emotional. The traditional view of Christendom in regard to marriage and the family is based on

a comprehensive objective view of man's whole nature and his weaknesses, and a rational appreciation how the best individuals can best be procreated. Precisely because it regards matrimony as so good it hedges it around with reasonable restrictions; that is what the rational mind does with all good things, and the better a thing is probably the more restrictions in order to prevent the swamping of the best by the less good.

Dr. Malleon's letter is full of appeal to emotion. The spoilt child, in spite of all appeals to reasonableness, nevertheless can only answer, "Yes, but I want to." So Dr. Malleon says of her childless married woman, "Oh, but she wants to." I suggest that rationality does not consist in devising means by which desires condemned by the normal conscience may yet be gratified. Rationality does not suppress emotion and desire, but controls them.

Many experienced practitioners have known cases where a woman who has had herself sterilized on similar emotional grounds has subsequently on cool rational reflection bitterly regretted it. For several millennia women have ministered to men's pleasures and borne children. These two functions have not markedly raised women's status in the eyes of men. The women who have made men sit up and take notice have been those devoted women who have renounced these functions, not because they were bad but because, although so good, still better functions, like the supplying of a mother's place to children lacking a mother, could be pursued. Such supermothers I have known who excited profound rational respect and admiration. It is not rational but emotional to enthuse over the woman who has a child by artificial insemination.—I am, etc.,

London, N.16.

E. H. STRANGE.

SIR,—Recent letters in the *Journal* have argued against artificial insemination on the grounds that it is immoral and contrary to marriage vows.

I feel sure that all rational medical men will agree that it is time the profession as a whole became more far-sighted in its outlook on these matters. This is a changing world, and the things which appear to us most stable, such as human nature and morals, must change inevitably. Authorities tell us that life has existed on this planet for 1,000,000,000 years, and there is no reason to believe that it will not continue to exist for millions of years. Our ancestors 60,000,000 years ago were probably some kind of ape. Millions of years hence our descendants may be as unlike us, physically and mentally, as we are unlike apes. A new moral code will have developed by then to meet the demands of changed conditions. Our conception of marriage will possibly have been completely lost. Of course, in a lifetime one can only hope to see a tendency to change, and this will be recognized only by the more enlightened among us. It should be realized that it is quite futile to fight against this tendency. We can see to-day a tendency for man to take his destiny into his own hands. Artificial insemination is one small expression of this tendency.—I am, etc.,

Hartlebury, Worcs.

R. F. STRONGE.

"Dissident Doctors"

SIR,—Dr. Piney's energetic and somewhat emotional response (Nov. 11, p. 640) to Dr. Frederick Dillon's plea (which to me seemed eminently reasonable) for a scientific approach to medico-political problems admirably demonstrates the urgent need for that plea. "It is very odd," says Dr. Piney, "that we doctors . . . should be so easily gulled by the propaganda of authoritarianism." To me it is very odd that he should pay authoritarianism the gratuitous compliment of suggesting that it is the outcome of a scientific approach to politics. It is really rather tragic that at this present juncture the profession, which should be the body par excellence to advise the nation and its legislature on how to implement their resolve to have a better medical service, should speak with so many voices. The old jibe has it that doctors seldom agree, and one would not need to go beyond the pages of the *Journal* to justify it. Yet the jibe is becoming less and less true in the doctor's professional sphere, where a progressively scientific approach is leading to a rather remarkable agreement of opinion. Surely the inference is clear.

I am sure that Dr. Dillon's view (and Karl Pearson's) is right; but I doubt if his appeal will be heeded by many. The issues will, as heretofore, be determined by a clash of prejudice, and a limited advance, probably in the right direction, will be made. This may be for the best. It will leave the real solution to be worked out *through the scientific approach* by younger and less prejudiced thinkers when these are released from their urgent task of ensuring that human progress is possible at all.—I am, etc,

Aberdeen

E R C WALKER

Colonial Medicine

SIR,—The spate of articles, letters, etc., purporting to give pictures of medicine in these long-suffering Colonies of ours continues. May I trespass on the otherwise unsullied pages of the *Journal* to register a further plea, even at the risk of being thought caustic? Might it not be impressed upon intending authors, and then repressed upon them, that there are very, very, very few doctors whose opinions are of any interest locally, or of even approximate accuracy, until they have completed about five years of work actually in the West African Colonies? We do not write a history of England after a fortnight at Brighton. No more can doctors write on West African diseases until they have a certain knowledge of the people, some knowledge of the language, and especially some knowledge of the background of family life. Nor is this knowledge acquired from a few months in the coastal belt. Might we not apply the old adage of "Coasters" after seven years, "old Coasters" after fourteen years, to West African medicine, if we substitute "less ignorant" and "more experienced, but more humble" respectively?—I am, etc

Colony of the Gambia

J S MINETT

Debridement et Épluchage

SIR,—The use and misuse of these and allied words have already given rise to far too much confusion and misunderstanding.

Debridement is derived from *debrider* which is the antonym of *brider* (to bridle, to tie up, to fasten, to constrict). *Debrider* is given the following definitions. To incise or slit up¹, to cut adhesions or tissues which strangle organs (e.g., *debrider une hernie*), or to incise the edges of a wound to provide drainage for pus.² *Debridement* has nothing to do with debris.

Épluchage is used by very few French writers, the majority using *excision de la plaie* (excision of the wound). It is certainly an error to use *épluchage* for *excision*. *Épluchage* means¹ to peel or pare a fruit, and, used figuratively, to examine or criticize in detail. Moreover *épluchage* is not given in Garnier and Delamare's dictionary, which is the standard work in France.

Le débridement d'une plaie means the enlargement of a wound, and *excision d'une plaie* excision of a wound.—I am, etc,

¹ Harrap's Standard French and English Dictionary, London 1934

² Nouveau Petit Larousse Illustré, 310th ed. Paris 1940

³ Dictionnaire des Termes Techniques de Médecine—M. Garnier et J. Delamare, 12th ed., Paris, 1938

The report of the London School of Hygiene and Tropical Medicine for 1942-3 records a heavy programme of teaching and research successfully carried out. Fourteen courses were attended by 921 medical officers of the British and Allied Forces during the year under review. Shortened courses were also provided for new officers of the Colonial Medical Service, and there was a short course in epidemiology for Polish graduates and senior students. The Ross Institute has continued its work in India, Ceylon, and Kenya, where investigations on onchocerciasis in the East African goldfields are in progress; and arrangements have been made for a helminthological survey in Northern Nigeria. Sir Malcolm Watson has retired from the directorship. Research work undertaken includes experiments on the effect of insecticides on an East African tick, *Ornithodoros moubata*, comparative studies on the digestion and breakdown of haemoglobin in different blood-sucking insects and ticks; and an investigation of the chemistry and biochemistry of patulin. A large number of original papers were published during the year by members of the staff.

Obituary

SIR JOSEPH ARKWRIGHT, M.D., F.R.C.P., F.R.S.

Joseph Arthur Arkwright, who died after a short illness at King's College Hospital on Nov. 22, became an eminent bacteriologist though he did not devote himself to the serious study of bacteriology until he was 40 years of age. During the earlier years of his professional life he was a general practitioner, and the experience gained in the practice of medicine beneficially influenced his subsequent researches.

Born in 1864, he was educated at Wellington, Trinity College, Cambridge, and at St Bartholomew's Hospital. He graduated M.B., B.Ch. in 1889 and became M.D. in 1895. After serving as house-physician at St. Bartholomew's and the Victoria Hospital for Children at Chelsea and as house-surgeon at the West London Hospital he embarked on private practice in Worcestershire in 1893. Arkwright was a good physician and successful in his practice, but after 10 years he developed an allergy to disinfectants causing an intractable eczema of his hands. This malady was so great a hindrance in general practice that he was obliged to abandon it. As he had a keen interest in natural history he decided to equip himself in bacteriology. To this end he applied to become a private research worker at the Lister Institute. His application was entertained, and in 1905 he joined a small band of research workers, which included A. E. Boycott and John Ledingham, in the bacteriological department under Prof. George Dean. Arkwright soon became a competent bacteriologist, showed a marked aptitude for investigation, and in 1908 was appointed one of the Institute's bacteriologists. He continued to enhance the reputation of the department by his discoveries for nearly thirty years.

In 1911 Arkwright joined the R.A.M.C. and was posted to Malta to take charge of the pathological laboratory of St. George's Military Hospital on the island. Returning to England in 1917 he devoted himself to the study of the aetiology of trench fever. He served on the Commission set up by the War Office to investigate this disease, under the chairmanship of Sir David Bruce, and was responsible for a section of its experimental work. In 1920 he was seconded for one year for special work to the Ministry of Agriculture's Committee on Foot-and-Mouth Disease. In January, 1922, at the request of the Egyptian Government, he went to Egypt with the late Arthur Bacot to make a study of typhus fever and its method of transmission. Both workers contracted the disease and, although his younger companion died, Arkwright recovered from a very severe attack, largely due to the nursing and care he received from his wife, who went to Egypt to nurse him. Returning to England in June, 1922, he was back on duty at the Institute in September of that year. He relinquished his position in 1927. Retirement, however, made little difference to his scientific activity. He retained his laboratory and was made an honorary member of the staff. He enjoyed the feeling that he need not come to the Institute unless he wanted to, but he came just the same. In latter years administration claimed much of his time and energy. He was a member of the Medical Research Council from 1930 to 1933 and of the Agricultural Research Council from 1931 to 1940. In 1926 he was elected to the Fellowship of the Royal Society, serving on the Council from 1931 to 1933, and in 1932 he succeeded Sir David Bruce as the Society's representative on the Governing Body of the Lister Institute. He was proud of this and gave valuable service in helping to guide its destinies. In 1937 he received the honour of knighthood in recognition of his public services.

Arkwright's researches in bacteriology covered a wide range. The best known are those on the variations of bacteria, on the aetiology and transmission of trench fever and of typhus fever, on the physical phenomena concerned in bacterial agglutination, and on immunity to, and the spread of, foot-and-mouth disease. In all these fields, of investigation he left his mark, and in the case of the first four he was responsible for the articles on the subject in the *System of Bacteriology* edited by Fildes and Ledingham and published by the Medical Research Council in 1929-31.

In the early days of bacteriology, owing to lack of methods of procuring pure cultures, bacteria were supposed to be capable of extensive variations in morphology and properties. Under the influence of Koch the pendulum swung in the opposite direction, and they were regarded as immutable. The latter view, too, had soon to be modified. Variations in form, colony formation, fermentative powers, agglutinability, and virulence were discovered to occur, even when the culture was made from a single bacterium. Variations could be imposed but sometimes appeared to be spontaneous; some were reversible, others irreversible. Arkwright encountered the phenomenon of variability whilst investigating the properties of meningococci isolated from epidemic and sporadic cases. This was the first piece of bacteriological research upon which he embarked. The phenomenon of bacterial variation fascinated him. He continued to study it for more than 20 years, during which he made some conspicuous contributions to the subject. His chapter on bacterial variation in the *System of Bacteriology* is a scholarly exposition of the knowledge existing at that time by one fully conversant with biological principles.

The researches on trench fever were made when he was a member of the War Office Commission charged with the investigation of this disease. In them he had the advantage of the co-operation of his entomological colleague, Arthur Bacot. Trench fever had been proved to be transmissible by inoculation of a small amount of blood from patients suffering from the disease by McNee and others, and this had been confirmed by the American and British Commissions. Circumstances favoured the view that the infection was lice-borne. A small microbe named *Rickettsia quintana*, less than 1/2000 of a millimetre in diameter, had been discovered in the intestines of lice a few days after feeding upon patients. Microbes of a similar character had been shown to be associated with Rocky Mountain spotted fever and typhus, so that it was conjectured that *Rickettsia quintana* was the cause of trench fever. Arkwright and Bacot confirmed the statements that these small microbes appeared in lice after they had been fed on patients and that lice containing rickettsias could produce trench fever in volunteers upon whom they fed. They found, however, that the surest way to produce infection was to rub the intestinal content of the lice into the lightly scarified skin. The association of the infectivity of lice with the presence of rickettsia was proved by them with the use of lice, fed for many generations on Bacot, of which the intestines were free from rickettsia. As no other pathogenic microbes and no filterable virus could be discovered in infective lice it seemed probable that *Rickettsia quintana* was the causal agent of trench fever. Efforts to cultivate the parasite outside the intestine of the louse were terminated because, after demobilization of the Army, trench fever disappeared. Arkwright therefore transferred his attention to another louse-borne disease, typhus fever, the causation of which seemed also to be due to a rickettsia (*Rickettsia prowazeki*). The study of typhus could not, however, be undertaken in London with the same facility as that of trench fever. There were no cases available and human volunteers could not be used. He had to fall back on animal experiments, and, having obtained lice which had fed on typhus patients in Ireland, infected a monkey in London and passed the disease to other monkeys and to guinea-pigs. He subsequently used these animals for his experiments, but inoculation with material containing the infection of typhus produced only an uncharacteristic febrile illness in monkeys, rats, and guinea-pigs. The association of infectivity with the presence of rickettsias in the lice was found. Experiments on animals with human lice were often frustrated, however, because they didn't live long on a diet of animals' blood and, to keep them alive during the few days required for the rickettsias to multiply in the intestine, Arkwright and Bacot had recourse to rectal feeding of the lice with human blood! To avoid this difficulty, experiments on monkeys were made in which the small monkey louse was used. These told the same story of association between infectivity and the presence of *Rickettsia prowazeki* in the gut of the insect.

The handling of lice carrying the infection of typhus is a dangerous pastime, and a high proportion of research workers doing so have become infected and several have thus lost their lives. This danger did not deter either Arkwright or his intrepid colleague Bacot, and when, in 1922, they received an invitation from the Egyptian Government to investigate typhus fever in Cairo they accepted it with alacrity, as likely to afford them exceptional facilities for carrying on their work. For typhus was endemic there and recovered cases on which to feed their lice were available. They had not proceeded far with the investigation, however, when they both contracted the disease, of which Arthur Bacot died.

Arkwright's contribution to the study of foot-and-mouth disease began in 1920 when the Government decided to permit an investigation to take place in this country. A committee was formed by the Ministry of Agriculture to plan and direct the inquiry, and Arkwright accepted an invitation to join it. He undertook later the direction of part of the researches which it was proposed should be made with the employment of small animals at the Lister Institute. He had a small team to work under him and a suitable experimental animal was available, as guinea-pigs had been recently shown by Waldmann to be susceptible and their infection to be followed by sufficiently characteristic symptoms. Among the subjects on which valuable results were obtained were the plurality of the virus of foot-and-mouth disease in this country, immunity to different varieties, and the possibilities and limitations of enhancing resistance to infection by immunization with vaccines prepared in different ways. The survival of the virus in frozen carcasses and other materials, the viricidal action of heat, light, and chemical agents, and the susceptibility of a number of animals which might play a part in distributing the disease were also explored. These researches were published in a series of reports of the committee, and although Arkwright's name appears as joint author of but few of them, they owe much of their success to his inspiration and guidance. In 1931 he succeeded Sir Charles Martin in the chairmanship of the committee. From time to time Arkwright also contributed significant observations on the spread of diphtheria and cerebrospinal fever, and in 1912 he published *The Carrier Problem in Infectious Diseases* with Ledingham as co-author. It presented in readable form the existing knowledge of the part played by the human carrier in the spreading of the six infectious diseases on which the facts are accurately known.

Arkwright was a courteous and kindly person, remarkably modest of his own attainments. He possessed a keen sense of humour and, by his ability to see the humorous side of what were to others irritating occurrences, he avoided quarrels. He was unselfishly good to junior workers with him, and saw to it that they obtained more than their due share of credit for the results of researches inspired, planned, and guided by him. Indeed he possessed the Christian virtues in good measure and was an example to us all.

C. J. M.

H. C.

HENRY BRIGGS, LL.D., F.R.C.S.

We have to record the death on Nov. 22 at Hoylake, at the age of 88, of Dr. Henry Briggs, for twenty-three years professor of midwifery and gynaecology in the University of Liverpool. To mark his long and valuable service in that chair the university made him emeritus professor in 1921 and conferred on him the honorary degree of LL.D. in 1934.

Henry Briggs, son of James Briggs, was born at Pilkington, Lancashire, and from Manchester Grammar School went to study medicine, first at Owens College and then at the University of Edinburgh, where he graduated M.B., C.M. in 1877. He learned his anatomy under Sir William Turner, winning a senior medal in that subject, and clinical surgery under Lord Lister, winning a medal and first prize. He returned to his native county as demonstrator of anatomy in the Liverpool Medical School, and remained in that city until his retirement from active work. He obtained the F.R.C.S.Eng. diploma in 1884 and lived to become one of the oldest Fellows on the list. His early appointments at the Liverpool Royal Infirmary were those of senior resident medical officer, surgical tutor, and anaesthetist, and he lectured for a time in surgery at University College, Liverpool. From that point onwards he devoted himself to obstetrics and gynaecology, becoming surgeon to the Liverpool Maternity Hospital and to the Liverpool Hospital for Women. In 1898 he was elected professor, and held that post until 1921. He founded a new teaching department in his specialty, and took deep personal interest in the building up of its pathological museum, to which he gave a great many specimens of educational value.

Prof. Briggs joined the British Medical Association in 1878, was an associate member of the North Wales Branch, and presided over the Section of Obstetrics and Gynaecology at the Annual Meeting held in Liverpool in 1912. He was also a past president of the North of England Obstetrical and Gynaecological Society and of the Obstetrical Section of the Royal Society of Medicine. He served for some years on the Central Midwives Board for England and Wales under the chairmanship of Sir Francis Champneys. With Edinburgh he kept in touch by acting as examiner in obstetrics for the university, and the Obstetrical Society of Edinburgh made him an Honorary Fellow. His published writings covered a wide range of subjects in his department.

R. L. RAWLINSON, B.Ch.

We regret to record the death of Dr. R. L. Rawlinson, director of the radiological department of the Brompton Hospital. Rupert Lewis Rawlinson was educated at Cambridge and St. George's Hospital, qualifying in 1912. In addition to his appointment at the Brompton, he was honorary radiologist to the Victoria Hospital for Children, medical officer in charge of the electrotherapy department of the Royal National Orthopaedic Hospital, and consultant radiologist to the Ministry

of Health. A colleague writes: The death of Dr. R. L. Rawlinson has deprived us of a great radiologist. His experience was vast and his opinion on a "chest x-ray," though always delivered with characteristic modesty, was unrivalled. Many will recall the wise and humorous commentaries which were a feature of his daily sessions in the reporting room. For the past five years, since the outbreak of war, Dr. Rawlinson lived at the Brompton, where he was a much-beloved member of the residents' mess. Those who met him there will always remember his friendliness and his whimsical humour, which,

although often shrewd, was never unkind. He was reticent by nature, and only those who knew him well were allowed to glimpse the varied store of knowledge which his unassuming manner so often concealed. As a schoolboy he was interested in natural history, and this remained his chief recreation, he became an expert on alpine rock plants, British moths, and other kindred subjects. In his youth he was a mountaineer of no mean order and he was always a keen fisherman. A kindly, generous man with a great sense of humour, he had an abundant capacity for making friends. The news of his death will bring a sense of personal loss to many generations of old Brompton men, as well as to a host of others who were his comrades.

Medical Notes in Parliament

The Coming Session

On Nov. 28, in the Speech proroguing Parliament that day reference was made to the passage into law during Session 1943-4 of Bills providing for the rehabilitation of disabled persons, the building of houses, and the improvement of water supplies and sewerage in rural areas. The publication of proposals for a national health service and a comprehensive system of national insurance was also recorded.

On Nov. 29 the King opened a new Session. The Speech from the Throne said: "My Government intended that, as opportunity serves, progress should be made with legislation arising out of the proposals already made for a comprehensive health service, an enlarged and unified scheme of national insurance, a new scheme of industrial injury insurance, and a system of family allowances."

Measures embodying proposals for a national water policy were also promised.

During the debate on the Address in reply to the King's Speech Mr. ARTHUR GREENWOOD said many members were disturbed by the relegation of certain proposals to a category of those which should be dealt with "as opportunity serves." It was the House's duty to see that promises which had been made were implemented.

Mr. CHURCHILL said there was no question of postponing a Dissolution to carry legislation which, with the best will in the world, could not be carried this Session.

Sir CHARLES EDWARDS regretted that the King's Speech did not mention the health of the people. The Welsh death rate from tuberculosis was 751 per 1,000,000, which was still too high. The medical officer of health told him that for a hospital in Monmouthshire the waiting period was six months and for Monmouthshire people it was over three months. Children under 5 or of school age were in contact with persons

suffering from tuberculosis and awaiting institutional treatment. Of 250 awaiting admission, 42 shared their bedroom with another person.

Manufacture of Penicillin

Mr. GEORGE GRIFFITHS on Nov. 29 raised the question of the manufacture of penicillin in the United Kingdom and the agreement of the British Government with the United States Government concerning it. He said penicillin was closely guarded. Priorities were given to five or six companies. Instead of the British Government taking over the control of the manufacture of insulin they had handed it to the United States and only 5% was made in this country. There was an agreement with the United States that the Forces should have penicillin first. He agreed, but said civilians should have it before German prisoners. In the West Riding County Council laboratory a Czechoslovak doctor had been able to manufacture pure penicillin and lost only 5%, though British manufacturers lost up to 45%. The West Riding County Council could not extend the laboratory and had asked the Ministry of Supply for facilities to do this. The Ministry said the council could continue the manufacture in its own way but must not supply the civil population with penicillin unless they were in West Riding County Council institutions. The council said the Ministry should allow penicillin to be given to anybody where medical officers said it was necessary. This penicillin laboratory was at Wakefield. Penicillin was also made in Bradford and Halifax, but was the "raw stuff" and could only be rubbed into the skin. Was it not time that the monopoly of five firms was ended and that everyone in the country who needed penicillin should be able to get it?

No reply was made by the Government.

Ministry of National Insurance

When the committee stage of the Ministry of Social Insurance Bill was taken on Nov. 14, Mr. PETHERICK moved an amendment to alter the title to that of "Ministry of National Insurance." He said that the name "social insurance" did not mean anything, except that all insurance was to some extent bound up with society. Dr. RUSSELL THOMAS supported the alteration of the title. He said that the word "national" did stimulate some sort of patriotic spirit. He disliked the word "social" immensely because, he believed, it originated in Germany. Mr. Lloyd George borrowed his scheme from the social aspirations of the Germans, but he had the decency to call it "national insurance" when British doctors were going to refuse to work the scheme because of its obvious injustices.

Mr. PEAKE said that the Government included the word "social" because it had been current for many years in international usage. It was a matter, however, for the Committee, and the Government would accept the amendment.

Sir WILLIAM BEVERIDGE said that clearly "social security" was the title in the Atlantic Charter and was understood by people in this country and everywhere as the right title. He opposed the amendment.

The amendment was carried by 170 votes to 80.

Col. ELLIOT moved an amendment to ensure that the close connexion between treatment and payment which existed in Scotland should be continued there. The new steps about to be taken, he said, could be utilized by the existing Minister—the Secretary of State for Scotland. The control of all the great amount of insurance money would pass from Scotland if the Bill went through in its present form. Sir WILLIAM JOWITT, opposing the amendment, said that the object of setting up the Ministry was to make one Minister solely responsible for the various forms of social insurance. If the amendment was accepted a complete division of authority would result. The new Ministry must work on the main principle of devolution. It must decentralize, and leave, so far as possible, Scottish officers sitting in Scotland to deal with Scottish problems with the very minimum of interference from and reference to England. If, for example, an epidemic was breaking out in one of the great cities of England or Scotland, there was at present no means by which the approved societies could communicate with the Ministry of Health. If there were a co-ordinated system of paying sickness benefits on the faith of doctors' certificates, he hoped they would have a Department which would see that these statistics were analysed and checked, so that useful information could be obtained. The Department would be run in collaboration between the Minister of National Insurance and the Secretary of State for Scotland, so that the Ministry of National Insurance could give the Secretary of State what the latter had never been able to have before—the mass of information which came from the payment of sickness benefit, as it must be, on doctors' certificates. It might be that a large number of people in a particular area were getting benefits at a particular time. That

would at once be a pointer, and the medical officer would look into it to see what was the matter. That was something they could not do to-day. The amendment was negatived by 221 votes to 26.

Sir HERBERT WILLIAMS moved an amendment, which, he said, raised the question whether they were going to separate entirely the responsibility for medical benefit from that for cash benefit. The Committee should think before it decided that the right place for medical benefit was outside the scope of the Minister of National Insurance. The Minister should take with him the administration of medical benefit. Dr. MORGAN opposed the amendment. He said that the question of medical benefit was purely a health matter. They could not separate curative and preventive medicine. He wanted to be sure that under the regulations and procedure with regard to medical certification there should be consultation between the two Departments, so that the Minister of National Insurance would not have the power alone to make regulations and decide exactly what medical certification had to be done. The doctors should be free to certify, according to their conscience and their own ideas, within the accepted limits of the ordinary medical procedure with regard to prescribing.

Sir WILLIAM JOWITT said the Government could not accept the amendment. It was desirable that the distinction between medical benefit, which meant medical treatment and assistance, and sickness benefit, which meant periodical payments of sums of money after certification by a doctor, should be drawn in the most emphatic way at the earliest time.

The amendment was withdrawn.

The committee stage was concluded, and the Bill read the third time. Sir William Jowitt said it would be an enormous task to get the Security Bill ready. It was by no means true, as he had heard it said, that it was nearly ready. He would do his utmost to see that no undue time was lost in getting on with the job.

Medical Services in Jamaica

A report is expected shortly from a committee, under the chairmanship of Sir Alexander Russell, which has been set up to review the medical and health position of Jamaica, to consider the reorganization of the administration of the medical and health services, and to make recommendations. No application has reached Col. Stanley from Jamaica for assistance to promote improved medical services.

On Nov. 14 Sir E. GRAHAM-LITTLE asked the Secretary of State for the Colonies whether he was aware that licences to import penicillin into Jamaica had been withheld on the advice of the British Mission in Washington, and what steps he proposed to take to ensure that people in Jamaica might obtain urgently needed supplies. Col. STANLEY replied that licences to import penicillin commercially were doubtless withheld by the Government of Jamaica in accordance with the conditions which had to be imposed in order to ensure that the limited supplies which could be released for civilian purposes were used to the best advantage. Use had to be restricted to centres where adequate facilities existed for controlled clinical trial. To ensure that all supplies reaching the Colony were so used, it was arranged that imports should be through Government channels. As, however, the Jamaica Government encountered some difficulty in obtaining supplies, interim arrangements had been made for an emergency supply to be sent to Jamaica commercially.

Vitamins for Prisoners of War

On Nov. 28 Major MCCALLUM asked the Secretary of State for War whether adequate steps were being taken through the Red Cross authorities to supply to our prisoners of war in Germany, other than those in hospital, the essential requirements in vitamins which were lacking in the low diet afforded by the German Government, particularly now that the supply of Red Cross food parcels had had to be reduced to half a parcel a man a week. Sir JAMES GRIGG said that the composition of the standard food parcels sent out by the British Red Cross Society and Order of St. John was designed and was reviewed by experts in nutrition in relation to the rations issued by the detaining Power. All practicable steps were being taken to restore the normal flow of Red Cross parcels, and it was hoped that the full issue of parcels might be restored shortly. His medical advisers informed him that the reduction in the issue of parcels was unlikely, unless unduly prolonged, to prejudice materially the health of the prisoners. Major MCCALLUM asked if it was a fact that the parcels containing vitamin supplies went only to the men in hospital and not to the men who were not in hospital and who for long years had suffered from lack of vitamins C and D. Sir JAMES GRIGG said that extra vitamins were included in the parcels for sick prisoners, but food sent to the ordinary prisoners contained a supply of vitamins in the normal way.

Release of Medical Student from Navy

On Nov. 28 Sir E. GRAHAM-LITTLE asked the First Lord of the Admiralty if he would consider for release from the Royal Navy a medical student who volunteered for the Royal Navy in 1940 when he had nearly completed his studies for the second examination of the medical degree, but was now anxious to finish his course and assist his father, an overworked medical practitioner, or if he would secure priority of demobilization for this student. Mr. A. V. ALEXANDER replied: No, Sir. I am afraid it is not possible to give any special preference to medical students for release from the Royal Navy. While I appreciate the motives which prompted this young man to join up at a time when he was reserved, there are so many students serving in the armed Forces whose studies have been interrupted by the war that it is not possible to give any of them exceptional treatment. The position has not been overlooked, however, in connexion with the various Government schemes for resettlement and further education.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Charles Robert Harington, M.A., Ph.D., F.R.S., Director of the National Institute for Medical Research, has been elected an Honorary Fellow of Magdalene College.

At a Congregation held on Nov. 21 the degree of M.D. was conferred upon A. B. MacGregor, G. W. Harris, and I. R. S. Gordon.

UNIVERSITY OF WALES

THE WELSH NATIONAL SCHOOL OF MEDICINE

The following candidates have satisfied the examiners at the examination indicated:

M.B., B.Ch.—*Medicine*: Julia P. Gibbs, Sarah M. Lewis, B. H. McCracken, J. E. T. Sobey, M. J. Tanner, J. W. Thomas, P. H. Thomas, W. H. Williams.

SOCIETY OF APOTHECARIES OF LONDON

The Society of Apothecaries of London announces that Brig. Lionel E. H. Whitby will deliver a lecture on "Blood Transfusion in Peace and War" at Apothecaries' Hall, Black Friars Lane, Queen Victoria Street, E.C., on Tuesday, Dec. 19, at 2.30 p.m. Members of the medical profession and senior students are cordially invited.

Applications are invited for the Gillson Scholarship in Pathology, which is awarded for the encouragement of original research in any branch of pathology and is open to candidates under 35 years of age. The scholarship is of the value of £105 per annum. Regulations may be obtained from the Registrar, Apothecaries' Hall, Black Friars Lane, Queen Victoria Street, E.C.4.

Medical News

The Pathological Society of Great Britain and Ireland and the Biochemical Society will hold a joint discussion meeting at the Royal Society of Medicine, 1, Wimpole Street, London, W., on Saturday, Dec. 16, at 11 a.m. The subject for discussion is cancer.

Sir Ambrose Woodall, F.R.C.S., has been given his portrait in oils and a cheque for £500 in recognition of 25 years' service as senior resident surgeon at the Manor House Hospital, Golders Green, London. Mr. A. V. Alexander, First Lord of the Admiralty, who is president of the hospital, made the presentation.

On Nov. 28, after a six-days trial at the Old Bailey, Alva Delbert-Evans, M.B.Toronto, aged 63, with addresses in the West End of London, was found guilty of conspiring with intent to procure abortion, and of having performed illegal operations on two women. William Spencer Lewis, aged 73, described as a surgeon of Staines, Middlesex, and Redcliffe Gardens, Earl's Court, who, with two women defendants, pleaded guilty to conspiring to procure abortion and who also pleaded guilty to using an instrument or other means to procure the miscarriage of six women, asked for thirteen other offences, twelve of which were of a similar kind, to be taken into consideration. In March, 1942, Lewis was sentenced at Surrey Assizes to three years' penal servitude for performing illegal operations on women with intent to procure miscarriage; but after serving fifteen months of that sentence he had been released on a Home Office order on medical grounds, his heart being affected. Mr. Justice Hilbery now sentenced him to three years' penal servitude, saying that but for the defendant's advanced age and infirmity he would have imposed a heavier sentence. He sentenced Dr. Delbert-Evans, who was alleged to have sent women to Lewis for treatment, to five years' penal servitude. One of the two women defendants was sentenced to imprisonment for six months and the other bound over.

A meeting of the Diagnosis Section of the Faculty of Radiologists has been arranged for Friday, Dec. 15, at 2.30 p.m. at 32, Welbeck Street, W, when a paper by Dr. Peter Kerley on the non-tuberculous lesions detected by mass radiography will be followed by discussion. Other radiological meetings to be held about this date are: British Institute of Radiology, 32, Welbeck Street, Dec. 14, 8 p.m., papers on intervertebral disk lesions, and Dec. 15, 5 p.m., medical members' meeting.

Brig. George Macdonald, MD, DPH, DTM, has been appointed director of the Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, and will take up this post on his release from military service. He studied medicine at the University of Liverpool and has carried out research work on tropical diseases in West Africa and other places. He was appointed assistant director of the Ross Institute in 1939, and joined the R.A.M.C. on the outbreak of war.

The Services

Temp Acting Surg. Lieut.-Cmdr C. P. Bailey, R.N.V.R., has been mentioned in dispatches. This name appears in a list of awards for gallantry, skill, determination, and undaunted devotion to duty during the landing of Allied Forces on the coast of Normandy.

Col. J. P. Huban, OBE, IMS, V.H.S., has been appointed Honorary Surgeon to the King in succession to Major-Gen. H. Stott, CBE, OBE, IMS (ret).

CASUALTIES IN THE MEDICAL SERVICES

Killed in action—Capt Paul Sabel Adler, Capt Charles Stewart Ross London, R.A.M.C.

Previously missing at Arnhem, now officially reported died of wounds—Capt Brian Browncombe, G.M., R.A.M.C.

Previously missing at Arnhem, now officially reported prisoner of war—Capt W. I. S. Hudleston, R.A.M.C.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales notifications of infectious diseases exceeded those of last week by the following figures: measles 49, scarlet fever 203, whooping-cough 113, acute pneumonia 3. There were 103 fewer cases of dysentery, and 23 fewer of diphtheria.

The incidence of scarlet fever in Lancashire went up by 07. Whooping-cough notifications in Yorks West Riding were 14 higher than last week. In contrast to the general trend, Durham reported a rise of 21 in diphtheria notifications. The rise in the incidence of measles, 249, was the smallest recorded or eight weeks. The counties with the greatest increase in his disease during the week were Yorks West Riding 97, Cheshire 96, Staffordshire 88, Devonshire 71, Yorks North Riding 62; a considerable fall was recorded in Lancashire 02, and Southampton 51.

Although dysentery remains at a relatively high level, 217 cases, the total is the smallest for the past fourteen weeks. The chief returns were London 33, Lancashire 27, Essex 23, Yorks West Riding 20, Middlesex 16, Glamorganshire 12, Gloucestershire 11.

Eighteen cases of paratyphoid fever were notified during the week, the largest weekly total since January, 1943. Twelve of these cases occurred in Middlesex, Heston and Isleworth M.B.

In Scotland measles notifications fell by 34, diphtheria by 7, and dysentery by 12, those for whooping-cough rose by 9. The largest returns for dysentery were Glasgow 36, Edinburgh 17, Renfrew County 10.

In Eire the chief feature of the returns was a rise in whooping-cough from 16 to 60. This disease was mainly notified in three areas: Dublin C.B. 23, Wicklow County, Wicklow U.D. 12, and 14 in the Rural District.

In Northern Ireland the high level of measles fell during the week by 16 cases; but the total for scarlet fever went up by 100. Of the 191 cases of measles 187, and 45 of the 90 cases of scarlet fever, were notified in Belfast C.B.

Week Ending November 25

The returns of infectious diseases in England and Wales during the week included: scarlet fever 2,350, whooping-cough 388, diphtheria 616, measles 7,137, acute pneumonia 755, cerebrospinal fever 41, dysentery 380, paratyphoid 1, typhoid 4, poliomyelitis 10.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 18.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire. (e) Northern Ireland

Figures of Births and Deaths, and of (a) The 126 great towns (b) London (administrative county) (c) The 13 principal towns in Eire (d) 1

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available

Disease	1944				1943 (Corresponding Week)			
	(a)	(b)	(c)	(d)	(a)	(b)	(c)	(d)
Cerebrospinal fever Deaths	45	3	19	2	51	2	26	3
Diphtheria Deaths	619	20	171	110	705	40	135	27
Dysentery Deaths	217	33	88	—	176	49	59	—
Encephalitis lethargica, acute Deaths	2	—	2	—	2	—	—	—
Erysipelas Deaths	—	—	62	15	—	—	50	13
Infective enteritis or diarrhoea under 2 years Deaths	55	3	7	29	39	1	11	24
Measles* Deaths	6,001	65	311	34	556	49	48	43
Ophthalmia neonatorum Deaths	62	6	19	—	74	3	20	1
Paratyphoid fever Deaths	18	1	18	—	4	1	2	—
Pneumonia, influenza (from influenza) Deaths	626	15	7	4	978	73	20	6
Pneumonia, primary Deaths	33	1	4	1	106	10	32	—
Poliomyelitis, acute Deaths	—	—	233	26	—	—	298	21
Poliomyelitis, acute Deaths	2	—	—	9	48	—	19	11
Puerperal fever Deaths	12	1	2	1	8	1	1	1
Puerperal pyrexia Deaths	127	8	11	2	134	7	13	7
Relapsing fever Deaths	—	—	—	—	—	—	—	—
Scarlet fever Deaths	2,335	56	357	37	3,098	258	356	35
Smallpox Deaths	2	—	—	—	1	—	—	—
Typhoid fever Deaths	7	—	2	13	8	—	2	12
Typhus fever Deaths	—	—	—	—	—	—	—	—
Whooping-cough* Deaths	1,410	46	116	60	1,866	151	233	61
Deaths (0-1 year) Infant mortality rate (per 1,000 live births)	366	25	66	30	323	37	64	51
Deaths (excluding still births) Annual death rate (per 1,000 persons living)	5,099	747	663	184	4,934	742	727	225
Live births Annual rate per 1,000 persons living	6,507	584	927	337	5,562	685	809	280
Stillbirths Rate per 1,000 total births (including stillborn)	225	18	29	—	216	27	20	—

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitology Westcent*, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent*, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent*, London.

ANY QUESTIONS?

Some Congenital Malformations

Q.—What, if anything, is known of the causes of congenital malformations—e.g., cleft palate, talipes, supernumerary digits? What advice on having further children should one give to parents whose history is as follows: Husband aged 38, healthy; wife aged 37, healthy. First child, boy aged 7 years, has right inguinal hernia, flat feet, and a hairy patch of skin on his back. Two miscarriages followed at about 3 months gestation. Fourth pregnancy—a boy now aged 3 years who is healthy but has a slight squint. Fifth pregnancy a girl born 4 weeks premature, died after 12 hours with the above-mentioned congenital malformations. Naturally the parents are anxious to know what are the chances of having a normal child if the wife becomes pregnant again.

A.—Cleft palate is often inherited, but opinions differ as to the mode of inheritance. It is probably determined by two recessive genes. Talipes equinovarus is inherited as a recessive in some families, but may be due to pressure *in utero*. There are various types of supernumerary digits; the commonest, an extra digit on the ulnar side, is inherited as a recessive, but it also occurs in association with other abnormalities, such as acrocephalosyndactyly. An extra digit on the radial side is usually inherited as a dominant. I do not know an inherited condition in which all these defects occur together. It is unlikely that there is a genetic relationship between any of them and inguinal hernia, flat feet, and a hairy patch on the back which presumably is over the site of a spina bifida occulta, or squint, although all these may be inherited. It is quite impossible to say what the chances are that another child will be normal, but with such a family history I should advise the parents to have no more children.

Threadworms in an Adult

Q.—A married woman aged 24 with pulmonary tuberculosis has had very severe threadworm infestation which resists usual medical treatment and is unaffected by appendicectomy. The discomfort is so severe that she is losing sleep and weight. Any advice you can give about treatment will be much appreciated.

A.—Medicinal treatment for threadworm infestation is alone inadequate. The gravid female worms emerge from the anus to lay their innumerable eggs on the external skin, and it is the constant reinfection by swallowing these eggs which is responsible for the continuance of the infestation. The adult worms live only 2 to 3 months and do not multiply in the gut. The chain of reinfection must be broken by frequent attention to personal hygiene, and also by rigid precaution against contamination of clothing, towels, bed linen, etc. The use of tight-fitting drawers to prevent scratching and infection of the nails, and of linen which can be boiled daily, will do much to lessen this risk and ultimately to eradicate the infection.

Right Radial Nerve Palsy

Q.—Shortly after landing in Normandy in June I was confronted, within 10 days, with two cases of right radial nerve palsy. Both men reported that on awakening in their slit trench they were unable to extend the right wrist. On examination, the extensors of the wrist and the brachio-radialis muscle were paralysed, there was tenderness over the musculo-spiral groove of the humerus, and an indefinite area of anaesthesia over the dorsum of the hand. Neither case showed any improvement after several days, so were evacuated. Is this a common condition? What are the pathology, prognosis, and treatment?

A.—It is almost certain that these men were suffering from a pressure paralysis of the radial nerve, akin to the variety that was said to occur especially on Saturday nights. Usually the nerve does not degenerate and the electrical reactions of the affected muscles remain unchanged (if degeneration has occurred faradic excitability

disappears between the 14th and 20th days after injury). Where this is the case the prognosis is excellent and no treatment is required, apart from maintenance of the mobility of the hand. The odd thing is that recovery may be delayed for as long as 5 to 6 weeks; then it progresses rapidly and is ultimately perfect. Recently, Denny Brown of Harvard has shown that the characteristic lesion in this non-degenerative type of paralysis (which the Oxford workers have christened *neurapraxia*) is a sharply localized demyelination. Perhaps this explains why the motor paralysis is usually more profound than the sensory; the motor fibres are larger and more richly myelinated than those concerned with cutaneous sensibility. And the delay before recovery may perhaps be due to tardy reconstitution of the myelin sheaths. The axons also undergo a histologically demonstrable change, but they do not lose their continuity and there is no true Wallerian degeneration.

It is also just possible that these men were suffering from one form of the obscure neuritis that has appeared from time to time in every theatre of war. The pathology of this condition is unknown and the prognosis is uncertain. But this explanation seems a little unlikely in view of the well-recognized liability to compression of the musculo-spiral nerve and of the fact that these men passed a night in a slit trench.

Regional Ileitis

Q.—What are the present views on the aetiology and pathology of regional ileitis, or Crohn's disease? What are the symptoms and treatment?

A.—Though the cause of regional ileitis is unknown, the disease is classified with disorders of the reticulo-endothelial system, since the earliest and most constant change is hyperplasia of the lymphadenoid tissue of the bowel wall and regional lymph nodes. The theories that it is due to tuberculosis or some other infective agent, or that it may be a manifestation of Boeck's sarcoid, are not proven. The cardinal clinical features are abdominal pain, loss of weight, and general debility; the signs of chronic intestinal obstruction; and a palpable mass either in the right iliac fossa or, more usually, in the pelvis. Barium x-ray studies show a long filling defect in the terminal ileum—the so-called "string sign." An x-ray examination of the chest is essential in making a differential diagnosis. The ideal treatment is primary resection with wide excision of the mesentery. This often means removal of the right side of the colon as well, but it depends on the extent of the oedema and thickening of the bowel-wall. In cases complicated by fistula formation the operation may have to be done in stages. The results of excision, both immediate and remote, are excellent. (See Hadfield and Garrod, *Recent Advances in Pathology*; and *St. Bart's Hosp. Rep.*, 1939, 72, 181).

Local Analgesia for Thoracoplasty

Q.—What is Magill's modification of Semb's (Stockholm) local anaesthetic technique for thoracoplasty?

A.—We are not aware that Dr. Magill has published any article under this heading, but the usual technique at the Brompton Chest Hospital (to which he is attached) is briefly as follows. For the first stage (upper) thoracoplasty, after adequate premedication, the patient is placed on his back and supraclavicular brachial plexus block performed, a mixture of 0.5% procaine, 1 in 1,000 amethocaine, with the addition of 1 in 250,000 adrenaline, being used. The patient is then turned on to his sound side and the line of incision is deeply infiltrated with half-strength solution (1 in 2,000 amethocaine and 0.25% procaine). Some of this solution is also injected under the posterior border of the scapula. Posterior thoracic nerve block corresponding with the ribs to be removed can be done at this stage, but is usually left for the surgeon to perform under vision when the flaps are raised. Subcuticular wheals for the reception of the towel clips are then raised. Anterior intercostal block was practised at one time but is now usually omitted as unnecessary. For second-stage thoracoplasty, the brachial plexus block is not required.

Failure to Ovulate

Q.—Is it a fact that in some women sterility is due to failure to ovulate? Assuming that there is no organic disease of the ovary, what would be the cause of this condition? Is there any means of deciding whether a woman ovulates or not? How can this condition be treated?

A.—It is an undoubted fact that sterility may be caused by failure to ovulate. As it is not known for certain what causes ovulation to take place it is difficult to say what causes this condition, though it is generally assumed that it is due to some defect or disorder of the anterior lobe of the pituitary. Evidence of ovulation and of the corpus luteum formation can be obtained by biopsy of the endometrium during the week preceding menstruation or on the first day of the menstrual period. A sample of the endometrium is easily obtained with a suction curette, and no anaesthetic is needed for this simple operation. After fixing and staining, the endometrium is examined microscopically for evidence of the secretory changes which indicate the presence of an active corpus

luteum. The most important of these is "ferning" of the endometrial glands. It must be remembered that periodic uterine bleeding, simulating menstruation, can occur in the absence of ovulation.

In cases of sterility due to failure of ovulation, an attempt can be made to stimulate the ovaries. Small doses of x rays to the pituitary and ovaries have been tried, and some successes have been claimed. Alternatively, some pituitary preparation may be used, and this is the most logical method of treatment in these cases. A new product, which is a combination of follicle-stimulating hormone from the anterior pituitary and luteinizing gonadotrophic hormone from pregnancy urine, has been found to have a profound stimulating effect on the ovaries. Mazer and Ravetz (*Amer. J. Obstet. Gynec.*, 1941, 41, 474) found that two women out of eight treated with this product for sterility, caused by failure of ovulation, conceived soon after treatment. Great care is necessary in its use owing to its very powerful effect.

Autohaemotherapy for Asthma

Q.—Why does injecting a patient's own blood intramuscularly have a good effect upon an asthmatic patient? I tried this recently with a tuberculous patient who suffers from asthma, and it did him good.

A.—Autohaemotherapy and auto-serotherapy are on occasion employed in the treatment of allergic skin conditions, especially eczema and urticaria; and usually only in asthmatics who (a) resist other forms of treatment, or (b) have a cause that is unknown or cannot be determined, and the attacks are thought to arise from substances occurring or manufactured in the body—for example, the treatment of menstrual asthma with serum derived from autogenous blood withdrawn during the premenstrual stage. Any improvement is usually of short duration.

It is thought that the blood in destruction liberates certain substances which on their own or on conjugation with other body proteins act as foreign substances and in some way alter the reactivity of the patient. Others consider that the blood contains the specific allergen and that the systemic administration of the minute quantities of this allergen present in the blood stimulates the production of specific antibodies. Hence it is thought that better results are likely to occur when minute quantities (0.1 c.cm. intracutaneously or 1.0 c.cm. subcutaneously) each 2 days for 12 injections are given than, say, injections 10 to 30 c.cm. intramuscularly once a week. Unfortunately for this suggestion it has been shown that blood or serum derived from a non-allergic person can lead to equal immediate temporary improvement.

With our recent improvements in the determination of and testing for specific causes the number of cases with indeterminable origins lessens and the doubtful temporary beneficial effects of autohaemotherapy are less often sought.

Rammstedt Operation

Q.—What is the condition found at the junction of the stomach and duodenum some months or years after the Rammstedt operation has been performed?

A.—The writer's experience of the conditions found at the pylorus some time after a Rammstedt operation is limited to two cases—one three weeks after operation and the other after an interval of six months. In the first the infant died of an attack of D and V, while still in hospital, and in the second the cause of death was an intercurrent condition; the result of the operation had been excellent. In both, the pyloric region was quite free from adhesions, and the oval scar over the front of the pylorus was very thin and tissue-paper in type. There was, however, no herniation of mucosa. The ridges left by the cut muscular edges could still both be seen and felt. The surprising feature was that the result at the end of three weeks looked almost the same as that after six months, except for a little more smoothing of the edges in the latter. Although I have several cases operated upon over twenty years ago which have not been seen and appear to be in good health, no opportunity has occurred of exposing the exact state of affairs. In one of these cases a barium meal showed some irregularity of the pyloric canal, but not sufficient to enable the condition to be recognized had the previous history not been known.

Senile Softening of Vertebrae

Q.—A patient, female, aged 69, is suffering pain in the back. X-ray examination shows a senile softening of the vertebrae causing pressure on the nerve roots. Is there any treatment for this condition?

A.—Senile softening of the vertebrae can be a serious disability in advancing years and treatment is difficult. To promote better calcium assimilation is a primary object, for which purpose irradiation with ultra-violet rays is desirable, combined with the administration of calcium and vitamin D, preferably parenterally, as the oral route is often ineffective in these cases. Support for the spine is essential to prevent the increasing kyphotic tendency, and rest in

bed on a firm mattress is desirable as a general principle but is often badly borne by the aged and can then be adopted only for part of the day. A well-fitting spinal brace or corset should be worn when up. For the immediate relief of the pain caused by pressure on the nerve roots injection of procaine, 1% in saline, may be effective, 10 c.cm. or more being injected round the affected nerve roots at their emergence from the spine, and with this may be combined infra-red irradiation and light massage.

X Rays for Herpes

Q.—What is the value of x rays in the abortion or treatment of herpes?

A.—Small doses of x rays are valuable in the treatment of recurrent herpes simplex, where the same area is constantly involved. They have little or no abortive effect on the actual lesion.

Subcutaneous Swellings

Q.—A woman aged 61 has for two years suffered from painful swellings of 2 to 5 days' duration in the subcutaneous tissues of hands, wrists, ankles, feet, and sometimes of the thighs, knees, and legs. They are at first small and tense, and then spread to a diameter of 4 to 5 inches. There is no heat or redness. Often one succeeds another rapidly so that the hands are nearly always swollen. Oedema is present at the height of an attack; later there is a soft, tender, ill-defined swelling without oedema. The pain and stiffness cause considerable disability. Sometimes there is slight bluish discoloration at the centre. Occasionally the hands return to normal. Blood pressure 100 mm. systolic B.S.R. 9 mm. in 1 hour. Urine, x-ray of hands, blood count, electrocardiogram, all normal. Haemoglobin 70.85%, unless taking iron. The patient, naturally alert and active, is easily fatigued, and is very sensitive to extremes of temperature. The condition followed acute cystitis, which was cured by sulphapyridine. Constipation is extreme, and a colonic irrigation was followed in a few hours by an unusually severe outbreak.

A.—The attacks are suggestive of sensitization to a foreign protein or a micro-organism. Skin tests should therefore be performed and search made for septic foci. The patient may also be tested for sensitivity to the bacteria present in her mouth, nose and throat, stools, etc. If no specific cause is found, non-specific desensitization may be attempted, preferably with injections of whole blood. The blood is withdrawn from a vein in the arm and injected intramuscularly. It is usual to give a series of six injections at intervals of 5 to 7 days; the amounts injected are 5, 6, 7, 8, 9, and 10 c.cm. A radical change of diet is often successful, particularly a lacto-vegetarian regimen with added lactose or rice-starch to promote an acidophil flora in the stools. Unfortunately this is difficult to manage in wartime. General sedation may also be of value, such as a nightly dose of barbitaluric acid if the patient is not sleeping well.

Water-tolerance Test and Pituitary Function

Q.—Is a water-tolerance test of much value in estimating pituitary function? Can you give details of the method of applying and interpreting the test?

A.—The water-tolerance test of Volhard is that most commonly used. The patient drinks one litre of water within one hour in the early morning. During the following four hours he micturates at intervals of half an hour. In health practically the whole litre is excreted within two hours. If a patient does not excrete the whole amount, water retention can be diagnosed but no information is given about the cause of the retention. In most cases it is cardiac or renal. A poor excretion is also shown by many obese patients whose cardiac and renal functions are normal. Signs of endocrine and autonomic imbalance often accompany the obesity in such cases, and it is tempting to postulate a lesion in the diencephalon, where centres regulating water and fat metabolism and pituitary function exist. The whole question of fluid metabolism is, however, still obscure, and in the presence of so many variables it would be unsound to regard Volhard's test as a test of pituitary function.

Penicillin and Disseminated Sclerosis

Q.—Have therapeutic trials been made on the value of penicillin in disseminated sclerosis? One theory about this disease is that it is due to a spirochaete, against which, presumably, penicillin would be effective.

A.—We know of no reports on the treatment of disseminated sclerosis with penicillin, either in this country or even in the U.S.A., where clinical research on penicillin has been on a wider scale and included a greater variety of conditions, some rather unpromising. Whether the treatment of disseminated sclerosis has any prospect of success certainly depends on the truth or otherwise of the spirochaetal hypothesis in connexion with this disease, and most will agree that this is rather too slender a thread to support much weight. But everything is worth trying once, and it seems justifiable, if supplies allow, to treat a disease of completely unknown aetiology, always provided that it has characters compatible with an infective origin.

Spread of the Common Cold

Q.—Is the common cold spread by fomites? What is the risk of infection from making the bed of a person who has a cold, and would it be diminished by wearing a mask?

A.—It is not possible to give an unequivocal answer to the first part of this question. There is good evidence that the common cold is due to a filterable virus, since men and monkeys have been infected by filtered nasopharyngeal washings from "colder" persons. But artificial cultivation of the virus is extremely difficult, and successful propagation by this means has been claimed by only one team of workers. We are therefore ignorant of the biological properties of the cold virus, including its resistance to natural drying. However, circumstantial evidence suggests that it may survive for a time outside the body. Bliss and Long found that monkeys in strict isolation became infected through food prepared by an individual with a cold. Influenza virus remains viable in the air of a room for some hours and on fabric for some days, so it seems possible that the cold virus will do the same.

Blanket dust has proved to be a source of infection with respiratory bacterial pathogens, and therefore it seems not unlikely—although there is no proof—that an individual inhaling dust from the bed-linen of a "colder" person may become infected in this way. Protection against infection by wearing a mask is possible if the mask is efficient—i.e., it must fit pretty closely to the face and must not allow the passage of fine dust. A mask of the snout design, made of six layers of butter-muslin or of gauze with a 42 by 42-strand mesh largely fulfils these requirements. Repeated laundering improves the efficiency of the mask by narrowing the interstices of the mesh. The transmission of the common cold is very well discussed by Browning in *Control of Common Fevers*.

Scalenus Anticus Syndrome

Q.—How is the scalenus anticus syndrome diagnosed and treated? How exactly is elevation of the arm for purposes of testing of cervical rib (or other pressure on the subclavian vessels) attempted?

A.—The term "scalenus anticus syndrome" is misleading. It originated in the United States and was first used for a group of cases presenting the clinical picture of cervical rib but in which no cervical rib could be demonstrated. The application of the words "scalenus anticus" to this group of symptoms was due to the fact that Adson and Coffey (1927) had clearly demonstrated the influence of the scalenus anticus, particularly in the matter of treatment of a typical cervical rib. Tenotomy of this muscle, by giving more room for the brachial plexus, would relieve the symptoms associated with a cervical rib and render excision of the cervical rib unnecessary.

It is rather a pity that Ochsner and his co-workers (1935) used the term "scalenus anticus syndrome," for, as Freiberg (*J. Bone Jt. Surg.*, 1938, 20, 860) later showed, it has distracted attention from the causal factors of postural relaxation and brachial plexus drag, from traumatic and arthritic lesions of the cervical spine and shoulder girdle, etc. Furthermore, enough notice has not been paid in the United States to the work of Telford and Stopford (*Brit. J. Surg.*, 1919, 7, 168; 1931, 18, 557), who have analysed the variations in the lowest trunk of the brachial plexus, the occasional separation beneath it of sympathetic fibres in a separate bundle, and the influence of this upon vascular symptoms distally. Other recent work has shown the important part which cervical intervertebral disk lesions may play in the production of this group of symptoms, which in many ways bears a striking similarity to sciatica. The work of other British neurologists is in this connexion well worth mentioning—e.g., Walshe, in the *Lancet* (1944, 2, 173).

I therefore prefer not to refer to any such thing as a "scalenus anticus syndrome." There are a variety of symptom complexes related to the brachial plexus and subclavian vessels of which a careful analysis must be made and for which causes must be sought at least as high as the spinal-cord segments concerned. In a downward direction the search should not end at the scalenus anticus or first rib, but should include lesions anywhere in the upper extremity which may fix or lower the shoulder girdle. Certain it is that undue attention to the scalenus anterior muscle may lead to premature surgical attack upon it when more conservative measures may suffice to relieve the patient. It is the same thing, of course, with sciatica in which knowledge of the influence of intervertebral disk protrusion has caused many surgeons to lose a sense of proportion.

To say, therefore, what the treatment should be would require a lengthy article and would cover a big field of psychology, orthopaedics, rheumatology, and neurosurgery; and for which a few lines at the end might be devoted to tenotomy of the scalenus anticus—a procedure which may allow a little more room for the constituents of the lowest trunk of the brachial plexus. Elevation of the patient's arm by the examiner should be done with the patient sitting and in recumbency. It is useful to do it in straight abduction and also combined with external rotation of the shoulder of varying degrees, changes in the arterial pressure being estimated

by palpation at the wrist or by a sphygmomanometer in the different positions of the limb. Explanation of the changes noted is not always by any means easy, and the possible influence of the clavipectoral fascia and the lower edge of the subclavius muscle in forming an edge, around which nerve and vascular structures may be kinked or by which other disturbances may be aggravated, should not be overlooked.

LETTERS, NOTES, ETC.

New Houses

Dr. J. GREENWOOD WILSON (Cardiff) writes: The note in your issue of Nov. 11 (p. 636) says: "The Ministry of Health appointed a Central Housing Advisory Committee to make recommendations on the design, lay-out, construction, and equipment of dwellings." As this is not an accurate statement and does perhaps some injustice to the previous labours of the Central Housing Advisory Committee, will you permit me to explain the position more precisely. The Central Housing Advisory Committee was appointed by statute (Housing Act, 1935) to advise the Minister of Health on housing matters. Since its appointment the committee has in turn set up a number of subcommittees, all of which have done valuable work. Most of the recommendations of the subcommittees have been accepted, with or without modification, by the main committee, which in turn has passed them on to the Minister, and who, in turn, has usually accepted and acted upon the advice thus offered to him. The Central Housing Advisory Committee itself appointed a subcommittee, under the chairmanship of one of its distinguished members, the Earl of Dudley, to make recommendations on the design, lay-out, etc., of dwellings. Its report, known as the "Design of Dwellings" or the Dudley report, was published after it had been accepted by the Central Housing Advisory Committee, its parent committee, and in turn by the Minister of Health himself.

Sensitiveness to Strychnine

Dr. FRANK CROSBIE (Ealing, W.13) writes: One case in my practice endorses Dr. D. R. C. Shepherd's warning (Nov. 25, p. 694). Seven years ago I prescribed a mixture for a middle-aged married woman. She took one dose and promptly collapsed. I saw her within a few minutes; the symptoms, if severe, were fairly transitory. Four years later there was an exact repetition of this train of events. The one item common to both prescriptions was tinct. nucis vom. m iv.

Tourniquets

Dr. J. L. BARFORD (Guildford) writes: On two or three separate occasions recently, when lecturing to mixed Army personnel, I have been astounded to be informed by members of the R.A.M.C. that they had been told that the latest instruction was that a tourniquet once applied should never be released. They were quite definite about this, and one—a very knowledgeable sergeant, R.A.M.C.—even murmured "histamine." I have tried in vain to ascertain at what school and by whom this iconoclastic instruction has been given. (See question and answer published Nov. 11, p. 648.)

Dyspareunia

Dr. S. H. WADDY (Huddersfield) writes: In reply to a query on dyspareunia (Nov. 11, p. 649) I note the crude, cruel, and embarrassing method of gradual vaginal dilatation is recommended for a young woman who is stated to be "rather highly strung and very apprehensive on examination." Surely this is the worst possible treatment and one calculated to make her loathe the thought of coitus, whether it be painful or not. I have a patient whose whole married life appears to have been spoiled by such treatment being carried out during her honeymoon in the South of England. She has had a child, but all sexual thought and action is abhorrent and the memory of the honeymoon a nightmare. As this method is not always successful, as suggested in the reply quoted above, why not carry out the far easier, quicker, more aesthetic, and more certain digital dilatation under nitrous oxide or intravenous anaesthesia, either on one's surgery couch or in the patient's own home? I have never yet found further dilatation necessary. The patient can be assured that her difficulty is over and she need have no further fear.

An Appeal Renewed

Owing to the need for severely restricting circulation of the *Journal* while the paper shortage lasts, a number of institutions and individuals connected with medicine and its ancillary services can no longer obtain the weekly copy for which they formerly subscribed. Any member who might be willing to pass on his *Journal* after reading it (making himself responsible for dispatch and postage) would be given the name and address of a suitable recipient if he wrote to the Publishing Manager at B.M.A. House, Tavistock Square, W.C.1. A substantial number of offers came in response to the appeal published on Aug. 26, but there is still a long waiting-list.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY DECEMBER 16 1944

SMALLPOX VACCINATION BY THE MULTIPLE-PRESSURE METHOD

BY

H. J. PARISH, M.D., M.R.C.P.Ed., D.P.H.

Wellcome Physiological Research Laboratories, Beckenham Kent

During the smallpox epidemic in Scotland in 1942 (MacGregor and Peters, 1942, Sutherland 1943) some members of the staff of the Wellcome Laboratories asked to be vaccinated as a precautionary measure in case the epidemic should spread south. It was decided to offer to the whole staff vaccination by the multiple-pressure or multiple-puncture method. This is the technique of choice in the U.S.A., but has never been adopted in Great Britain, a perusal of the literature has revealed no completely satisfactory explanation for the differences in procedure in these two countries.

Technique

Multiple-pressure Method (see Leake, 1930a, 1930b, Kolmer and Tuft 1941)—The site chosen was usually the left upper arm over the deltoid muscle, but a few women elected to be vaccinated on the lower thigh. The skin was swabbed gently with acetone, following American practice, care being taken not to rub so vigorously as to damage the epidermis and thus encourage the development of secondary vaccinal vesicles. A very small drop of lymph was placed on the cleansed area with a glass rod, and "pressures" were applied to the skin through the drop with the side of the point of a Hagedorn needle. The needle was moved rapidly up and down with enough force to demonstrate the elasticity of the skin but not so vigorously as to draw blood. (A few hours after the operation there was no visible lesion.) In accordance with American writers' recommendation for the vaccination of adults, 6 to 10 pressures were used for primary vaccinations and 30 pressures for secondary vaccinations. 30 pressures are recommended for primary vaccinations of young babies because they are less prone to reaction than adults. The area covered by the pressures was only 1.8 in. in diameter. After vaccination any excess of lymph was removed gently with a pledget of cotton-wool. No dressing was applied.

Scratch Method—This technique is only referred to briefly by way of contrast with the multiple pressure method. The usual recommendation in this country is a superficial scratch 1/8 in. in length. Parallel scratches are regarded as unnecessary by American workers (Kolmer and Tuft, 1941), nevertheless, the public health authorities of Glasgow, in their anxiety for efficient vaccination during the large epidemic of smallpox in 1942, advised three parallel scratches, 3/8 in. long and 1/8 in. apart (MacGregor and Peters 1942). The usual method in Great Britain was formerly "cross hatching" (scratches crossing one another) but reactions tended to be unduly severe and it was given up. It is legally prohibited in Germany.

Intradermal Method—Since it is obviously undesirable to inject intradermally any contaminated fluid, this method is unsuitable for ordinary glycerine-cured lymph, which does unfortunately contain living bacteria. (The Therapeutic Substances Orders, dated Oct. 21, 1942, and Feb. 11, 1944, permit the issue of vaccine lymph containing not more than 20,000 living bacteria and other visible micro organisms in each c.c.m., provided tests for *Cl. tetani* and beta haemolytic streptococci are negative. Glycerin is added to vaccine lymph in normal times in this country to keep down the bacterial content; in the U.S.A.

brilliant green is added in addition.) The intradermal route should be very satisfactory, however, for culture virus, since an exact volume of virus suspension, without extraneous bacteria, would be injected into each patient. The multiple-pressure method appears to be preferred in America, since it is claimed that the percentage of "takes" is just as high, additional advantages being simplicity and painlessness during performance.

Advantages of the Multiple-pressure Method

The multiple pressure method is regarded as better than the scratch method for the following reasons: (1) Reactions are less severe and less painful. Scars are smaller. (American authorities are at variance with the Report of the Ministry of Health (1928), for they place little reliance on the area of scar formation as an indication of the degree of immunity. They claim that there is no evidence that the duration of immunity is less with the multiple pressure method than with other methods.) (2) The technique is more rapid, the whole operation taking about 10 seconds, this assertion of greater speed is doubted, however, by experts in the scratch method. (3) The epidermis is left nearly intact and there is no bleeding—in contrast with the general "messiness" of the scratch method especially when the latter is ineptly performed. The risk of septic infection is thus eliminated. (4) The multiple-pressure method obviates the use of any control site for estimating the degree of trauma in the so-called "immune" reaction (immediate reaction). This is a doubtful advantage, since many experts including Marsden (personal communication), never use any form of control as part of the scratch technique, if no specific reaction is obtained the subject is not regarded as immune until the inoculation has been repeated with lymph of proved potency and the same result obtained. (5) Since excess vaccine lymph is wiped off gently and there is minimal trauma, the immediate application of a dressing is unnecessary (Leake, 1930a, 1930b). I am inclined to doubt this assertion, however, because some patients in my series infected their fingers by touching the primary lesion and developed secondary lesions at other sites, a protective dressing would have prevented this accident. The case for and against a dressing is well discussed by Stimson (1936). Marsden (1942), who uses the scratch method, recommends a simple dry dressing fixed by strips of elastoplast.

Potency of Vaccine Lymph

Only if the potency of the lymph is suspect or if there has been exposure to smallpox do the Americans deviate from the above simple technique. Multiple vaccinations—30 pressures at more than one site—are then advised in order to obtain more "takes". (It will be remembered that the practice during the recent Glasgow outbreak was also modified to obtain more "takes"—viz., vaccination by multiple scratches instead of the usual single-scratch technique.)

The Regulations for the potency of vaccine lymph laid down under the Therapeutic Substances Act may require revision in the light of further advances in our knowledge and

experience. The use of a standard lymph, preferably a dried preparation, would be advantageous, and it might also be feasible to stipulate an upper limit of potency in addition to the lower limit now enforced. The issue of a more stable product is desirable. So long as wet lymph is issued, undesirable and rapid deterioration is inevitable unless the tubes are kept continuously at a temperature below 0° C. The practitioner often keeps vaccine lymph in a drawer at room temperature, and as time elapses his proportion of "failures" may be unduly high. This may explain the official preference in this country for the scratch method, which may be more "drastic," as generally performed, than the American multiple-pressure method. Evidence should be collected to settle this point. (It may also explain the experience of Goodall (1942) of a somewhat higher successful reaction rate among those cases in which blood was drawn than among those in which bleeding did not occur. Immediately after this statement in the abstract of Goodall's paper in the *Bulletin of Hygiene* was the reviewer's comment: "It should be realized, however, that the latter group would include any cases in which the incision was too superficial for success—a not uncommon cause of failure." Both the above statements seem strangely at variance with American experience with the multiple-pressure method, where damage to the skin is trivial.) The findings of Rivers, Ward, and Baird (1939) clearly show that the potency of a vaccine lymph used for revaccination makes a decided difference to the numbers of persons who show incomplete protection against smallpox. A highly potent lymph at the time of use is of primary importance whatever technique is adopted.

Reactions of some severity are to be expected in association with successful first vaccinations, more particularly in adults.

Reactions correlated with Degree of Immunity

Reactions may conveniently be classified in three categories which represent for practical purposes three grades of immunity. (1) If the patient has no immunity, or very little, he will develop a "typical" reaction, the so-called primary "take" or vaccinia. This is represented by a papule developing in 3 to 4 days; followed by a vesicle which is at its maximum in 9 to 10 days; followed in turn by a pustule and a scab which separates about the 31st day. Occasionally, in persons with no immunity, the reaction is more severe and of longer duration. In all cases there is some degree of associated adenitis. Constitutional upset with rise of temperature is invariable, and sometimes necessitates absence from work and rest in bed. (2) When there is partial immunity an accelerated or vaccinoid reaction may be expected, sometimes referred to as secondary vaccinia. Here the reaction is less severe, all the changes being speeded up and the maximum vesicle formation occurring in 4 to 7 days. Finally, (3) the typical response in a person who is highly immune is an immune or immediate reaction, characterized by papule formation reaching its maximum in 8 to 72 hours and seldom going on to vesiculation. The American writers state that if no reaction occurs the lymph should be regarded as suspect and the test repeated; in the present series it was found that some of the "no reactions" reported were really "immune reactions" which the patient had failed to observe or had ignored on account of their triviality and short duration. An additional control of the potency of the vaccine lymph used for such patients, if this were needed, was furnished by the numerous relatively severe reactions observed after vaccinations which were performed at the same time with the same batch of lymph. American authors also mention that a rough criterion of a fully potent lymph is that it should give more than 50% of vaccinoid reactions in a group of persons vaccinated more than 10 years previously; this percentage figure was exceeded by a considerable margin in our group.

Marsden (personal communication) does not accept the immediate or immune reaction, which he regards as a misnomer; it does not indicate immunity, he believes, but merely sensitization to lymph. To quote his paper (Marsden, 1942): "Nothing less than a red deep-seated indurated swelling beneath the seat of inoculation, developing about the third day and subsiding gradually, should be accepted as a specific reaction; and when the revaccination has been performed in the face of smallpox infection, or if the interval since the primary

vaccination has been considerable, the process should be repeated at least once. Under similar circumstances, if no specific reaction be obtained the subject should not be regarded as immune until the inoculation has been twice repeated with lymph whose potency is proved by its effect on other patients."

Henderson and McClean (1939) produced evidence that, in a susceptible person, vesiculation must occur before vaccination can be regarded as successful. They inoculated volunteers intradermally and subcutaneously with a specially purified vaccine lymph, and found that immunity to subsequent vaccination by scarification was obtained with certainty only if there was vesiculation at the site of the primary vaccination.

Results of Vaccination on 214 Persons

The results obtained with the laboratory staff were analysed with reference to the type of reaction which developed and the history of previous vaccinations (Table I).

TABLE I.—Vaccination of 214 Adults

Previous Vaccinations*	Reactions					Total
	Nil	Immune or Immediate	Accelerated or Vaccinoid	Typical or "Primary" Moderate	Severe	
None	0	1	13	33	15	62
One	11	6	70	4	4	114
More than once ..	2	15	16	23	2	38
Total	13	22	99	59	21	214

* Based on patients' histories, which were supplemented in most instances by direct evidence from scars.

The information about previous vaccination depended mainly on the patients' statements, which could not always be confirmed by inspection of scar sites; the original notes had sometimes to be revised, therefore, after further discussion. Again, the severity of reactions observed in the present investigation did not always fit precisely under any of the headings in the table. The 13 reactions which are listed as accelerated or vaccinoid, in the group of patients who stated they had never been vaccinated previously, could almost all have been classified, in retrospect, as moderate "typical" or "primary" and transferred to the next column in the table; the majority of these reactions were intermediate between "accelerated" and "typical." Intermediate grades are to be expected in any study of biological reactions, but a more elaborate and cumbersome classification appeared inadvisable. At all events, the figures in the table give a reasonably accurate analysis of the available data.

The main feature of the table is the decreasing severity of reactions, depending on the frequency of previous vaccination. There were many more severe reactions in persons vaccinated for the first time than in the other two groups. The majority of persons who had never been vaccinated before gave moderate or severe "typical" or "primary" reactions, and persons who had been vaccinated more than once before gave "immune" and "accelerated" reactions in approximately equal proportions. One person who had never been vaccinated before gave an "immune" reaction on repeating the inoculation; there is no obvious explanation of this unexpected result.

In a further analysis it was seen that sex (79 males and 135 females) had apparently no influence *per se* on the grading of the reactions observed. Stout persons tended to have more severe reactions than thin.

The degree of reaction in relation to one or more previous vaccinations was further analysed with regard to the time which had elapsed since the last "successful" vaccination (Table II). Fewer persons gave "immune" reactions when the interval which had elapsed was long. In the "over 30 years" group there were many "typical" or "primary" reactions, mostly of moderate severity. It is noteworthy, too, that two persons who had been vaccinated 10 to 20 years previously gave reactions classified as severe; these were women who elected to be vaccinated on the thigh and reacted so severely that they had to be off work for some weeks. More severe reactions appear to be associated with thigh than with arm vaccinations (Buchanan and Laidlaw, 1942), and we agree with certain other workers that the thigh is an unsuitable site and should rarely

be employed. At the foot of Table II are given for comparison the data of reactions occurring among persons with no previous vaccination

TABLE II—*Degree of Reaction in Relation to One or More Previous Vaccinations (Males and Females)*

Years Since Last Successful Vaccination	Reactions					Total
	Nil	Immune or Immediate	Accelerated or Vaccinoid	Typical or Moderate	Primary Severe	
Less than 5	2	1	1	1	0	5
5-10	6	13	41	4	2*	66
10-20	7	4	24	15	1	51
20-30	2	1	20	15	3	41
More than 30	2	1	20	15	3	41
Total	13 (8.6%)	21 (13.4%)	86 (56.6%)	26 (17.1%)	6 (3.9%)	152
Of No Previous Vaccination						
Total	0	1 (1.6%)	13 (21.0%)	33 (53.2%)	15 (24.2%)	62

* Women with thigh vaccinations

Abnormal Reactions, Complications, etc.

(a) In two cases the reaction did not appear till the 10th and 12th days respectively after vaccination. The patients believed they were immune, but they did in fact develop a moderate and a severe reaction respectively. It is not known why there should have been an unusually long delay in the incubation period of these persons who had little or no immunity. (The statement has been made that "if a reaction is not found on the second or sixth day the vaccination must be repeated, as either the virus was impotent or the technique was at fault" (Gloyne 1943). Apparently the reasons given for repetition do not invariably hold, as is shown by our experience, and also since, on occasion, primary and "repeat" vaccinations have both shown typical "takes" developing possibly after different time intervals (Anderson, personal communication).)

(b) In seven subjects "supernumerary" vesicles developed around the vaccination site

(c) Three persons developed so-called "vaccinal rashes," which were papular and pustular and of scanty distribution, and not to be confused with generalized vaccinia—a much more serious condition (Jubb, 1943). In our series there were no cases of generalized vaccinia and no encephalomyelitis

(d) There were four cases of auto-inoculation or auto-vaccination. The first patient had complained of a "stiff neck," which was explained by a typical lesion of the scalp with an associated adenitis at the back of the neck. The second patient had single lesions of neck, finger, buttock, and thigh, the third, two lesions of the cheeks and one of the left arm, and the fourth, single lesions of elbow and leg and three lesions on the body. The somewhat high incidence of subsidiary lesions in this series may possibly be explained by the natural interest of laboratory workers in a new method and their desire to follow carefully all stages in the development of their vaccinia. The lesions, as a rule, were not protected by any form of dressing, and were certainly palpated by some persons

(e) A patient who had been vaccinated on the thigh and developed a severe reaction infected her daughter, aged 19. The daughter developed a typical primary lesion of the thigh, with associated adenitis. Mother and daughter had had baths on successive nights and used the same bath towel. It was a family joke that the daughter always used a scrubbing-brush in her bath and rubbed herself down so vigorously afterwards that her skin was reddened; this may serve to explain her vaccination via the bath towel! (A local medical practitioner who heard of this accident told me that his father had infected his own nose after vaccinating a child and had to be away from his practice for several weeks.)

(f) Two patients developed boils and had successive crops for many weeks, and one patient had a neuritis of forearm and hand which lasted about 48 hours and cleared spontaneously. Both conditions were probably coincidental, although the patients tended to blame the vaccination.

Discussion

The multiple-pressure method of vaccination is an innovation in this country, and aroused considerable interest among the staff, who were impressed by its apparent simplicity and painlessness at the time of performance. There was therefore no difficulty in obtaining volunteers, although some persons may have regretted their enthusiasm when severe reactions developed. It is fortunate, perhaps, that the multiple-pressure method was used, as even more severe vaccinal reactions might have followed scratch methods, with the added possibility of septic infection. A factor in the severity may have been "green lymph"—i.e., lymph issued and used soon after preparation, and kept, as in our experiment, in cold storage until required for use. The worst sufferers were certain persons who were being vaccinated for the first time in adult life or revaccinated after the lapse of many years. The remedy is therefore primary vaccination in infancy followed by periodic revaccination throughout life. A sore arm and disturbance of health necessitating absence from work are thus obviated. (American practice is to carry out primary vaccination in the first year of life, and revaccination at 5 or 6 years and again when puberty is reached. In the American Services further vaccinations are performed yearly, there is little trouble from reactions.)

Some of the instances of spread from the original site to other parts of the body, and in one instance to another individual, would seem to indicate that warning should be given to the patient and his relatives of the highly infectious nature of vaccine lymph. The usual American procedure is to dispense with any form of protective dressing but the wisdom of this recommendation is questionable. The risk of auto-vaccination is by no means negligible, and subsidiary lesions may lead to permanent disfigurement. These risks apply to vaccination by any method and not by the multiple-pressure method alone.

I have also been informed of doctors developing lesions from applying their lips to vaccine capillary tubes to blow out the lymph. Here again a word of warning is necessary, and some other method of expelling the lymph—e.g., the use of a special rubber test—is essential.

It is disturbing that a significant number of soldiers in this war who have been vaccinated at home and found to be negative have developed typical "takes" when revaccinated overseas. The explanation may be poor-quality lymph at the first vaccination or bad technique, or both. Although the scratch method was implicated in these observations, at least an equal number of "discrepancies" might be expected with the multiple-pressure method. Whatever method of vaccination is adopted the only safe working rule is to disregard all histories of previous vaccination that are not supported by direct evidence. As already quoted Marsden (1942) stresses the necessity for a sceptical attitude towards a negative or an "immune" reaction in the face of a smallpox epidemic or if a considerable interval has elapsed since the primary vaccination. Two repeat vaccinations may be indicated with lymph which is of assured potency on the basis of tests on other patients.

The difficulty of obtaining an accurate record of previous vaccinations has already been mentioned. In cross-examination it was ascertained that some persons had obviously confused vaccination against smallpox with inoculations of diphtheria prophylactic. It would be extremely useful if some form of health record could be devised which would accompany each patient and give accurate information of all inoculations (date, preparations, and batch number, dose, degree of reaction, etc.) and of infectious diseases and other illnesses. "One more card to be lost!" was the abrupt comment of one well-known fever hospital superintendent when this idea was discussed, but if this serious defect in the scheme could be circumvented more reliable vaccination histories would be obtainable for consideration alongside the direct visual evidence provided by scars.

Summary

The multiple-pressure method was used for vaccinating 214 members of the laboratory staff.

The advantages of this method, which is in common use in the U.S.A., are discussed.

The potency of calf lymph before issue is controlled by official regulations, but storage under suitable conditions is requisite if

results are to be satisfactory. Whatever method of vaccination is adopted, lymph must be highly potent at the time of use.

The necessity for obtaining direct evidence of a successful "take" is stressed. Unless only a short interval has elapsed since a satisfactory primary vaccination, a negative or "immune" reaction on revaccination should be distrusted until confirmed. Two reinoculations with lymph of proved potency may be necessary before this finding is accepted.

There is insufficient appreciation of the highly infectious nature of vaccine lymph. A dressing should always be applied immediately to the site of vaccination to reduce risks of auto-inoculation.

Severe reactions necessitating absence from work would be obviated if vaccination in infancy and periodic revaccination were the general rule.

Some system of permanent health records which would accompany each patient is desirable. Full details of vaccinations and other inoculations, including reactions, would be entered and would supplement the direct evidence presented by vaccinal scars.

I have to thank Dr. J. Pickford Marsden, River Hospitals, L.C.C., for his helpful advice while this paper was being prepared for publication.

A TWO-STAGE METHOD OF TREATMENT IN DIABETES

BY

R. H. MICKS, M.D., F.R.C.P.I.

Physician, Sir Patrick Dun's Hospital, Dublin

This communication describes a simple method of carrying out adjustments of insulin dosage or diet (or both) in those diabetics for whom a change of some sort is obviously necessary. It is particularly applicable to the patient who is ambulant or under treatment in his own home.

It is described as a two-stage method of treatment because its first object is the restoration of the patient to vigorous health by insulin without any restriction in diet other than the close spacing of meals which prevents hypoglycaemic attacks. During this stage no attempt is made to maintain normal levels of blood sugar or a sugar-free urine, and the dose of insulin is controlled by daily observation of the patient's body weight and the record of the volume of urine passed. When normal weight has been reached and maintained for some time on a constant dose of insulin, then the secondary object of diabetic treatment—namely, the lowering of the blood-sugar levels to near normal—can be tackled (if it is thought well to do so), and the effect of carbohydrate restriction observed.

The method may be summarized in a few words: the patient is restored rapidly to health and vigour by insulin on a diet which is more than adequate, the question of blood-sugar levels being left over to a later date; diet charts and blood-sugar estimations are not needed for the first stage, though they are necessary for the second.

Advantages of the Two-stage Method

A two-stage method of treatment (though applicable to hospital work, and in fact used in my own hospital practice) is not needed by the experienced diabetic specialist who has his patient in hospital, who can have frequent blood-sugar estimations carried out, and who can make certain that the patient takes a prescribed diet. For it is possible for a physician so placed to roll both stages into one, and combine his most important duty (the discovery of how much insulin is needed, and how often) with the much less important one of controlling hyperglycaemia by a rationed diet. But it offers very definite advantages to physicians who have to carry out adjustments for the already instructed diabetic outside hospital. For them it is a "safety play" which enables them to restore

a slightly maladjusted diabetic to effective health as rapidly as possible, leaving to a later date the question of exact dietetic control. It enables them to use insulin freely without fear of hypoglycaemic attacks. If at a later stage they decide to tackle the question of dietetic restriction, they will then be in the happy position of knowing that if these restrictions bring about hypoglycaemia the fault lies with the diet being too low, and not with the insulin dosage being too high.

Not the least of the advantages of the two-stage method is that the patient himself becomes correctly oriented towards his disease. He learns that his restored health is due to injecting insulin, and not to abstaining from carbohydrate. He learns that loss of weight, thirst, and polyuria (the cardinal symptoms of diabetes) are signs of underdosage with insulin and must be noted and reported whenever they occur. Too many diabetics imagine that the only yardstick whereby they can measure their health is a sugar test on the urine, and fail to learn the far more important lesson that the adequately treated diabetic should so live that he is free from all the symptoms of his disease.

The First Stage

During this stage the physician's only concern is to restore the patient to full health. He allows the patient to satisfy his appetite so that wasted tissues may be built up and hypoglycaemia avoided; he gives enough insulin often enough to keep the urinary output as near normal as possible and to produce a steady daily gain in weight. If he fears hypoglycaemia—for example, at night—he does not let that stop him from increasing the dose of insulin, but he takes the precaution of ordering glucose at the appropriate periods. The rationale is the same as that of most specific replacement therapies: make sure that enough is given. Prophylactic glucose enables this to be done without risk.

Insulin.—Unmodified (soluble) insulin should always be used in even minor diabetic relapses. Except in cases of coma and threatened coma (which should be rushed into hospital), doses of about 30 units twice daily, with a small evening dose, will be adequate in many instances and entail little risk of hypoglycaemia during the first few days, but there is of course no general rule. If a marked improvement does not set in on a dosage not very much higher than the patient's usual maintenance dose, the physician should suspect that coma may be nearer than he at first thought.

Diet.—The two essentials are that it shall be adequate and contain small meals interpolated between the chief meals of the day, with additional glucose whenever a hypoglycaemic attack is to be feared. Occasionally an overconscientious diabetic who has relapsed through cutting down his total intake to near the point of undernutrition will be afraid to increase his diet, but such patients will usually take glucose without any dark suspicions about their doctor's intelligence. It must never be forgotten that the diabetic who cannot eat or who vomits is a candidate for coma, and therefore a case for hospital.

Weighing.—Daily weighing of the patient is essential, and home treatment must not be undertaken without scales in the house. If diet is more than adequate and the weight does not rise, then insulin dosage is too low, and a polyuria will indicate the period or periods of the day at which it is inadequate. If the weight refuses to rise, and the diet is adequate and there is no polyuria, then the cause of the loss of weight is not simply diabetes; there must be some concomitant disease—for example, tuberculosis or gall-bladder disease.

Urine Measurement.—The patient should record the time and approximate volume whenever he passes urine. Measurement need not be done with great accuracy (a half-pint milk-bottle marked with stamp-paper may be used), and the ambulant patient can make a rough guess if he passes water away from home. There is no constant figure for all diabetics, but, apart from a few puzzling exceptions, the 24-hour output can usually quickly be reduced to within or about 50 oz. Adequate insulin dosage in a previously inadequately treated patient will always markedly lower the urinary output. If the urinary output during the night is relatively high, that points to the need for a bedtime dose of insulin.

Testing for Sugar.—Testing the urine for sugar should be done during the first stage only with the object of avoiding hypoglycaemia.

Ketosis—If a decrease in the degree of ketonuria (if present) does not take place a few hours after the first injection of insulin it is probable that the case is more serious than at first appeared. If the physician has not got the reagents for Rothera's test he should assume that a copious pale urine implies ketosis, and that if a single reasonable dose of insulin does not produce a scantier yellow urine, then the ketosis is severe and the patient not very far from coma.

Previously Untraced Diabetes—These cases should always be in hospital until a thorough survey of their general health has been made and they have learned about hypoglycaemia. But they can be discharged at an early date, and the study of their insulin requirements can be continued at home.

Minor Relapses—The two stage treatment is the quickest way of overcoming a minor relapse without disturbing the patient in his employment. It is usually essential for quick recovery that the patient if on a modified insulin should return for the time to the unmodified.

The Second Stage

Restriction of the carbohydrate or other constituents of the diet can be most easily carried out after the patient's return to normal weight and vigorous health. It should not be attempted till he has been for some weeks on an unvarying dose of insulin, for it is commonly found that soon after a severe relapse or an attack of coma the dose of insulin required to maintain a steady rise in weight begins to decrease till it settles down usually at about what it was before the relapse. Till then the patient probably needs more food than normal attempts to restrict his intake may delay his return to normal health, and by producing hypoglycaemic attacks, tempt his doctor to premature reduction of the insulin dosage.

In most patients who are on an unmeasured diet the blood sugar levels are higher than normal. The majority of writers on diabetes teach perhaps correctly, that any avoidable degree of hyperglycaemia is harmful; others including myself (Micks 1943) can see no proof of this, and suspend judgment. All writers agree that in some cases normal blood sugar levels can be maintained only at the cost of frequent hypoglycaemic attacks.

So if it is decided that the attempt should be made to control the patient's blood sugar by a rationed diet, it must be understood in advance that in some cases it will be defeated by hypoglycaemic attacks, and in other cases the patient may refuse to co-operate or the nature of his employment may make the attempt a failure—for example when it entails irregular spells of violent exercise.

There are three important points about the management of the second stage. The first is that it can be carried out only with the help of frequent blood sugar estimations as well as charts. The second is that hypoglycaemic attacks in an affluent diabetic are a serious matter. The diabetic should be taught to look upon them as a crime and not as an inevitable occasional mishap. The third is that if cutting down the carbohydrate intake produces hypoglycaemia, this must be corrected by restoration of the cut, not by reduction of the dose of insulin. Or at least, a cut in insulin is made with the object of preventing hypoglycaemia occasioned by a reduction in diet, then the patient must watch his weight and urinary output if the weight falls and the urinary output rises he should be put back on to his old dose of insulin and a larger diet.

In some patients especially those leading a sedentary life it will be found that the food intake (without any deliberate attempt to control it) is in fact constant from day to day, and the carbohydrate intake not so high as to produce a significant hyperglycaemia. In such cases the question of rationing the diet does not arise.

The following general advice may be given to physicians who consider attempting this second stage of fine adjustment.

Do not generalize. Consider each case individually. Do not attempt it without blood sugar estimations. Do not set the patient estimating his own urine and cutting down his own diet without blood sugar controls. Think carefully before persuading the patient to adopt any way of life which makes him less healthy. Look on hypoglycaemic attacks as a reproach both to the patient and to himself.

Coma and Threatened Coma

The treatment of coma is an entirely different matter from correcting relapses unaccompanied by coma or maintaining the diabetic in health. Insulin must be given, sometimes in very large amounts not by any rule but just as an anaesthetist gives an anaesthetic—that is until it has begun to work. Intravenous saline too in large quantities is often needed to correct dehydration and sodium depletion. So coma cases should always be brought at once to hospital, for many cases which are saved by the work of the full team of a modern hospital could not be saved by a physician, however skilful, working single handed in the patient's home. Quite apart from stocks, instruments and laboratory facilities, at least four pairs of hands are usually needed. But, nevertheless treatment should always be started the moment the case is seen, and 40 units given if necessary every 15 minutes until either a marked improvement begins or the patient reaches hospital. There is no risk of hypoglycaemia during the first few hours of the treatment of coma and it would probably be correct to say that the risk of hypoglycaemia does not begin until after clinical improvement has set in.

Acute Non-diabetic Complications

Acute illnesses in the diabetic (for example, acute infections and conditions calling for operation) should be treated in hospital on account of the risk of coma supervening the disturbance of the patient's nutrition, and the need for an increased dosage of insulin as well as for parenteral administration of fluid. But such cases have sometimes to be admitted to a hospital to which no medical specialist familiar with diabetes is attached. When confronted with such an emergency even a surgeon may succeed in keeping a diabetic out of coma if he acts on the rule, 'Plenty of insulin, plenty of glucose, and plenty of saline'.

In acute complications it is obvious that the adequacy of treatment cannot be controlled by weighing and Rothera's test becomes of prime importance for the output of urine cannot be used as a control for insulin dosage. There are two reasons why no attempt should be made to reduce the urinary output in acute infections and in operation cases. The first is the ever present danger of dehydration, the second is the risk of crystalluria if sulphonamides are being administered.

To the non specialist concerned with maintaining a diabetic in health throughout an acute infection or a surgical operation and after treatment (conditions in all of which the patient is threatened with dehydration from the non-diabetic illness as well as with dehydration and coma from the diabetes) the following rough rule is offered. *Maintain a more than adequate water and sodium intake give enough insulin often enough to keep Rothera's test negative and give enough glucose to prevent the urine from becoming sugar free.*

Shifts

Shifts from unmodified insulin to modified types such as globin (which I have found very satisfactory in a number of my milder cases) or protamine zinc insulin or mixtures can be very simply managed without putting the patient in hospital. The daily weight chart shows whether the dose of the new insulin is inadequate and the urinary volume record shows during what period of the 24 hours the insulin effect is lacking. It is of course essential to make sure, by preliminary observation, that the patient before the shift was receiving an adequate dose of unmodified insulin. Sometimes it will prove impossible to shift the patient on to a one shot treatment without hypoglycaemia, and the attempt has to be abandoned. It is to be hoped that some of the standardized mixtures or unmodified and modified insulins now undergoing trial will make it possible to free all patients from the trouble of two or more daily injections.

Theoretical Considerations and Fallacies

Experimental work has yielded little knowledge that is of help in the treatment of diabetes, for it has pronounced new riddles instead of solving the old ones. But, as discussions with colleagues have shown that reluctance to try individual treatments in diabetes is often based on mistaken notions, it is well to consider how much is known about diabetes in man.

The Nature of Diabetes.—The treatment of diabetes is not based upon exact knowledge of its pathology or of the mode of action of the specific remedy. Diabetes takes numerous forms, and it would perhaps be well to refer (as has been suggested) not to "diabetes" but to "the diabetes," using the plural, just as it is now customary to write of "the epilepsies" rather than of "epilepsy." In the young it is nearly always "severe" in the sense that a high dose of insulin must be given and its action maintained during the greater part of the 24 hours, while in the old it is often mild. But, on the other hand, some young diabetics can lead an active life on so little as 20 units a day, while occasionally, even in the old, several hundred units a day may be required.

Diabetes often exists by itself, but in some cases it may be associated with disease of the liver, of endocrine organs other than the pancreas, of the vascular system, or of the central nervous system, and it may be impossible to decide whether the relationship is a causal one. The disease may change in "severity" from time to time for no apparent reason.

The Action of Insulin.—The action of insulin, especially in relation to the secretion of endocrine organs other than the pancreas, is imperfectly understood, but one thing seems certain: insulin does not "burn carbohydrate," for its most clearly demonstrable action is not concerned in the process by which carbohydrate is broken down to yield energy, but in that by which it is built up from glucose to glycogen. This point should be emphasized, for some textbooks still teach that insulin is "the spark which fires the glucose." No better illustration of how little is known of the mechanism of insulin action can be given than the experiment in which anterior pituitary lobe ablation is performed on the pancreatectomized dog: the animal, which before pituitary ablation was severely diabetic and could be kept alive only by insulin, can after the operation be kept alive without insulin. That is to say, insulin is apparently not essential for maintaining life in a hypophysectomized dog; for, if such an animal is sacrificed, no trace of insulin can be found in its tissues anywhere.

In practice in man the dose of insulin required to maintain the patient in health varies from case to case and sometimes from time to time, but in any individual patient the dose necessary to maintain him in health is independent of the carbohydrate intake.

The practising physician need know one thing only about insulin—that it is a specific remedy for diabetes, and will always cure diabetic coma and will always maintain the diabetic in health except when the disease is complicated by other factors.

The Relationship of Diet to Diabetes.—Two things are certain. The first is that the diabetic cannot maintain vigorous health unless his intake (when deduction has been made for calories lost in the urine) is at least adequate for his metabolic requirements. The second is that if the diabetic has lost weight the diet must be more than adequate for his immediate needs, in that it must contain sufficient nutriment to rebuild wasted tissues.

It is not by any means certain that a more than adequate diet (resulting in a high blood sugar) is harmful to a diabetic who is taking enough insulin. There are theoretical grounds for believing that it may be so, but these are largely based on observations on patients and animals treated without insulin, and it is possibly fallacious to apply them to patients receiving doses of insulin which are approximately the same as the estimated normal output of the pancreas.

It is, however, certain that, provided insulin dosage is adequate, no immediate ill effects are seen as the result of a surplus intake of carbohydrate. Such uncontrolled patients do not suffer from periodic ill-health, do not have hypoglycaemic attacks (provided their meals are closely spaced), and do not tend to become fat; the uncontrolled patients in the younger age groups do not develop arteriosclerotic and degenerative complications, and it is doubtful whether the uncontrolled patients in the older age groups show an incidence of these complications higher than the controlled diabetics. It is of course possible that ill effects may follow a persistent hypoglycaemia, but if so they are remote.

Diabetic Complications.—There is no explanation of the occurrence of retinitis, cataract, arteritis, and peripheral neuritis in diabetics. It is possible that in the future it may be shown that the incidence of these changes may be lowered by some modification in the diet or by insisting that even mild diabetics should take insulin, but at present the reason for these complications is unknown. It seems certain that, once they have occurred, their course is not greatly affected by insulin or adjustment of diet.

Infection and Diabetes.—There is no evidence that a high blood-sugar level disposes the tissues towards infection; nor does clinical experience suggest that operations on diabetics are more commonly followed by infection than in non-diabetics. Diabetics suffering from infections respond just as well as non-diabetics to the appropriate antibacterial treatment, provided that adequate antidiabetic treatment is also given. The presence of severe infection in a diabetic often demands large doses of insulin to prevent or treat coma. When such large doses are given it is of course necessary to maintain a liberal carbohydrate intake if hypoglycaemic attacks are to be avoided. There need never be any hesitation in giving such cases plenty of glucose, for experience has shown that rapid recovery from serious infections can take place in spite of a persistently high blood-sugar level.

It is now generally accepted that diabetic gangrene is not a metabolic disorder due to high blood sugar, but simply the effect of arterial narrowing.

The Diagnosis of Coma.—A common misunderstanding is that the danger of threatened coma is measured by blood-sugar estimations or tests for ketonuria. It is of course true that in coma the blood sugar is always very high, and it is also true that a positive ketone test is a sure sign of a maladjusted patient and should receive serious attention. But the diagnosis of coma is a clinical diagnosis. The very thirsty diabetic is not far from coma, and as soon as any cerebral symptoms appear (the first is usually slight drowsiness) the patient should be treated as if in coma (according to the American usage of the term, he *is* in coma); when tachypnoea or signs of circulatory failure appear death may occur at any time, if treatment is not started at once.

It cannot be too widely known that uncomplicated diabetic coma is curable so long as the patient remains alive; it never reaches an "irreversible stage" where even the most heroic treatment fails.

Summary and Conclusions

A two-stage method of making adjustments in insulin dosage on diet (or both) is described. It is specially useful when the patient is ambulant or under treatment in his own home.

It makes use of the observation that restoration to vigorous health may be attained by adequate dosage of insulin, an adequate diet, and no dietetic control apart from the close spacing of meals which prevents hypoglycaemia.

During the first stage the physician's only object is to restore the patient to vigorous health by adequate dosage of insulin. He does not attempt to restrict the carbohydrate intake.

He assesses the adequacy of his dosage by the patient's daily gain in weight with the further aid of a record kept by the patient of the time urine is passed and the volume of urine. Blood-sugar estimations and diet charts are not needed at this stage.

The second stage can be begun when the patient has been restored to vigorous health and his insulin requirements have become stabilized. If this stage is undertaken diet charts and blood-sugar estimations are needed, for its object is the restriction of the carbohydrate intake in order to maintain low blood-sugar levels. Dietetic control is not always practicable, and it is possible that it is not necessary. By the two-stage method it becomes easier for the physician to separate those patients in whom dietetic control can be maintained (if decided upon) from those in whom it cannot.

Its chief advantages are that it enables major or minor changes in insulin dosage to be made with little fear of hypoglycaemia; it focuses the attention of both patient and doctor upon the primary object of diabetic treatment; it enables the doctor to consider dietetic control after restoration to health instead of imposing it as a preliminary.

The application of the method to the chief difficulties met with in general practice is discussed.

REFERENCE

Micks, R. H. (1943). *British Medical Journal*, 1, 598

It will be noticed that we do not employ the symbols G C, E C, P C, O O, and +, widely used throughout the Services, to signify the presence and quantity of gonococci, epithelial cells, pus cells, and other organisms respectively. Let us suppose we receive a history sheet bearing the notation G C —, E C —, P C —, O O —. We take this to denote that organisms with the morphology of the gonococcus were seen. But, because many other organisms (it is not stated whether they were Gram-positive or Gram negative) were also present, we would like to know whether these Gram negative diplococci were intra- or extra cellular, for if they were extra-cellular and numerous Gram-positive organisms were present it would require the aid of a venerologist to ascertain whether or not they were gonococci.

The statement "P.C.++ and E.C.++" leaves much useful information unsaid, as it alludes only to the number of cells present and gives no indication of their size, type, or state of degeneration.

One of our sick-berth ratings has been specially trained in the carrying out of three procedures—the two-glass test, the Gram stain, and the irrigation technique. It is impossible to overstress the importance of the two-glass test. The simplicity of this procedure is obvious and its merit as a guide in a day-to-day study of the course of the disease indisputable. We are indebted to Pelouze for an invaluable routine method of graphing the results of the test, which we always place at the bottom of the first page of our records.

Below is a table showing the number of cases of urethral discharge which we have treated, listed under three simple headings; 76 of them were due to the gonococcus:

Total Cases	Non-specific Urethritis	Gonococcal Urethritis	
		Anterior	Posterior
93	17	49	27

Here we are not concerned with the non-venereal infection; nor would it be consistent with the theme of this paper to publish a detailed analysis of the venereal cases. The latter, however, do serve to illustrate the problems we have met.

The first of these is that, of the 76 cases of gonorrhoea, only 36 came to us with the history of a primary discharge of not more than three days' duration, whereas 40 gave one of the following histories: (1) discharge of more than 72 hours' duration; (2) relapse; (3) reinfection; (4) persistent discharge in spite of treatment. Secondly, of the cases in this latter group of 40, some came to us with no case notes, while the majority had inadequate histories. It was reasonable to expect that a large number of these cases would have infection of the posterior urethra, which indeed proved to be so. Individuals with such a complication are potential hospital patients, and it follows that they present the greatest difficulty in treatment.

How often we have wished that the Navy would state emphatically that cases in which the posterior urethra is considered to be infected are to be discharged to hospital! There is no doubt that this measure would considerably reduce the number of cases of the type discussed in this group. We appreciate the fact that it is not always possible to discharge such cases to hospital, and that there are few medical officers afloat who have sufficient experience and facilities to treat such cases on board, but for our purpose this small group need not be considered.

In the matter of treatment we make no plea for uniformity, but certain negations must be appreciated. Here the caution "I leave well alone" is often a timely warning where simplicity of therapy encourages meddling. We are of the opinion that on the one hand not enough use is made of existing facilities, admittedly often limited, while on the other there is a tendency to plunge into the realm of the venereologist. Do not let us be swept along with a flood of new therapies.

Here it might be of interest to mention some of the major faults in the treatment of gonorrhoea that we have observed following through our case histories.

1. The failure to appreciate the exact nature and extent of the pathological changes which have taken place, due often, it appears, to an inadequate knowledge of the detailed anatomy of the urethra and its adjacent structures.

2. The Dangers of Prostatic Massage.—There is a general appreciation that the prostatic tissue is involved in infections of the posterior urethra. Further, Lees and Lloyd have both shown that the administration of chemotherapy for gonorrhoea encourages an inflammatory response in the prostate. This is due to the inhibitory effect of the drug on the metabolism of the organisms, thereby allowing the tissue defences the maximum opportunity of destroying them. With this in mind it is obvious that digital irritation of the gland at this stage is contraindicated. We never carry out this procedure until seven days after the cessation of sulphonamide administration.

3. The Passage of Sounds.—An ill-timed prostatic massage can do enough damage; sounds can do a hundredfold more. Certainly, in experienced hands they are of established value, but in their indiscriminate use lies the danger of causing stricture, epididymo-

orchitis, etc. Be it sufficient here to make one generalization: Never pass a sound if the gonococcus can be demonstrated; when performing a test of cure it is wise to wait until three weeks after the discharge has ceased before employing sounds.

4. Perseverance with Sulphonamide Drugs.—Medical officers frequently do not realize that a case that has failed to respond to two courses of a sulphonamide is unlikely to benefit from a third course of double the optimum dosage. All too often cases of gonorrhoea are flogged with course after course of sulphonamides.

5. Failure to Perform a Thorough Test of Cure.—It is sometimes impossible to discharge cases to hospital for urethoscopic examination or even for a Wassermann test. Nevertheless a reasonably satisfactory test of cure can and must be performed, particularly after an apparent "sulphonamide cure." If the medical officer is likely to lose sight of the case it should be impressed on the patient and his executive officer that complete tests of cure must be performed as soon as the opportunity arises.

Conclusion

It was our original intention to submit this communication to the Medical Director-General for publication in a Royal Naval medical journal. Had we done so we would have left unsatisfied a conviction that our plea might have had a wider appeal. Prominent in all our minds at the present time is the desire to do everything in our power to achieve unity and team-work in the profession. For others the war may well have passed the critical stage, but for us the outcome lies at this very moment in the balance. This paper is a plea in a limited sphere for a more co-operative attitude and a closer inspection of one's personal routine. By so doing, each individual one of us may feel that he is helping to turn the scales.

Summary

There is a need for greater co-operation and team-work in the management of cases of gonorrhoea.

Stress is laid on the importance of a comprehensive history sheet, and methods of tabulation are discussed.

Conclusions are drawn from 76 cases of gonorrhoea treated on board ship, and some common faults in therapy which have come to light are recorded.

We wish to acknowledge our indebtedness to the Medical Director-General of the Navy, Sir Sheldon Dudley, for permission to publish this communication.

TREATMENT OF WOUNDS BY DELAYED SUTURE

BY

WILLIAM PATRICK, M.B., F.R.C.S.Ed.

Lieut.-Colonel, R.A.M.C.(T.A.);

Lately Officer in Charge, Surgical Division, General Hospital, C.M.F.; Assistant Surgeon, Royal Infirmary, Glasgow

The initial operative treatment of soft-tissue wounds in junction with sulphonamide or penicillin therapy, and a secondary suture along with the technique of penicillin administration, are intended to prevent or minimize infection as well as to encourage early healing. In spite of these efforts in the forward areas, it is my experience that very many granulating wounds, some of considerable size, still reach the base hospitals with infection well established. Some time has usually elapsed since the injury, and these wounds are regarded as "old," but healing by granulation tissue should not be accepted as the inevitable outcome.

Part of our obligation is to obtain a soundly healed wound in the shortest time. This infected granulating type of wound takes weeks and sometimes months to heal if left to granulate, nor is it wise to attempt a secondary suture. In my opinion these wounds can be very easily treated by the "cure" of excision and suture, as opposed to the "prevention" of the early treatment, and it is on that account that this method has been investigated.

Operative Technique

This should consist of four phases: (1) control of infection and the preparation of the wound; (2) estimation of the optimum time for operation; (3) the practical details of the operation; and (4) the post-operative care of the wound.

1. Control of Infection.—If there is no infection in the wound no special pre-operative treatment is necessary. As a general

the degree of infection varies. In some cases no alteration of the ordinary routine treatment need be made: if the infection is resistant or fairly heavy a course of penicillin locally will be required to bring the wound into a state suitable for operation. It is very necessary in this late type of wound to have as low a degree of infectivity as possible before excision; only certain estimation of non-infectivity is by bacteriological control. Contamination of the wound should be avoided full precautions during dressings; rest in bed should be regarded as a necessary part of this phase.

2. *The Optimum Time.*—It should be said quite definitely that there is no fixed optimum time for this type of operation. It is found, however, with the technique adopted, that better results were obtained in older wounds, but, with satisfactory results from the suggested pre-operative treatment, the waiting period may be cut down considerably. Each wound can be assessed only by its clinical condition, the degree of infection determines the best time to operate.

3. *Operative Details.*—Practically all wounds can be done under a simple pentothal anaesthesia, followed by gas and oxygen if necessary. Local infiltration is not recommended. The first essential is to adopt a complete surgical preparation for any major operation and to avoid any tendency to skimp preparation. The technical steps are as follows:

(a) A clean and complete excision of the epithelial edges and all the granulation tissue down to and, if necessary, through the deep fascia. The correct axial direction for the excision will have been determined already by the initial operative treatment; this will be mainly longitudinal. A margin of $1/8$ in., or at the most $1/4$ in., will be sufficient to cut beyond the epithelial edge into normal skin, the ends of the incision must be very exact and allow the opposing skin edges to lie neatly in apposition. The length of the incision is of no consequence; the incision should be at a right-angle to the skin surface. This leaves a clean operation field exactly comparable to a planned operation incision, except for the possible gap in the deep fascia.

(b) The skin edges are next undercut and freely mobilized, this enables even a moderately wide gap to be sutured without tension—a point of great importance.

(c) Haemostasis should be as absolute as possible.

(d) The skin edges and the depth of the wound are now dusted with a fine "hoar-frost" covering of penicillin or a sulphonamide, alone or in combination.

(e) Any hole or gap in the deep fascia covering the underlying muscle should be carefully repaired, this, in my opinion, prevents the scar from becoming adherent.

(f) The wound is now carefully sutured. In most cases closure can be complete if one feels certain that all dead space has been obliterated, occasionally it may be safer to use a small fine drain in one end of the wound for 48 hours, or a small central "bleb" may be left in the suture line.

(g) The completed suture line is given a final "hoar-frost" dressing, and a firm pressure-bandage is applied.

Post-operative Care.—To standardize this phase the drain, if any, was removed after 48 hours. The first dressing was done on the 10th day, when the sutures were removed. The suture line again powdered, and a firm pressure-bandage reapplied. The second and third dressings were done on the 6th and 22nd days respectively, by which time healing was complete and the wound in a condition to stand up to rehabilitation. All dressings were carried out with aseptic precautions in the theatre. Wounds on the flexor surfaces of limbs, of buttocks, and the back require careful post-operative supervision. The patient was confined to bed until healing of the wound was complete. A limb was always immobilized if necessary, to obtain rest. All cases of this nature were segregated in a "clean" ward.

Practical Features of the Investigation

A number of granulating wounds, practically all infected, were submitted to the strictly uniform operative detail described above. In order not to obscure the effectiveness of the operative part of the technique, no particular attention was paid in any way to pre-operative control of infection. No case was specially selected. A wound was decided, crudely perhaps, to be suitable for suture simply when it looked clean—there was no bacteriological control. The bacteriostatic agents employed were sulphanilamide, sulphathiazole, and penicillin which was probably some months old: its strength was 5,000

units per gramme); three separate series of cases were treated, and each was given a different powder.

The success of the technique was judged entirely on the healing of the wound and any degree of infection which may have developed. It has been estimated on a percentage basis for tabulation as follows:

- (i) Completely healed on 10th day without infection and remained healed subsequently . . . 100%
- (ii) Very minor stitch-hole infection: wound a little "grumbly" but dry and healed at 2nd dressing on 16th day . . . 90%
- (iii) Definite stitch-hole infection with some pus or discharge, perhaps slight wound-gap in places; but dry and healed on 22nd day . . . 80%
- (iv) Infection prolonged after 22nd day: some definite breakdown of suture line, likely to be some granulation . . . 70%
- (v) Failures, and generally poor or worse results than in previous group . . . below 70%

Clinical Results of Method

Series 1.—This consisted of 10 cases. The bacteriostatic powder used was a mixture of penicillin and sulphanilamide in a proportion of 1 in 10. The wounds in this series were on the whole rather above the average size, and the time-interval between wounding and suturing was relatively long. (See Table I.) The results were quite satisfactory, 8 wounds

out of 10 (80%) being completely healed within 3 weeks. One buttock wound was poor (it actually healed completely later on after a re-suture); one thigh wound (No. 8) collapsed completely without being infected (the edges and granulation tissue had not been excised, owing to the extent and depth of the wound, and therefore there was no framework on which reparative tissue could build). The penicillin-sulphanilamide

Medical Memoranda

Hernia of Caecum into Lesser Sac of Peritoneum Complicated by Volvulus

CASE REPORT

The patient, an obese female, arrived at hospital with a history of abdominal pain and vomiting of four days' duration. There were no previous attacks, but she had a strangulated umbilical hernia several years ago, at which time she had similar symptoms. Her present pain, however, starting as a colic, had become continuous. Examination revealed a dyspnoeic and severely shocked patient, with a rapid pulse of poor volume, a cold and clammy skin, and cyanosis of the extremities. The abdomen was greatly distended, and diffusely tender and rigid. No external hernia was present. A diagnosis of strangulated intestinal obstruction with peritonitis was made. The administration of plasma intravenously, oxygen by a B.L.B. mask, and evacuation of the stomach failed to improve her general condition, and she died in a few hours.

Post-mortem examination revealed a large swelling in the lesser sac of peritoneum, which displaced the stomach and liver upwards and towards the right side. The liver was compressed under the right cupola of the diaphragm, which was itself displaced upwards to a marked degree. No tapering left lobe was present on the liver. On removal of the gastro-colic omentum the swelling was found to be an intestinal sac measuring $20 \times 15 \times 12$ cm. and filling the whole of the lesser sac of peritoneum. Further investigation showed that the condition was a hernia, through the foramen of Winslow, of the caecum and terminal ileum, and that the hernia had undergone volvulus through 180° , which caused complete obstruction. The

walls of the distended caecum were very thin and congested, but not gangrenous or perforated. The small intestine was greatly distended and diffuse peritonitis was present. The foramen of Winslow was considerably larger than normal, and the hernia was ultimately reduced without puncturing the intestine. The ascending colon had a long mesentery continuous with that of the ileum.

COMMENT

Since the first case, recorded by Blandin in 1834, about 50 cases of intestinal herniation through the opening into the lesser sac of peritoneum have been described. It is possibly the rarest type of internal hernia (Silverstone, 1939). Excellent reviews of previous cases have been given by Ullman (1924), Dewis and Miller (1927), Silverstone (1939), and Edwards and Stewart (1943). It appears that in only 10 cases was the caecum present in the lesser sac. In no case was a volvulus reported present, so the case described here is apparently unique in this respect.

The distortion of the liver and the large size of the foramen of Winslow suggest that the hernia had been present for a considerable time without giving rise to symptoms until the volvulus was superimposed. Dewis and Miller (1927) stressed the fact that this form of hernia can be present without giving rise to obstruction, and can apparently reduce itself. The only congenital abnormality was the long mesentery of the ascending colon, without which, of course, the herniation would have been impossible.

Reviews

REACTION TO INJURY

Reaction to Injury. Pathology for Students of Disease. Based on the Functional and Morphological Responses of Tissues to Injurious Agents. By WILEY D. FORBES, M.D., Professor of Pathology, Duke University. (Pp. 797; illustrated. 50s.) London: Baillière, Tindall and Cox.

This volume contains the first two sections of a treatise on pathology which will be complete with the publication of the third and fourth parts, now in course of preparation. It is an ambitious piece of work; its central plan is based on the belief that the essential element in disease is the reaction of the whole individual to the agents and influence comprising his environment. Pathogenesis supersedes specific aetiology, and the old conventional division of pathology into "general" and "special" sections goes by the board. The reader's attention is centred from the start upon "broad relationships and general principles rather than upon isolated facts, and often deceptively dramatic details." The author's outlook has been quite obviously deeply influenced by W. G. MacCallum, to whom he owes "so much that it almost must remain unsaid." Even a short examination of the text quickly recalls MacCallum's great classic.

The author's attitude to his public—the student—is refreshing and stimulating. He regards the student of disease, for whose guidance the book was written, as being "quite as intelligent as his instructors" and entitled to be dealt with as a responsible junior colleague. For these reasons basic principles are treated fully and accurately, controversial subjects are closely and clearly argued, and recent research work is fully described. This is therefore no book for the student who wishes to assimilate temporarily just enough pathology to pass his final examination. Even the illustrations, which as the author states are not chosen for decorative purposes, need attentive study. They are excellent, and are closely correlated with the text and accompanied by full descriptive legends. Each chapter ends with a carefully compiled bibliography.

The next edition of this book will be awaited with interest and it is safe to predict that the completed treatise will occupy an important place in pathological literature.

PSYCHIATRY

A Textbook of Psychiatry for Students and Practitioners. By D. K. HENDERSON, M.D., F.R.F.P.S., F.R.C.P.Ed., and R. D. GILLESPIE, M.D., F.R.C.P., D.P.M. Sixth edition. Oxford Medical Publications. (Pp. 719, 25s.) London: Oxford University Press, 1944.

Henderson and Gillespie has deservedly established its place as the standard textbook of psychiatry in this country. The appearance of a sixth edition in this era of paper shortage is evidence enough of its importance and popularity. As the authors point out, psychiatry is extending its borders so rapidly that the young psychiatrist is faced with an alarming list of sciences, from statistics to physics, with which he may be expected to be familiar. Still his subject is growing in value and is of supreme interest. Perhaps the most important change in this edition is the greater importance accorded to the psychoneurotic reaction types in view of their frequent occurrence in the practices both of the specialist outside the mental hospital and of the family doctor. This group is held to be the result of unconscious mental conflicts in contrast to the constitutionally determined mental illnesses such as depressions, paranoid reactions, and the rest.

A new chapter is devoted to special methods of physical treatment, consisting of insulin therapy, cardiazol therapy, electric-convulsion therapy, leucotomy, continuous narcosis, and narco-analysis. As the authors say, the continued success of these methods, in spite of the absence of logical reason for their success, may result in new light appearing on psychophysical mechanisms. The authors agree that electrotherapy is the best form of shock treatment, and that the most favourable results are obtained in depressives, including involutional cases. Leucotomy they say should be reserved for patients in whom all other suitable methods of treatment have been tried and failed; where the illness offers no reasonable hope of spontaneous recovery; and where the patient is disabled more or less completely from useful occupation or from moderate enjoyment of his life.

The paranoid "schizophrenic" type has been removed from the schizophrenic group and is discussed in relation to paranoia, with which it has more affinities. The chapters on epilepsy and war psychiatry have been enlarged and strengthened, and the other sections of the book have been revised and brought up to date. Old readers will welcome an old friend still youthful and vigorous but more mature, and new readers must have this textbook on their shelves.

GUIDE TO PHARMACOLOGY

Pharmacology By J. H. Gaddum. Second edition. (Pp. 460. Illustrated. 21s.) London: Oxford University Press, 1944.

When this useful text book was first published in 1940 the author observed in his preface that it was intended for medical students "at a stage in their education before general principles become obscured by a mass of practical details." He then went on to suggest that it might also be of use to medical men, because it tried to give them some knowledge of the kind of evidence that justifies the trial of new drugs. Certainly to-day medical men need this information more than ever for the introduction of new and potent remedies into clinical practice proceeds at almost a breathless pace. Prof. Gaddum begins with a chapter on diet, and proceeds with chapters on vitamins, hormones, stimulants to the central nervous system, and narcotics, ending with chapters on chemotherapy and general pharmacology. At the beginning of the book he gives metric equivalents for apothecaries and avoirdupois weights and for imperial measures. Another pleasant foretaste to the book proper is a three page summary of pharmacological literature for those who wish to explore further.

Prof. Gaddum is a sure and delightful guide, and writes a simple straightforward English free from ambiguity. He has a happy knack of nying a fact in the mind by the judicious use of a sly humour, as when he refers to the annoyance felt by miners when they found that the remedy for "stokers' cramp" was only salt and water. The discovery that a certain amount of calcium was needed to maintain activity of isolated tissues hung upon the fact that Dr. Sidney Ringer, when his assistant took a holiday, used distilled water in making up isotonic solutions for the study of isolated hearts. The hearts did not beat. When Ringer's laboratory assistant made up the solutions he used tap water to save himself trouble.

In a short note on manganese the author observes that exposure to clouds of manganese dust causes atrophic changes in the basal ganglia of the brain and that oral administration may cause cirrhosis of the liver. Reference might perhaps have been made here to another condition in which there is an association between cirrhosis of the liver and lesions in the basal ganglia—namely, in the rare clinical condition known as atrophic degeneration or Wilson's disease. The two chapters on hormones include a few illustrations which tell a lot in a short space. Particularly effective is the photograph of two frogs in a dish, one of which had been injected by an antidiabetic agent; the frog is completely black from the expansion of its melanophores, while its untreated control is normally speckled.

Some of Prof. Gaddum's notes on the therapeutic uses of the substances he discusses are tantalizing because he whets the appetite without always satisfying it. Primarily, of course, his book is not a book on therapeutics, but if he discusses the clinical use of androgens in old age and eunuchoidism one would like to see a brief summing up of the question of the hormone treatment of enlarged prostate. There are one or two small points of criticism: for example, should not aneurism be spelt thus—i.e., without a terminal "e"? And is it really correct to say that progesterin is "Greek for pregnancy hormone"?

Notes on Books

The report presented by the Director-General to the second session of the Council of the United Nations Relief and Rehabilitation Administration, held in Montreal last September, has been published on behalf of the European Regional Office of U.N.R.R.A. (11, Portland Place, London, W.1) by H.M. Stationery Office at 2s. 6d. This report covers the progress of the administration's past activities and its proposed activities during the immediately foreseeable future, as well as the work of the Central Council since its first session. A further publication will follow containing statements made by representatives of the combined chiefs of staff, the reports of the

intergovernmental allocating agencies, and the text of the council's resolutions.

On Aug. 30, 1944, Dr. The Svedberg, professor of physical chemistry in the University of Uppsala, reached the age of 69. His colleagues, pupils and other friends in scientific and industrial research decided to commemorate the occasion by a book dedicated to him and bearing his name on the cover. For reasons explained in the preface the contributions have been limited to the field of chemistry in its widest sense including work in the borderland of other sciences, and technology in particular, to which Prof. Svedberg during recent years has devoted so much of his time and energy. The editorial committee hopes that this volume will give something in the nature of a cross-section of Swedish activities in chemical research during difficult years.

Preparations and Appliances

APPARATUS FOR CONTINUOUS PENTOTHAL

Major D. E. DUNNILL, R.A.M.C. writes

The preparation of a simple portable and completely self-contained apparatus for the giving of continuous pentothal anaesthesia seems to fill a gap in the anaesthetist's armamentarium and the following notes and illustration describe one which has been evolved in the light of experience gained during three years of use.

It consists of a case, size 13 x 6½ x 6 in. which contains a standard Army transfusion bottle for giving intravenous saline. Positive pressure is applied with a bellows and measured on a mercury manometer and the rate of flow through the drip feed is regulated by a screw clamp. The rubber tubing from the drip feed to the intravenous needle has interposed a two-

way tap the second arm of which takes a standard Record syringe, so that at any time the saline can be cut off and pentothal injected. All that is necessary to maintain a steady flow of saline into the vein is an occasional glance at the manometer and drip feed, and a squeeze on the bellows when the pressure falls. Pentothal is injected as often as desired from the syringe, which contains the usual 5% solution.

The case is designed to fit the arm of an operating-table, but can be used anywhere else, such as on a bedside table, and the whole apparatus is easily removed for sterilization. Since, however, the tubing from the two-way tap to the needle is detachable for boiling after each case, the rest of the apparatus remains sterile and can be used repeatedly.

The apparatus is manufactured by Messrs. Down Bros., Ltd., 22A, Cavendish Square, London, W.1.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY DECEMBER 16 1944

A.R.M. ON WHITE PAPER

The Annual Representative Meeting held last week was one of the most momentous in the history of the B.M.A. Nearly 270 Representatives from all parts of the British Isles left their practices for the greater part of a week at a time of the year and a time of the war when work is as hard as it can be. By attending in what must be a record number they thus showed how fully they felt their responsibility to the future of the profession they represent. Any chairman of such a meeting may well have felt dismayed when confronted with more than 370 motions on the White Paper. To add to his apprehensions was the news of the formation of a "ginger group" of the deepest blue, some 80 strong, who, with the intention of forming a solid voting block in the A.R.M., were formulating their policy at private meetings. But the solid good sense of the meeting and the suave tact of the Chairman of the R.B. turned to good use the combustible material that was there, and the representative machine proceeded, somewhat unevenly at times, to a stage from which the Negotiating Body can safely continue the next part of the journey. Throughout the whole four days the skilful guiding hand of the Chairman of Council took the meeting out of the mazes into which it occasionally wandered. The A.R.M., indeed, owed much to his remarkable grasp of the present medico-political situation, and to the sheer practical common sense with which he cleared away the fogs of confused thought.

The net result of the four days' discussion was a decision to negotiate with the Government on the basis of the White Paper only if it were altered in essentials. The starting-point for negotiations is summed up in this motion, put by the Chairman of Council and carried unanimously:

"That it be an instruction to the Association's representatives in the Negotiating Committee that, without prejudice to other issues, including the 100% question, remuneration and compensation, consideration of administrative structure, central and local, should precede consideration of all other questions, and that agreement on this subject is an essential prerequisite to discussion of other subjects."

This gathers up the trends of the many discussions and deliberations that have taken place since the White Paper was published. The medical profession will refuse to work any scheme for a comprehensive National Health Service unless it is fully satisfied that the administrative structure, central and local, is properly framed to receive such a scheme. While at times several speakers found it hard to distinguish between administration and control, and so urged the doubtful thesis, "No control, therefore no administration," the two concepts were finally disentangled. Sound administration is essential, but the profession will resist any administrative proposals which, in the words of one motion, would tend "in any respect to limit the free-

dom of judgment and of action of the practitioner, or to weaken his full responsibility for the patient." This was part of a motion moved on the first day by Glasgow under the agenda heading of "General Attitude." It stated, in addition, opposition to a State-salaried service, to civil direction of practitioners, to government of the profession by local health authorities, and, in short, "to most of the machinery of the White Paper." This general attitude was reinforced by another motion which declared the administrative proposals and form of control envisaged by the White Paper to be "inimical to efficiency and progress"; and the fear of Government interference with the doctor-patient relationship found expression in another motion that was passed. In fact, the general trend of the debate showed that current disapproval of the White Paper as a whole is shared by a much bigger proportion than the 53% of the Questionary. Further reflection and deliberation on the Government's proposals have clearly expanded the volume of discontent with it. This discontent finds its most concrete expression on what is known as the 100% issue. The alternating waves of assent and dissent on this question should make quite plain to the general public that the medical profession is not interpreting this matter in terms of finance. Effective ridicule was directed by one speaker against those who screeched out the old parrot cry, "Vested interest!" against anyone who thought it unnecessary to make public provision for medical advice and treatment for those well able to secure these things for themselves. The medical profession has one "vested interest" which it is its first duty to defend, and that is the sane and unbroken tradition of professional beliefs and institutions that have evolved along with society over hundreds of years. It is this tradition and these institutions which have made possible the emerging of medicine out of magic into medical science. It is therefore the first duty of the profession to preserve what is good in this tradition so that it can continue to evolve in ways that have been well tested by generation after generation of medical men and women. The public will never get good medical service except from men who are rightly proud of their profession and satisfied with the scope of service offered by it.

The Representative Meeting passed as a substantial motion the Isle of Wight amendment that "pending further information on . . . the machinery whereby private practice is to be continued . . . there be confirmed the view of the A.R.M., 1943, 'that a comprehensive medical service should be available to all who need it, but it is unnecessary for the State to provide it for those who are willing and able to provide it for themselves.'" This vote was against that unification of services under central control which is characteristic of totalitarian regimes. In its opposition the meeting showed a characteristic British distrust of the simplified logic of the doctrinaire. It preferred, in the opening words of a motion by Bournemouth, "that health legislation should proceed by evolution," and went on to pass a motion which urged as the first objective the completion of the National Health Insurance scheme for those at present insured under it by making available to them "institutional, specialist, and all auxiliary services." When this has been done, then the completed service should be

extended to dependants of the insured and to others of like economic status. The approach is at least realistic, and takes into account the fact that medical men have come to live on more or less easy terms with the N.H.I. scheme, this being so it would seem logical to complete it, to extend it and to make it more acceptable to the profession by making the capitation fee an adequate reward for work done. We may relate this to an important motion passed with a unanimous vote later in the meeting—namely, that new legislation on health service proposals should be presented in a separate Bill, and should not be incorporated in or be dependent on the financial provisions of the social insurance measure. It would certainly be unfortunate if the Government were to legislate for a new health service in the present session as a way of giving the public an apparent morsel of the new social security measure, legislation on which will not be introduced until a new Parliament has been elected.

As to the administrative machine to be devised, the meeting dropped the idea of putting central administration in the hands of a corporate body, and supported with a large majority the Council's proposals set out in paragraph 40 under the heading of "The Central Body" in the Council's Report on the National Health Service published in the *Journal* of May 13 (p. 646). From the point of view of the profession, the essence of administration is that doctors should have an effective voice at all levels of organization and that this effective voice should be secured by electing medical men on to the various responsible bodies. For fear lest politics should muzzle medicine, the meeting insisted upon the safeguard that the statutory body corresponding to the Central Medical Advisory Committee should have the right of publication of its recommendations, whether they are agreed to or not by the Minister. As to local administration, the meeting agreed with the Council's recommendation that regional councils should be set up, these to be 'representative of local authorities, the medical profession, including general practitioners and the medical staffs of voluntary and municipal hospitals, the representatives to be appointed by the groups or bodies concerned'.

At the end of the meeting the Chairman of Council summed up the four days' deliberations (reported in this week's *Supplement*) in the fewest possible words, which we reproduce here, as they give pith to the matter.

We have expressed ourselves in favour of development of the service.

We have disapproved of the White Paper as it stands.

"We have decided to negotiate.

We have appointed our share of the Negotiating Body.

We prefer the service to proceed by evolution from N.H.I. by first the development of the hospital system and then the extension of the general practitioner services.

We have stated emphatically that we do not wish to be employed by local authorities, that there should be no civil direction, that there shall be no whole time salaried service for general practice, and that we shall have no clinical control.

We have instructed our negotiators that their first action shall be to try to agree with the Government the form of administrative structure, and that no action shall be taken in the matter of negotiations until the administrative proposals have been agreed.

THE BLACK TWIN OF SILICOSIS

According to Rosen's recent book,¹ medical and public interest in the disease now officially known as the pneumoconiosis of coalworkers (aptly termed by a working miner "the black twin of silicosis") has fluctuated during the past few centuries. Certainly the evidence points to a considerable incidence in the English and Scottish bituminous coalfields after the industrial revolution, but this seems to have declined by the 1880s—probably due to improved ventilation and working conditions—only to be succeeded by a wave in the Welsh coalfields, where anthracite seams were being developed rapidly at the close of the century. The present day particular association of pulmonary diseases due to dust with anthracite mining was demonstrated by independent surveys carried out about the same time in the U.S.A.,² the U.S.S.R.,³ and in this country.⁴ Not that the association is exclusive, for in the Welsh steam coal mines the incidence is by no means negligible; indeed, a remarkable correlation between "rank" of coal and incidence of pneumoconiosis, from highest in anthracite to lowest in bituminous is evident when various criteria are used.⁴ The coal mining industry dominates all others as a source of pulmonary disease. The seriousness of the problem in the Welsh coalfield is shown by an incidence rate over fifty times that of the rest of Britain, while disablement certificates in Wales have increased from 387 in 1939 to 985 in 1943 (a new compensation scheme operated from July 1943) in a population that had declined from 130,000 to 113,000 in the same period.⁵ Cases are becoming so common that the Silicosis Medical Board has a waiting list of six months, even with preliminary filtration by general practitioners and the Welsh National Memorial Association. There is no doubt that the major cause of this recent rapid increase is the detection of hitherto unrecognized cases, and this process is not likely to slacken until the recommended⁶ periodic examinations become part of the health control of miners and until men who are underground though partly disabled are given the opportunity of alternative productive work.

Pneumoconiosis in miners is still a complex and rather baffling disease. Though some American workers believe the relatively small amount of quartz in the dust to be the main cause, it is doubtful if this is the whole story, it may be that other silicates, antidotal substances, and the adjuvant action of the coal itself are important. The progress of the disease is slow and insidious⁶, its predominant symptom is breathlessness on exertion, its main complications are tuberculosis and cardiac failure, its diagnosis in life rests largely on the x-ray picture (for an atlas of the chest x-ray changes see the first M.R.C. report⁴). There is frequent lack of correspondence between x-ray appearance and symptoms in individual cases, but if statistical groups are taken, the more extensive and severe the disease

on the radiograph the more likely is disability to be present.

What of the future? Treatment of the established condition was symptomatic until powdered aluminium came into use; suggestive results in metalliferous miners suffering from silicosis have been recorded lately,⁷ and a carefully controlled trial in coal-miners is indicated. Rehabilitation and resettlement schemes for men partly or even wholly disabled from mining are an urgent and immediate problem; some thousands have gone into war industries of their own accord and have been working happily there, but planned arrangements will be needed for peacetime conditions. For purposes of prevention great hope lies in water infusion of the coal face to allay the dust at its source.^{8 9 10} This method, which was first introduced in Britain, certainly reduces the dust; but it will be imperative, by follow-up of selected groups, to be able to say in five to ten years whether the reduction has been adequate to eliminate serious disease. Mechanization, though it tends often to increase dustiness, may, if combined with dust-allaying methods, be ultimately beneficial through reducing the human factor; perhaps we shall even see underground gasification, as in some Russian mines.¹¹ To carry out and co-ordinate these socio-medical tasks, together with further basic pathological research into causation, a special research centre has been recommended.⁵ This may lead to a National Pneumoconiosis Bureau that shall take over the compensation functions of the present Silicosis Board, conduct periodic examinations of all miners, and be concerned, together with the Ministry of Fuel and Power, with preventive methods⁵; the experience of the South African Miners' Phthisis Bureau would justify such a development.

POSTERIOR PITUITARY AND THE UTERUS

It was in 1906 that Dale discovered the stimulating action of an extract of the posterior pituitary gland on the isolated uterus. It was subsequently shown that the posterior pituitary contains two active principles, though neither has yet been isolated in a pure form, and it is still not certain that they have separate existences in the body. The oxytocic principle (pitocin) acts exclusively on the uterine muscle, and the vasopressor principle (pitressin) on the muscle of the arteries and certain smooth muscle of the dominal viscera. The antidiuretic function of the posterior pituitary is apparently associated with pitressin. The reaction of the isolated uterus to posterior pituitary extract varies from species to species. In certain circumstances pitressin stimulates the human uterus, and pitocin has its greatest effect towards the end of pregnancy and in labour. Chassir Moir¹² has recently studied this problem. The non-pregnant uterus undergoes regular small contractions in the first half of the menstrual cycle. Later these are gradually replaced by larger and more prolonged contractions which merge eventually with the contractions of menstruation. The uterus reacts to undifferentiated posterior pituitary extract at all stages of the cycle, but it was found—rather surprisingly—that the non-pregnant uterus reacts only to pitressin and not at all to

pitocin. In early pregnancy the reaction of the undisturbed uterus to pituitary extract is slight, though after evacuation of the uterus the reaction is more pronounced. Both pitocin and pitressin were found to have a motor effect on the aborting uterus, though the response to pitressin is more constant and probably greater. In late pregnancy posterior pituitary fractions have a very variable effect, but, in general, much larger contractions are caused by pitocin than by pitressin, and in labour also. For the first three or four days after parturition pitocin is still more active than pitressin, but towards the end of the first week the oxytocic effect of these two principles is about equal. This extremely important study has certain clinical corollaries. If pituitary extract is used to check haemorrhage in abortion the undifferentiated extract should be used, because pitocin is relatively inactive at this time. But in later pregnancy and in labour pitocin has some advantages; it is relatively free from antidiuretic effect and may therefore be employed for the induction of labour in cases of toxæmia; it is less apt to cause pituitary shock and is therefore to be preferred for the treatment of post-partum haemorrhage; it should be used when intravenous injection is required, but in a dose not exceeding 2 units.

Moir¹³ has also reviewed the literature and clinical use of oxytocic drugs generally. Pituitary extract seems to have little advantage over ergometrine in the treatment of post-partum haemorrhage, though he believes that pituitary extract is the more active of the two preparations in the anaesthetized patient. Against this is the danger of pituitary shock—a complication especially likely to occur if the extract is given more than once within a space of half an hour. Pituitary extracts have a relatively transient action on the uterus, which passes off in about half an hour. In a recent letter in these columns¹⁴ Moir points out that advantage may be taken of this fact by injecting pitocin into the fundus of the uterus to aid in the expulsion of the placenta. If expression of the placenta is unsuccessful haemorrhage is checked, and manual removal may be performed half an hour later. While deprecating the routine use of oxytocic drugs before the placenta is delivered, he points out that this manoeuvre may, in suitable cases, avoid the necessity for manual removal. It may be added that the evanescence of the effect of posterior pituitary extracts is in itself a danger, and when they are given for post-partum haemorrhage it is well to supplement them with an oxytocic of more prolonged effect, such as ergometrine praeprata.

THE NUTRITIVE VALUE OF YEAST

Weight for weight yeast is the most nutritious foodstuff known. Perhaps "foodstuff" is not the correct term, as yeast is not taken in any quantity as a food. The small amounts added to bread are negligible from the nutritive point of view—a point of view which is developed in a recent monograph by Somogyi.¹⁵ On a dry-weight basis yeast contains some 50 to 60% of protein—far more than any animal source—and this is stated to be as good biologically as the protein in milk. No animal can rival yeast in the proportion of protein it holds in its tissues. Yeast contains the essential amino acids tryptophane, methionine, valine, leucine, isoleucine, histidine, and lysine. It is an excellent source of the B vitamins, and has nearly 2% of potassium, 5% of phosphorus, and 0.03% of iron, all essential constituents of the diet. Among other important substances in yeast are glutathione and ergosterol (both 0.5 to 0.6%), glycogen (40%), lecithin (2 to 4%), and nucleic acid (26%). If yeast is irradiated the ergosterol

¹⁵ *Beihft. Z. Vitaminforsch.*, No. 4, 1944, Berne.

is transformed into calciferol equivalent to 3,000 to 4,000 i.u. of vitamin D per gramme of yeast. A fifth of a gramme of irradiated yeast a day would thus suffice for the prophylaxis of rickets in the young infant. If there are no technical difficulties in the way of producing irradiated yeast on a commercial scale rickets could be prevented for a trifling sum.

The vitamin-B content varies in different kinds of yeasts, the best source being brewers' yeast, which may contain up to 25 mg. of vitamin B₁ per 100 grammes, this may be increased to 90 mg. per 100 grammes if the yeast is grown in special media. The "average man," it may be recalled, is thought to require about 2 mg. of vitamin B₁ daily. The riboflavin content of yeast varies from 1.8 mg. to 5 mg. per 100 grammes, and that of nicotinic acid from 10 mg. to 100 mg. Yeast is the richest-known source of vitamin B₆, of pantothenic acid, and of biotin—three other members of the vitamin B complex.

It is possible that yeast may play an important part in human nutrition in the future. It is a source of protein and vitamins (far cheaper than vitamins out of a bottle) and could be used to fortify the refined diets of our modern civilization. Bakers' and brewers' yeast are not altogether suitable for human consumption because they are not tasty enough. As pointed out previously,¹⁶ food yeast, or the dried yeast *Torulopsis utilis*, is more palatable than bakers' and brewers' yeast and can be manufactured more cheaply. If it is made on the scale now contemplated it can be produced for sixpence a pound. Thus for three-halfpence a day it would be possible to obtain 50 grammes of first-class protein and an adequate supply of all the B vitamins necessary for human nutrition—but who would eat it?

CONWAY EVANS PRIZE

The Presidents of the Royal Society and of the Royal College of Physicians have awarded the Conway Evans prize to Sir Thomas Lewis, M.D., F.R.S., F.R.C.P., in recognition of his great contribution to medical knowledge in the normal and abnormal mechanisms of the heart and circulation of the blood. This prize, in accordance with the will of the late Dr Conway Evans, who was medical officer for the Strand district, is awarded from time to time for scientific work of outstanding distinction. It was given to Sir Charles Sherrington in 1927, and since to the late Dr John S. Haldane in 1933 and to Gowland Hopkins in 1938. It will be seen that so the prizes have been awarded infrequently with the intention that they should be given only in recognition of outstanding contributions to science, thus fulfilling the intention of the donor. Sir Thomas Lewis has worked essentially in a field which he has called "clinical science," and he has clearly indicated how the modern developments of science in general can be applied to the many problems of medicine at the bedside.

THIRTY YEARS OF DISTRICT NURSING

District nursing—the service if not the name—has been in existence not for thirty but for a hundred years. It may perhaps be dated from the foundation by Elizabeth Fry of the Institute of Nursing Sisters for the poor in their own homes. Queen Victoria's Jubilee Nurses date back for more than half a century. But it was in 1914 that the Central Council for District Nursing in London was established. To commemorate thirty years' history a pamphlet has been published recalling some of the Council's achieve-

ments. At the inaugural meeting, held at the offices of the old Local Government Board, Sir William Collins was elected chairman, and he is still chairman to-day, a noteworthy record of public service among many others which Sir William has to his credit. Dr (now Lord) Addison, first Minister of Health, was the first vice-chairman. The Council, in addition to the general co-ordination of the work of district nurses, has applied itself to many useful activities. An early effort was to produce a directory of 20,000 streets in the County of London, showing the nursing association by which each was served. Arrangements were made for the home nursing of measles, rubella, and whooping-cough, and, at a later date, of scarlet fever. Maternity nursing had special attention. Nursing of public assistance patients was put on a new basis with the abolition of Boards of Guardians and the taking over of public assistance by the L.C.C. in 1929. A system of daily visits to people who could not meet the expense of, or even accommodate, a private nurse, and yet were not eligible for charitable nursing, was inaugurated. The Council has also done much to make uniform and more adequate the salaries paid to district nurses. To-day it can be said that in Greater London, with the exception of some new areas of population in Middlesex, an adequate service of district nursing is functioning and forms an indispensable auxiliary to the work of hospitals and medical practitioners.

TREATMENT IN PSYCHIATRY

The annual report of the medical director of the Cassel Hospital, Dr C. H. Rogerson, is concerned largely with a contrast between the older and the newer methods of treatment in psychiatry. The more recent treatments are already well known. After paying a well-deserved tribute to the psychotherapeutic work of the late Dr T. A. Ross, the first director of the hospital, the report mentions the additional techniques of analysis and elucidation which have been developed in the past few years, and describes especially the method of "narco-analysis." At the Cassel Hospital, instead of receiving an intravenous barbiturate for the purpose, the patient inhales nitrous oxide from a standard apparatus for obstetric anaesthesia. The report considers that it has much value where a deadlock in the process of psychological analysis is reached. Continuous narcosis has been used for the early stages of acute anxiety states and for more chronic cases associated with much agitation or excitement. Modified insulin therapy has been used to hasten the disappearance of basic anxiety symptoms after the psychological treatment has made the root of the neurotic symptoms clear. Electric shock therapy, which is so valuable for endogenous depressions, has not been found of benefit in anxiety neurosis, conversion hysteria and obsessional neurosis. (Incidentally, the term "affective neurosis" is used instead of anxiety neurosis, and the term "affective psychosis" for mild depression.) A remarkably successful example of prefrontal leucotomy is reported. The new methods obviously open up the field of treatment in a convincing variety of ways, but in the opinion of the director they do not supersede the older methods. The postgraduate training scheme in psychiatric nursing made possible by the bursaries provided by Sir Felix Cassel is described. It represents a comprehensive curriculum which should prove most stimulating to the nurses fortunate enough to obtain this opportunity.

At the recent meeting of the General Medical Council Sir Herbert Lightfoot Eason, C.B., C.M.G., M.S., was elected President for the term ending on Nov. 30, 1947.

B.D.H. CONTRAST MEDIA

for use in X-ray Diagnosis

IODATOL—Iodised Oil B.P.

For the usual purposes for which iodised oil is generally employed, *e.g.*, bronchography, hysterosalpingography, localisation of cord tumours etc.

SHADO-CREAM and SHADOFORM—

Preparations of Barium Sulphate B.P. For oral or rectal administration in X-ray visualisation of the gastro-intestinal tract.

PHENIODOL B.D.H.—

For oral administration as Pheniodol Meal B.D.H. in cholecystography.

T.I.P.—Iodophthalein B.P.

For those radiologists who wish to continue to practise the older method of cholecystography T.I.P. is still available in forms suitable for intravenous and for oral administration.

IODOXYL B.D.H.—Iodoxyl B.P.

For intravenous pycelography and arteriography.

THE BRITISH DRUG HOUSES LTD. LONDON N.1

X-Ray/E/24

Genatosan Ltd. offer a choice of:— ALLANTOIN MEDICATION

Allantoin is a cell-proliferant and healing agent, which promotes healthy granulation and epithelial repair in damaged tissue. Now manufactured in the Genatosan Laboratories, it is used extensively both in wound therapy and in the treatment of numerous skin affections.

PURE ALLANTOIN for the compounding of prescriptions.

ALLANTOIN OINTMENT 2% in compound wool fat base, for varicose ulceration, indolent wounds, bedsores, eczematous skin affections, etc.

ALLANTOIN SOLUTION. (Sterile). A 0.4% solution in sterile normal saline for irrigation of wounds and impregnation of gauze packings.

Also presented in a water miscible, non-greasy cream (A.B.S.) containing 2% Allantoin, 5% Sulphanilamide and 1% Benzocaine (analgesic), for wounds, burns, ulcerative surfaces, impetigo, etc.

ALLANTOIN with SULPHANILAMIDE. Combining tissue repair with antisepsis.

ALLANTOIN 4% with SULPHANILAMIDE 96% POWDER for application to superficial or open wounds.

2% ALLANTOIN OINTMENT WITH 5% or 10% SULPHANILAMIDE.

Further information will be supplied on request.

Manufactured by **GENATOSAN LTD., LOUGHBOROUGH, LEICESTERSHIRE**

Competition between, and overlapping responsibilities of, different departments, so often insurmountable obstacles in tackling this major problem of public health, can, as the Doncaster case proves, be overcome with some good will and understanding among the parties concerned.—I am, etc.,

Doncaster.

E. G. W. HOFFSTAEDT.

"Unusual" Case of Tuberculosis

SIR.—The case of generalized tuberculosis reported by Major Mylchreest and Capt. Scott (Nov. 25, p. 693) is hardly to be considered "unusual" if we take a wide view of tuberculosis. It is certainly unusual in these islands and among the white inhabitants of America, though it is not unknown. The authors do not say whether their patient was a white or a black American, but I assume he was white. The case is very much in line with the common tuberculosis of the African, and the authors will find the contrast between Africa and European tuberculosis well set forth in the report of the South African Tuberculosis Committee (1932), "Tuberculosis in South African Natives with Special Reference to the Mine Labourers on the Witwatersrand," on page 156. I think that most workers would differ from the authors in the conclusion that "the absence of macroscopic cavitation in the various affected organs argues a comparatively high resistance on the part of the patient." The persistent pyrexia and erythema nodosum are common in the early undeclassified cases of tuberculosis without such or any resistance to the germ. It is, perhaps, a natural error for medical men brought up in the midst of the very "resistant" types of tuberculosis common in this country to regard as unusual any variation from the normal and chronic type seen here, but I feel that the case quoted is not unusual if we take into account the whole of tuberculosis from a wider point of view.—I am, etc.,

S. LYLE CUMMINS.

Injuries from Flying Glass

SIR.—In his interesting article on flying-bomb casualties Mr. R. C. Bell (Nov. 25, p. 689) states: "The penetrating power of flying glass is, in the main, low. It is unusual for it to pierce the deep fascia; usually it lies just under the skin in the fat." This has not been my experience, and I doubt if it is the experience of many who have had to deal with these cases. Penetration depends a good deal on the thickness of the glass, its velocity on impact, and whether the glass hits the tissues edge-on. The cases with which we had to deal were wounded by ordinary window-glass of dwelling-houses, and most of those dealt with as in-patients suffered only from superficial but also from penetrating wounds, as obvious from the bombing raids of 1940-1 that glass did penetrate deeply, and early on you were kind enough to publish some observations of mine giving examples of such cases (*B.M.J.*, 1940, 2, 719). The same holds true for glass cases caused by flying bombs—only all the more so, as one would expect from the greater blast effect.

With recent casualties we have found glass wedged in the bones of the skull, embedded deeply in the neck, in the chest causing a sucking wound, and in the abdominal cavity. It has been found in the muscles of the extremities and in the muscles of the back, and has cut right through tendons. It has severed main arteries and nerves, and, according to Romanis (*Practitioner*, Aug., 1944), most of the big arteries of the body have been cut by flying glass. Two of our neck wounds involved the trachea on its lateral aspect in one the injury was suspected owing to the air suction in the wound, and the glass splinter was found projecting into the trachea; in the other case the left recurrent laryngeal nerve was injured, but the real cause was not discovered until the patient coughed up the splinter. The abdominal injuries included laceration of the transverse colon, the caecum, and the mesentery. In one case post mortem it was found that glass had traversed the greater part of the lung, pierced the diaphragm, and caused a large haematoma in the liver. But it is unnecessary to go on citing cases. As a rule glass shows up well on x-ray films, and many radiographs bear evidence of the depth to which glass splinters may penetrate.

I agree with Dr. Bell that it is unwise to attempt to deal seriously with multiple surface wounds. Excision of these as

recommended by some is out of the question, and the wounds are sometimes so numerous that one case alone would provide enough emergency work for two or three surgeons. Such treatment would undoubtedly re-establish shock, which one has probably laboured hard to counteract. In any event, with present-day methods of counteracting sepsis these wounds do not require elaborate or prolonged surgery. Wounds of the face sometimes require attention on account of haemorrhage, and if conditions allow should be cleansed thoroughly to rid them of dirt or grit; otherwise staining remains. Prof. Kilner (*Practitioner*, Aug., 1944) recommends washing with C.T.A.B. (cetavlon), hydrogen peroxide, and saline, and if dirt or grit is still present removing with a fine curette or nail brush. In general it is surprising how tissues whose viability is in doubt often recover. An elderly man had the cartilaginous portion of his nose almost completely shorn away. It was found wrapped in a handkerchief but still attached by a central bridge of skin at the philtrum. It was cleaned and stitched back in position and it healed without loss of tissue.

But one must be alive to the possibility, or rather probability, of glass penetrating deeply, and what on the surface may appear, a simple puncture may go deep and involve important structures. X-ray examination will help then and later. There must be a goodly number of people going about with glass in their tissues, and if the surgeon is sometimes puzzled by an unusual tumour he may find on removal that it proves to be glass.—I am, etc.,

London W 1

MICHAEL J. SMYTH.

Insulin Syringes

SIR.—May I observe in your columns the confusion occasioned by the presence of an "insulin syringe" provided for the simplification of insulin dosage. Insulin is now dispensed in strengths of 20, 40, and 80 units per c.cm. The syringes are all marked in graduations equivalent to 20 units per c.cm. I have had two recent examples of dangerous inaccuracy of dosage when the carrying out of the injections was delegated to persons about the household.

The first was a new case living a few miles out in the country. I provided the family with the necessary equipment, including a bottle of insulin of 40 units per c.cm. strength and an ordinary c.cm. syringe, graduated in c.cms and minimum marks, and advised them that it was not an "insulin syringe." I then asked the district nurse to co-operate by giving the injections and teaching the patient's wife to give the injections. The patient having refused to go to hospital, I proposed to start with a low dosage—10 units twice a day. In a very few days I was asked for a further supply of insulin. The insulin provided should have lasted about a week. On investigation I found that the nurse had been using the minimum graduations as insulin unit graduations, drawing the insulin up to its 10 minimum mark, and this was equivalent to 24 units of insulin, which was what the patient was receiving twice a day. This accident saved a good deal of time in finally stabilizing the patient's glycosuria at 36 units twice a day.

The other case was one that I had taken over and found was having two doses a day of 40 and 35 units of protamine insulin of 40 units per c.cm. strength. The patient was not well though more or less sugar-controlled. I sent him to a consultant for advice as to changing his treatment, and he was immediately changed to the same dosage of soluble insulin with immediate improvement in his health and also improvement in his sugar control in the urine. But on this new treatment I was very soon asked for a further supply of insulin, so I asked to be shown the syringe used and how far up the insulin was drawn. The syringe was a 2-c.cm. "insulin syringe," marked in c.cms, and insulin units up to 40 in the 2 c.cms, and I was shown that for the morning dose the insulin was drawn up to the c.cm. (40 units) mark. In other words this patient had been having, unknown to himself and his doctor, 80 units of protamine insulin in the morning and 70 in the evening. Small wonder that he had not been feeling well. But neither the consultant nor myself found out the reason for his ill-health immediately.

Apparently the sum of simple proportion required to calculate the correct dose of insulin is too complicated even for the best-educated sometimes in these days of concentrated insulin solutions when using the so-called "insulin syringe." I would therefore advocate that the best syringe for insulin injections in the home is the standard syringe marked in c.cms, and tenths of a c.cm., because the calculation required in making up the dose from whatever insulin is provided is more simple.—I am, etc.,

Thetford, Norfolk.

T. L. OLIVER.

Vitamin B in Post-operative Treatment of Head Injuries

SIR.—One of the many purposes for which the vitamin B complex can be employed is in the post-operative treatment of head wounds, such as the penetrating cranial injuries we are seeing due to the campaign on the Western Front. Such injuries are commonly followed by a psychological state involving a shallow emotivity and undue dependability, a sort of vaguely juvenile state, difficult to describe but readily recognizable by observers who have seen any quantity of these cases. Some of these cases are complicated by schizoid tendencies, such as negativism, though these latter tend to be fleeting and are not exhibited in any dramatic degree of development. The administration of the vitamin B complex unmistakably accelerates the return to normal of these cases. It also tends to dissipate more quickly the disorientation and confusion exhibited in a proportion of them. Where these latter symptom complexes are displayed the addition of extra nicotinic acid to the regime is advisable. The preparations used are tab. benerva co., the dosage being, for the most part, two tablets three times a day. Tablets of nicotinic acid (mg. 50) three or four times daily were added in some cases.

The improvement in the physical condition of cases so treated is quite unmistakable. We have noticed a particularly striking improvement where speech difficulties were associated with lesions in the neighbourhood of Broca's area. One patient in particular, able to enunciate indistinctly only husky monosyllables, chiefly affirmatives and negatives, was able after three weeks to hold a short but clearly distinct conversation. Making every allowance for the fact that his improvement may have stood in a merely coincidental relationship with the administration of vitamin B, we feel the suddenness of the improvement and its rate of acceleration subsequent to the administration of the vitamin B can only be ascribed to the effect of the latter.

One case where confusion was a marked feature of the condition improved considerably with vitamin B, which later, due to an error, was then not given for several days. During this period the patient's condition slumped badly, but showed considerable amelioration when the vitamin was again utilized.

In the experience of one of us vitamin B is also efficacious in clearing up the symptoms of the post-concussional syndrome, where the latter is not accompanied by penetrating wounds or tangible intracranial injury.

We realize to the full that we have not accumulated sufficient data to write dogmatically or to produce a paper on the efficacy of the vitamin B complex in cases of head injury. We are, however, sufficiently satisfied with its beneficial effects to feel that it is worth an extended trial. Our main motive in writing this letter is to stimulate the interest of others in this particular treatment of a type of injury of cardinal importance at the present time.—We are, etc.,

A. GUIRDHAM,
F. KOHN.

Pseudo-migraine and its Relation to Neurofibrositis of the Scalp

SIR—I was interested in the observation made by Dr. Pether on the effect of barometric changes on the recurrence of migraine in some of his patients. It is, of course, a well-established fact that patients who suffer from the various rheumatic ailments are most susceptible to barometric changes, and I find that when seen they will say that their pains were much worse on days when the weather was most changeable. There can be no doubt that those patients who suffer from neurofibrositis of rheumatic origin feel barometric changes the most. And so it would appear that many so-called sufferers from migraine who have attacks during barometric changes are really suffering from neurofibrositis of the scalp, which gives rise to headaches of a migrainous character exacerbated by emotional disturbances, barometric changes, dietetic errors, and exposure to inclement weather.

The condition is due to a fibrositis of the scalp, and the painful spots are usually found in the temporal muscles, above the eyebrows, and in the tissues at the origin of the sterno-mastoid muscles at the base of the skull. After firm digital pressure has been applied to any of these spots the patient will complain that this manipulation is causing a headache, similar in character to those from which he suffers.

After the acute attack has subsided massage over the tender spots should be started, using the tips of the thumb and index finger of the right hand. A vigorous side-to-side movement is used over the tender spots for a few seconds only, as at the first sitting it is extremely painful. This treatment should be carried out on alternate days, using, at each subsequent sitting, deeper and more prolonged massage, which now can be more easily tolerated. Within a few days the headaches will be far less severe, and within a month the patient should be cured. The operator will feel that the tissues around the painful spots become, after three or four treatments, much softer, thus demonstrating that the fibrositis is being resolved into healthy tissues; this coincides with the amelioration of headaches.

It would appear that the cause is metabolic in origin, so that it is advisable for patients to go on a purin-free diet and while they are under treatment to keep their head warm. Many sufferers from chronic headaches that are no migrainous in character will also derive great benefit from this type of treatment. In this category would be placed patients suffering from headaches following trauma and men who suffer from headaches which they think are due to hyperpiesis. In the latter the painful nodules are found at the origin of the sterno-mastoid muscles at the base of the skull.

In true migraine there are no tender nodules on the scalp.—I am, etc.,

London, W.1.

LOUIS MOSS.

Latent Mastoiditis in Infancy

SIR.—Frequent reference has recently been made to latent mastoiditis. It is stated that in infants advanced mastoid infection is commonly present without otoscopic signs of middle-ear disease.

Patterson and Stewart Smith (Nov. 18, p. 659) report 71 cases with evidence of mastoiditis post mortem, only 12 of which showed clinical otitis media before death. Leathart (Nov. 1, p. 637) apparently discards otoscopic signs in favour of a bal patch on the back of the head and glands in the posterior triangle of the neck. Alexander and Eiser, in their excellent paper (Sept. 30, p. 425), found purulent otitis media in 60 of 140 cases of infantile D. and V. Leathart contends that the majority of the remaining 80 cases, in fact, had mastoiditis without otoscopic signs.

Is it, therefore, to be accepted that this delicate membrane the tympanum, which alone conceals a suppurating cavity, frequently shows no detectable change? It is generally agreed that the mastoid antrum and the middle ear in infants should be regarded as one cavity, and though, theoretically, obstruction in the aditus may lead to resolution in the one and progress of the infection of the other, at necropsy these infants invariably have pus in middle ear and antrum. It is the experience of many observers that the tympanum does, in fact, show inflammatory signs in the great majority of infants suffering from the common febrile illnesses, whether gastro-enteritic or respiratory tract infection. In a recent closed epidemic of severe gastro-enteritis involving 13 infants under 9 months of age, definite otoscopic signs of otitis media were found in all save one. These cases were not all in the suppurating stage when myringotomy was performed, but in more than half frank pus was found, and the majority of the remainder developed purulent otorrhoea during the ensuing two days. It is suggested, therefore, that the otoscopic signs of middle-ear disease in infants are not as unreliable as Leathart and others believe.

Is it not rather that our examination of the tympanic membrane is imperfect? First, it is not easy to obtain a completely unobstructed view of the whole drum in a good light, and the conclusion reached with an indifferent view can be most misleading. Secondly, a frost-like layer of desquamated epithelium (or drying exudate) commonly covers the drumhead in acute cases, which gives it a false white appearance. Only when this is gently removed with a moist swab is a fiery-red membrane revealed. Swabbing of a normal drumhead, even in a crying baby, never reproduces the appearance of inflammation. Thirdly, after a few days of active infection in the middle ear the tympanum wears a greyish thickened appearance with very little bulge, and only slight dulling of the lustre.

which may be most deceptive. This drum, which is tough to incise, invariably conceals frank pus. These signs are well known to those who have experience of infants, may there not be others equally misleading?

It is important that the frequency of otitic infection in the infant be more widely recognized, and vital that its relation to D. and V. be better understood. The dogmatic statements of Mr. Leathart on this matter, however, may do more harm than good—I am, etc.,

Newmarket

R. ARDEN JONES

SIR—The article by Drs. Patterson and Smith is an important one showing as it does the extremely great frequency with which pus is found post mortem in the mastoids of infants. For the past 12 months I have had the privilege of assisting Mr. P. W. Leathart in his work at the Royal Liverpool Children's Infirmary, and I venture to suggest that a large number of the cases considered in this article would never have come to post mortem if an attempt at mastoid exploration had been made during the illness.

It is stated "none of our patients had any of the local complications which might reasonably be expected if the pus found in the mastoids was the result of an acute primary active process, and, moreover, so virulent as to cause death from toxæmia and dehydration." Mastoid infections in infants are rarely of the acute fulminating type, hence the difficulty of diagnosis. They nevertheless do great harm by acting as a low grade subacute or chronic septic focus with toxic absorption, which, in the delicate infantile organism, often precipitates diarrhoea and vomiting. This condition is then maintained until either the mastoid infection resolves or the infant dies. Unfortunately, without operation, resolution is uncommon.

It is not contended that diarrhoea and vomiting alone is invariably the means to death in mastoiditis of infancy, but that it is very commonly so. The chronic septic absorption may in a smaller number of cases result in a susceptibility to respiratory infections, marasmus, and sometimes septicaemia as terminal events. The article fully supports this view, as in the diarrhoea and vomiting group 71% of cases had mastoid pus. This is quite considerably more than in the other groups considered which showed 26%, 50%, and 33%. The diversity of organisms found in no way affects the argument. Any septic condition within the mastoid will provide toxins.

Drs. Patterson and Smith write "Finally, the highly infectious nature and the mode of spread of gastro enteritis in infants' wards in hospital form, we think, one of the strongest points against latent mastoid infection, being the key to the aetiology of this condition." True, infective gastro enteritis of the type mentioned is, in our experience, rare, and the infants almost invariably recover providing a mastoiditis secondary to the vomiting is not contracted.

The operation for mastoid drainage in an infant can be performed with very little disturbance to the patient. It is so fortunate that this article (drawing as it does conclusions not justified by the facts) discourages what is so often a life-saving procedure—I am, etc.,

Liverpool

H. ZALIN

Artificial Insemination

SIR—As this seemed exotic and unlikely to appeal to the people of this country, one felt it was better to remain silent. The fact that the secretary of the M.D.U. thinks it necessary to prepare safeguards—from a legal standpoint—for doctors participating makes one anxious to assess the profession's attitude. A statement in the *Journal* of Nov. 25 by Dr. Malleison affirms that recent correspondents find fault with the procedure from the point of view of the Catholic Church (whose dictates on other obstetric matters are not accepted by the profession at large). It might be remarked here that the Church promulgates and upholds the moral law and that artificial insemination is not a mere obstetric matter. An epitome of the views of an eminent Catholic theologian will make this clear. I asked him about this and about the statements in the *Journal* that the Church had not spoken on the subject.

This is not a mere medical question. To regard it as such is to miss the important side—that this matter is bound up

with human relations, vital human relations. The emphasis must be on human relations, as opposed to the reproductive relations of animals. There is nothing so fundamental in human society as the union of man and woman. Everything else is built on that. Human love unites husband and wife, permeates the family, and holds together human society. The question of the union of the sexes and the procreation which follows is a sociological question in its widest sense. Artificial insemination, therefore, raises a sociological problem in which the medical profession as such has only a minor role to play. The Church, as the moral guide of the many millions of its members, has a duty as well as a right to pronounce on the moral aspect of all problems of human conduct, whether they be problems of purely individual conduct or problems that involve social relations. On this question of artificial insemination the Church has given a carefully considered decision. The Church pronounced it to be morally wrong in 1897. The reasons (not all of which apply to every case) are mainly: (1) A woman must be inseminated by her husband. They are two in one flesh and belong to one another. An invasion by other semen is a violation of their sacred union. (2) Insemination is not a medical operation but the climax of the physical expression of love. (3) Artificial insemination implies onanism (solitary self abuse or masturbation), which is immoral.

These are the main direct reasons, but in addition, and partly following from these, one may add that artificial insemination strikes at the very foundation of the family for the family is built up around the father and mother whose co-ordinated love and efforts direct the offspring, who are flesh of their flesh. There must be this vital link binding husband, wife, and children—I am, etc.,

Boscombe, Bournemouth

P. P. MCKINNEY

SIR—To reinforce the opinion so reasonably expressed by Dr. Joan Malleison (*Journal* Nov. 25) may I quote one case that supports her arguments indisputably, and proves that the love of children produced by artificial insemination is of the same quality and subject to the same variations as those produced in the usual manner.

A married couple whose home life was very near collapse undertook artificial insemination as a last resort in spite of the prognostications of their priestly advisers. It is impossible to describe the mental and physical improvement that has resulted from the production of a child and the change in the atmosphere of the home during gestation and after the arrival. A second child was produced after an interval of two years in the usual manner. Both are healthy, strong, and intelligent.

A question that is often asked is: Will the child of artificial insemination be the same physically and mentally as one produced normally?

The veterinarians have had much more experience in these investigations, and with more accurate knowledge the results look more hopeful but are still unsatisfactory though the famous horse Rock and was produced by artificial insemination and won the Derby, the Guineas, and the Oaks—which undoubtedly require speed, stamina and intelligence—I am, etc.,

Bath

J. HOBART NIXON

SIR—Many people look upon medical practitioners as sane and unbiased individuals capable, through long years of training of assessing a situation on its merits without undue prejudice or emotional over-emphasis. It is fortunate, perhaps, that the *Journal* has a limited circulation, for some of the letters that have been printed concerning artificial insemination prove how unreliable many of our colleagues are when medical questions with an ethical fringe are concerned. Those who invoke outworn religious dogma as a logical criticism of a new method of increasing the birth rate and bringing some degree of happiness to a barren couple are clearly swayed out of all reason by purely emotional (and therefore limited to personal) values. If such "reasoning" is of value it might be of interest to learn the views of any sterile doctors. Would they, I wonder, be so shrilly antagonistic? Incidentally, it is of interest to note that two women doctors—namely, Margaret H. Jackson and Joan Malleison—have recently written most intelligent letters in favour of this limited, but most useful, procedure.

The mental gymnastics indulged in by some doctors who adhere unrestrictedly to religious dogma are quite astounding. I have never been able to comprehend the odd and incongruous position of the Roman Catholic gynaecologist who advises against contraception regardless of all other factors in a given case. I recently referred a patient for advice on contraception to a well-known gynaecologist without knowing that he was an R.C. The patient received a short address on the evils of contraception and then departed—she had no time to tell him that she was living in a strange town where her husband was temporarily billeted, that accommodation was extremely scarce, and that the only available “digs” had been described by the landlady as “very quiet, with no animals, children, or other nuisances!” What chance had she of producing an infant in congenial and suitable surroundings? Certainly much less than the gynaecologist, who was living in his own home and who could, presumably, have a baby every year as a logical outcome of his own beliefs. Surely as doctors we should in all matters consider individual cases—i.e., our patients—rather than spout at them our own, often distorted, ideas, that are frequently legacies of the unenlightened doctrines of the Victorian era.

As individuals many may not yet be emancipated from this incomprehensible dogma, but when shall we learn to present an impartial case to our patients, who are entitled to hold views of their own?—I am, etc.,

IAN G WICKES

SIR,—May I be permitted to reply to the letter of Dr Joan Malleon in your issue of Nov 25. She pleads the “hard case” most eloquently, which, if I may say so, does more credit to her sympathies than to her good sense. But it is still a truism that “hard cases make bad law.” The Catholic Church condemns artificial insemination with donated semen on moral grounds, as she has condemned artificial birth restriction and euthanasia, which are likewise founded on the “hard case.” And may I remind Dr. Malleon of another true statement—namely, “the end does not justify the means”—and that, however much one may sympathize with the childless married couple (and the Church regrets this more than Dr. Malleon), it is nevertheless unjustifiable to infringe the moral law on their behalf, however attractive the results may appear to be. Dr. Malleon, in fact, paints a very appealing picture of the benefits which are supposed to accrue from this practice, but may I suggest that this is all very theoretical and is no doubt coloured by that emotionalism and lack of objectivity which she states characterizes the opposition.

It should be self-evident that a country's social health is dependent on the family as the social unit. The Church's pronouncements on the moral law have as one of their main objectives the preservation of this unit, and her condemnations are directed against those who would endanger it. Artificial insemination, using donated semen, entails self-abuse on the part of the donor, and this, when wilfully and deliberately carried out, is a moral offence no matter what the objective is. In the case of the woman inseminated, I should think the condition is closely akin to adultery in that the semen in her uterus is not that of her husband. It is surely obvious that both of these prerequisites constitute a grave danger to healthy family life.

It is interesting to note that the Catholic Church is frequently attacked for opposite reasons at the same time. In recent years she has been howled at by the “birth control” fanatics for objecting to artificial birth restriction and now her advice is scorned because she does not approve of unnatural means of promoting childbirth. It is in my opinion probable that this demand for stud farm procreation follows on the evil results of so called birth control which to quote the late G. K. Chesterton, really means “less birth and no control”—I am, etc.

JOSEPH PHELAN

SIR,—May I put clearly the difference in major premise which is between those who have recently written against the use of artificial insemination and those who appear to favour it? Argument at cross purposes and resultant confusion of thought may thus be avoided. One group would assert that knowledge of physiological facts as a result of research or invention implies the right to use such facts for any end deemed useful

to man. The other group would say that man should be guided in his actions by certain primary principles which are independent of his own changing subjective notions, as well as by what seems to him right and useful. In other words, that the end does not always justify the means even in hard cases. This attitude, which may be thought hard, involves a belief that departures from principle are “sinful” in the sense that if adopted with whatever good intention they will result ultimately in harm not only to others but also to those who adopt them. Dr. Ladell admits that masturbation is a departure from the normal, but finds justification for it in certain circumstances for those who have reached adult psychological development, can he not see that he could not logically deny the application of the same argument to homosexuality among troops normally heterosexual? This last may serve to indicate the value of principles and the unexpected secondary sequelae when they are jettisoned apparently for a good reason—I am, etc.,

Edgware, Middlesex

F HARWOOD STEVENSON

A Renal Service

SIR,—May I support Dr. Osman's plea for a national renal service? Little progress has been made in the treatment of those diseases of the kidney first described by Bright. There is no hospital in the London area which has a ward set aside for the study of nephritis, and I am doubtful whether there is one in the Provinces. There is an obvious need for a hospital of at least 100 beds in London in which to treat medical and surgical diseases of the genito-urinary tract—I am, etc.,

London W 1

CLIFFORD MORSON

Extra Milk for Patients

SIR,—My experience in trying to obtain extra milk for a patient who needs it very definitely, though her case does not come within any of the categories entitling her to be supplied with two pints daily, raises issues which must have considerable general interest. I have the impression that I—and my patient—are being penalized because I have not simply certified her as suffering from gastric ulcer, thus saving trouble to the officials concerned. On Oct 25, having been informed that the allowance of 2 pints daily must cease in a month's time unless I could supply a certificate in accordance with regulations, I wrote as follows to the officer in charge of the Food Office at B.

“I am very appreciative of your courtesy in dealing with this rather difficult case, and of the fact that you are in no way responsible for the regulations which it is your duty to administer. Since I understand, however, that this report is to be forwarded to a medical committee, I wish to take the opportunity of protesting to them (1) that I have not at any time been notified of the existence of a committee competent to vary the regulations in special cases, and (2) that I am compelled to submit an intimate medical report about a patient to a non-medical officer.”

“Mrs. A is a married woman aged about 55 who has long lived apart from her husband. She is a very difficult personality and has been under treatment for twenty years or more by various physicians, and for many years latterly by myself. She is what may be called a professional invalid, enjoying (almost literally) poor health both mentally and physically, she calls her mental condition, more or less correctly, a neurosis, and I shall be glad to give further details of this if required. Her physical condition has been poor throughout the time I have known her. I understand that she was treated for several attacks of severe colitis before she came under my notice. She has an extreme degree of general anæmiosis. For more than fifteen years she has lived on a special diet, consisting chiefly of bread-and-butter, milk, fish, chicken and oatmeal, with a little minced raw apple and occasional prunes. She has declared herself unable to retain any other articles of diet, and this seems to be a fact, whether the mechanism is physical or psychological. Under the restriction of a war dietary she has not materially altered her menu but has simply gone without the articles which were unobtainable, her height is 5 ft 8 in., and she has never to my knowledge weighed more than 9 st., during the war it has dropped by 1 st. and is now 7 st 6 lb with clothes, despite the fact that up to the present I have contrived (without perjuring myself) to obtain for her two pints of milk daily. She has no discoverable fat and is very anæmic, and I believe that she will die from inanition or otherwise within two or three months if she is not allowed this extra nourishment. I hope therefore that the committee may think fit to permit her to be supplied with this permanently, since no improvement in her condition is to be expected.”

Some three weeks later I was informed by telephone that higher authority had rejected the appeal on the ground that to increased ration could be permitted to anyone who voluntarily refused to consume the rations provided. Being informed that it was not in order for the local office to put this into writing, I took up the matter immediately by telephone with the Regional Office Tunbridge Wells, asking both that the statement made should be sent to me in writing and that I should be put into touch with a medical officer competent to discuss the matter on behalf of the Ministry. I stated my intention to publish the correspondence. I have not heard from any medical officer, but I have now received a letter from Mr B Knott of the Ministry of Food, Rationing Division, Colwyn Bay, the man part of which runs as follows:

"I understand you have approached the Divisional Food Office, Tunbridge Wells, about the refusal of your application for a priority supply of 2 pints of liquid milk a day for Mrs. A. of B.

"I would point out that your application and detailed statement of Mrs. A's condition were carefully considered by the Food Rationing (Special Diet) Advisory Committee of the Medical Research Council, who guide the Ministry in all matters concerning invalid diet. They are firmly of the opinion that no special rations or allowances of foodstuffs should be granted to people suffering from a neurosis or whose condition is psychological rather than physical in origin. They infer from your medical certificate that your patient is suffering from no organic disease which would prevent her from eating ordinary food, and in these circumstances they are unable to recommend that your request should be granted.

"The Ministry must of course abide by the authoritative opinion of its advisers especially at the present time, when supplies of milk are so restricted, and it is particularly important that priority allowances should only be granted where they are a medical necessity.

"I understand that your patient Mrs. A was allowed a priority supply of 2 pints of liquid milk a day when she submitted a medical certificate to the local food office some months ago stating that she was suffering from Classes II (c) and II (d) of the Schedule of Conditions qualifying for priority supplies of milk. This grant was, I am afraid, made in error. Your patient can only receive a priority supply under one class of the schedule, and her 'priority' must now be adjusted accordingly. Should you feel that you can justifiably certify this lady under Class II (c) or Class II (d) of the Schedule of Conditions she will be supplied with 7 pints of liquid milk a week. This, however, is the most the Ministry can allow, since the medical advisers consider that this provision is quite adequate for the treatment of people with either or both of these conditions.

The only comments I wish to make are (1) that my offer to give further information is ignored, (2) that I have given evidence of physical ill health, and (3) that Mr Knott being a non medical officer may quite possibly have never heard of fatal cases of anorexia nervosa nor of the acute melancholics die if they are not tube fed with milk. The inelastic cation of these regulations constitutes a temptation to the truth in the interest of one's patient, and I should be grateful for any suggestion as to a more satisfactory method in such a case—I am, etc

J NORMAN GLAISTER

Obituary

EDWIN GOODALL, CBE MD, FRCP

We regret to announce the death on Nov. 29 at Hove of Lieut-Col E. Goodall, for many years medical superintendent of the Cardiff City Mental Hospital and afterwards honorary consulting physician to that institution and (for psychiatry) to the Cardiff Royal Infirmary. He had been lecturer in mental diseases at the Welsh National School of Medicine and until his retirement from active work was a leading figure in the world of psychiatry. Everything that pertained to the pathology of the psychoses attracted and held his forward-looking mind, and no one felt keener disappointment when progress slackened at any point.

Edwin Goodall son of E. B. Goodall a Calcutta solicitor, was born in 1863 and studied medicine at Guy's Hospital, graduating M.B. B.S. Lond. in 1886 and M.D. in 1888, and taking the MRCP a year later. After postgraduate work in the University of Tübingen he became pathologist and assistant medical officer to the West Riding Asylum at Wakefield, he

was next appointed medical superintendent of the Joint Counties Asylum, Carmarthen, and later medical superintendent of the Cardiff Mental Hospital, whence his reputation spread far and wide as a pioneer in the scientific study and treatment of mental disorders.

At the Annual Meeting of the B.M.A. in 1903 he held office as vice-president of the Section of Psychiatry, in 1911 he was president of the Section of Neurology and Psychological Medicine, and at the Cardiff Meeting in 1928 he again presided over the same Section, he was also a past president of the Section of Psychiatry of the Royal Society of Medicine, and a Foreign Member of the Society of Medical Psychology of Paris. He was elected a Fellow of the Royal College of Physicians in 1903, delivered the Croonian Lectures on the pathology of mental disorders in 1914, and served on the Council of the College for two years. His presidential address to the Royal Medical Psychological Association, on conditions—bacteriological, toxicological, and haematological—bearing upon the psychoses, appeared in the *Journal of Mental Science* in 1923, and his Maudsley Lecture on the pathology of insanity in 1927. He was largely responsible for the opening of an out-patient department for early mental cases at Cardiff. A problem that deeply concerned him was how to get hold of the schizophrenics of psychiatry and the encephalitics of general medicine at the earliest possible stage and bring them in touch with research centres. Under his guidance the Cardiff City Mental Hospital came into close working association with the Cardiff Royal Infirmary, the latter being equipped with the necessary staff and laboratory facilities and authority to conduct animal experimentation, apparatus for collecting material was kept at the pathological laboratory of the Infirmary as well as at the Mental Hospital. A point he made over and over again was that the psychiatric clinic must be an integral part of the general hospital.

Edwin Goodall did excellent work in his branch of medicine during the last war, when he held the rank of lieutenant-col., R.A.M.C. For this he was mentioned in despatches and created CBE in 1919. He kept up with foreign work in psychopathology carefully assessed its bearings upon diagnosis and treatment and set out his conclusions in clear and forceful language.

W. A. COCHRANE M.B. F.R.C.S.E.D.

Mr William A. Cochrane the well known Scottish orthopaedic surgeon died at the age of 81 on Nov. 30 in Edinburgh where he was born and educated and held many appointments. From Daniel Stewart's College he entered the University and graduated M.B. Ch.B. in 1915, afterwards serving in France and Flanders with a commission in the R.A.M.C. as a battalion M.O. His war experience filled him with a desire to restore the maimed to useful life and on his return from the B.E.F. in 1918 he was appointed to the orthopaedic staff at Bangour Hospital then the main Services orthopaedic centre for Scotland and he there came under the influence of Sir Harold Stiles, the chief surgeon and Sir Robert Jones, who visited the hospital as consultant. After serving there he spent some time in the United States as temporary assistant in orthopaedics at the Massachusetts General Hospital, Boston, working in Dr Goldthwait's clinic. He returned to Edinburgh in 1921 well equipped for his chosen branch of the profession and took the F.R.C.S.E.D.

Cochrane played an active part in the development of the Fairmilehead Hospital for Cripples (now named after Princess Margaret Rose) of which he was surgeon in charge and did much to create a network of orthopaedic clinics in the south-east of Scotland. In 1937 he became a member of the National Advisory Council for Scotland on Physical Training and Recreation, he was also one of the orthopaedists for the south-east area of the Scottish Command. In Edinburgh where he practised, he was appointed associate assistant surgeon in orthopaedics at the Royal Infirmary and lecturer on that subject in the University. Cochrane joined the B.M.A. in 1924, was a member of the Orthopaedics Group Committee from 1938 onwards and for twelve years acted as assistant honorary secretary of the Edinburgh Branch for the purpose of clinical and scientific meetings. At the Annual Meeting of the Association held at Winnipeg in 1930 he was vice-president of the Section of Orthopaedics. He was the author jointly with

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales returns for measles, dysentery, and acute pneumonia were higher than last week by 1,136, 163, and 129 respectively. Only small fluctuations were shown by the other notifiable diseases.

There were 20 fewer cases of diphtheria than last week recorded in Durham, and 19 fewer in Glamorganshire. However, in the combined regions of London, south-east, south-west, south midland, and the eastern areas the notifications rose from 83 to 120. In these areas whooping-cough notifications rose by 74, but in the rest of England and Wales they fell by 96.

Acute pneumonia was slightly more prevalent throughout the country. Measles showed the largest weekly increase since February, 1943, and was particularly marked in the north. Lancashire had 295 more cases than last week, Warwickshire 202, Cheshire 135, Southampton 77, Staffordshire 68, Yorks West Riding 68, Nottinghamshire 64, Gloucestershire 50, and London 45.

The increase in dysentery was due mainly to the large outbreak in Yorks West Riding, Wortley R.D., where 130 cases were reported. The largest of the other returns were Lancashire 49, London 44, Surrey 20, Norfolk 16, and Glamorganshire 11.

In Scotland there was a general rise in the incidence of infectious diseases. The rises over last week's totals included measles 114, acute pneumonia 81, diphtheria 38, whooping-cough 35. A small increase in the incidence of diphtheria was general throughout the country: the largest returns were Glasgow 69, Lanark County 30, Edinburgh 19, Fife County 12, and Dundee 11.

In Eire there were 23 more cases of diphtheria than last week. Thirty-two cases were recorded in Dublin C.B., and the remaining 101 notifications involved forty-eight registration areas.

In Northern Ireland the incidence of measles rose by 68, and scarlet fever by 27. All but one of the 259 cases of measles were notified in Belfast C.B., which also reported 48 of the 117 cases of scarlet fever.

Week Ending December 2

The returns of infectious diseases in England and Wales during the week included: scarlet fever 2,279; whooping-cough 1,474; diphtheria 63; measles 7,810; acute pneumonia 761; cerebrospinal fever 3; dysentery 381; paratyphoid 3; typhoid 7; poliomyelitis 10.

Medical News

Prof. J. M. Mackintosh, M.D., F.R.C.P., has been appointed Dean of the London School of Hygiene and Tropical Medicine from January 1, 1945.

A meeting of the Association for Scientific Photography will be held at the Caxton Hall, Westminster, S.W., on Saturday, Dec. 30, at 2.30 p.m., to discuss "The Choice of Materials for Scientific Photography."

A meeting of the Eugenics Society will be held on Tuesday, Dec. 19, at 5 o'clock in the rooms of the Royal Society, Burlington House, Piccadilly, W., for a discussion on "Aspects of the Housing Problem." All interested in the subject are invited to attend.

Vacancies are available for training in child psychiatry at centres recognized by the National Provisional Council of Mental Health for this purpose. Applicants should have the D.P.M. or equivalent mental health experience, together with experience of children in specialist or general practice. Training fee, £60; length of training, one year, half-time. Application may also be made for grants or loans. Applications should be sent to the Secretary, Child Guidance Department, 39, Queen Anne Street, London, W.1.

Grants for more than £825,000, made by the United Kingdom Government under the Colonial Development and Welfare Act, 1940, have enabled the Uganda Protectorate to plan for the largest hospital and one of the most extensive health services in the British Colonial Empire. A grant of £477,500 will provide for the reconstruction and extension of Mulago Hospital, Kampala, so that 1,120 beds are available. A further sum of £350,000 for the extension of medical services will be used for the following: training of staff, £92,000; antimalarial campaign, £75,000; antivenereal diseases campaign, £63,000; antituberculosis campaign, £50,000; nutrition survey, £40,000; ambulance service, £30,000.

Mr. Thomas F. A. Stowell, M.D., F.R.C.S., has been re-elected to the Council of the Industrial Welfare Society, of whose advisory medical committee he is chairman.

Universities and Colleges

UNIVERSITY OF MANCHESTER

The following appointment is announced: Dr. G. J. Langley, F.R.C.P., Dean of Postgraduate Medical Studies.

The University has received a grant of £750 for the Department of Education of the Deaf from the Nuffield Provincial Hospitals Trust per the Manchester, Salford, and Stretford Hospitals Advisory Board.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Faculty held on Dec. 4 with the President, Mr. William A. Sewell, in the chair, James Black, M.D., and Matthew McLeerie, M.B., Ch.B., were admitted Fellows of Faculty.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1. on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

ANY QUESTIONS?

Etherington-Wilson Technique for Spinal Anaesthesia

Q.—What is the Etherington-Wilson technique for spinal anaesthesia, and where may full descriptions of the method be found? Is it a widely used technique?

A.—The original spinal technique described by Etherington-Wilson made use of Howard Jones's "light" or hypobaric 1 in 1,500 procaine solution in 0.5% saline. The lumbar puncture was performed in the sitting position, and the volume of solution injected and the time allowed for sitting up were calculated according to the desired height of analgesia. A full description of the method will be found in the *British Journal of Anaesthesia* (1934, 11, 43). Several modifications of the technique were recently described by Etherington-Wilson at a meeting of the Anaesthetics Section of the Royal Society of Medicine, and these will presumably be published in the *Proceedings*. The original method has been fairly widely used by some anaesthetists.

Stilboestrol for Masturbation

Q.—Are there any records of the treatment of masturbation by the administration of stilboestrol? Also, are there any contraindications against the administration of stilboestrol for long periods in the years of early and acute sexual desire?

A.—Yes. A record may be found in the *Journal of Nervous and Mental Diseases* (June, 1944, 99, 928) describing the case of a psychopathic seaman 19 years old whose sexual preoccupation and frequent masturbation were very favourably modified by 1 mg. of stilboestrol by mouth daily, the only apparent adverse effect being mild gynaecomastia. Treatment was given intermittently (see also *J. Amer. med. Ass.*, 1944; 125, 760). The writer has used stilboestrol in 5-mg. doses in a lad of 17 brought before the courts for sexual assault. The patient was gigantic with some acromegaloïd features. The stilboestrol permitted him to control intense sexual desire, and to reduce the frequency of masturbation considerably. Here, too, there was some resulting tenderness and swelling of the breasts.

Large doses of stilboestrol in the normal male, or in cases of carcinoma of prostate, may produce disappearance of libido, and impotence; also a considerable diminution in the sperm count, where such is possible. Experimentally, disintegration of the testicular structure occurs in small animals, but regeneration and normal sexual function follow withdrawal of the stilboestrol. It would appear that controlled doses of stilboestrol, given intermittently, may prove a useful and harmless form of therapy in selected cases. Prolonging the administration is associated with certain dangers indicated above. It would be unwise to neglect the appropriate treatment of an underlying psychoneurosis where such is present.

Chronic Otorrhoea

Q.—*In cases of chronic or relapsing otorrhoea in adults, is there any treatment other than the usual (and generally ineffectual) application of guttae spl. & boric. (or similar)? Is there any danger in irrigating, not syringing, the meatus with sterile saline solution? Can any sulphonamide preparation be used locally?*

A.—As there are many cases of chronic otorrhoea in which local treatment alone is useless the first step in successful treatment is accuracy in diagnosis. Two common causes of chronicity must be kept in mind: unsuspected nasal sinusitis, and chronic infection of the bone of the attic and mastoid. The success of local treatment depends as much on efficient removal of discharge from the middle ear as on the type of local application. Syringing is harmless, providing the ear is dried with cotton-wool or spirit. Inflation or suction may be needed before the middle ear is empty. After cleaning, powders—either sulphonamide, or boric, or boric and iodine—give on the whole better results than drops.

Leucodermia

Q.—*A girl aged 3 years is suffering from leucodermia. The first patch was noticed six months ago in the epigastric area. Patches are now present symmetrically in axillae, groins, knees, and anterior aspect of the neck, and are about 5 in. in diameter, slowly increasing in size. General health is good, although the tonsils are enlarged. What form of treatment, if any, will improve this complaint?*

A.—There is little to be done for leucodermia. Oil of bergamot 10% in spirit applied to the white areas has been suggested, and its effect may be augmented by exposure to ultra-violet radiation. Injection of one of the gold preparations is supposed to increase the chance of pigmentation, but in my experience it is valueless for this purpose. The skilful use of cosmetic preparations is a simple, if not very satisfactory, solution.

Sprouting Legumes

Q.—*In these days of shortage of citrus fruits, may we know the technique of sprouting legumes? Is this an economic proposition, which legumes are best used, and what and how much cooking is required?*

A.—When legumes are sprouted in order to improve the ascorbic acid content of the diet, it is usually recommended that they should be soaked for about 24 hours, drained, and then allowed to germinate for three or four days. The preliminary soaking is important and should be carried out at room temperature. If too hot water is used there is a tendency for the legumes subsequently to become mouldy, while if the soaking water is too cold germination may be delayed. On the family scale, germination may be carried out by allowing the soaked legumes to stand in a colander, but when larger quantities are involved the use of trays is advocated. The sprouting of legumes before cooking appears to be an economic proposition, and

respiration has ceased, the heart sounds are inaudible, but the cardiac complexes may persist for a considerable period of time; the onset of rigor mortis is the only certain proof of death.

Obstetric Forceps

Q.—*What type of short obstetrical forceps can be recommended for extraction of the head when it is low down on the perineum?*

A.—Wrigley's forceps were designed specifically as low forceps for extracting the foetal head through the vaginal orifice. It is an excellent instrument for this type of case. If, however, the foetal head is higher up, the best instrument is that advocated by DeLee under the name of the Vienna School forceps. This is a modification of the original Simpson's pattern. These forceps are quite simple to use. Most obstetricians use forceps of this kind for all cases and do not find it necessary to use Wrigley's forceps.

Smegma under the Prepuce

Q.—*What is the cause of smegma under the prepuce and how can it be treated? Several patients have complained of this disturbing factor, and it has been more marked after ratings have been on detached duties where regular bathing has not been possible. Is it the cause, or vice versa, of non-venereal warts? Microscopically only debris and varied crystals are seen.*

A.—Smegma is the normal secretion of Tyson's glands. It tends to be formed in excessive amounts in hot climates, and by evaporation it gives rise to dried debris and sometimes even to concretions. It is stated to be a cause of non-venereal warts, but this is by no means certain. Washing of course removes excess of the secretion, but under conditions of active service this may be difficult to effect.

LETTERS, NOTES, ETC.**Piercing the Ears**

Dr. P. C. MATTHEW (St. Ives, Cornwall) writes: I have performed this small operation fairly often, and find that the following refinements in technique are well worth while. (1) I inject 1/2 c.cm. local anaesthetic in each lobe; the patient then feels nothing except the initial prick with an 18-gauge hypodermic needle. (2) For piercing I use a large-bore intramuscular needle, pushed through the lobe into a cork; then I remove the cork, place one end of the split-ring or "keeper" in the open end of the needle, and withdraw the needle through the lobe, with the keeper following through. This avoids some difficult groping with the none-too-sharp end of the keeper, to find the holes. (3) I grease the keepers with vaseline and tell the patient to move them round at least once a day, and not to take them out until they remain perfectly free. This may require up to two weeks. (4) I make the perforation high up in the lobe: in time the lobe stretches, particularly with heavy ear-rings, and a hole made in the centre will eventually appear to be near the bottom, with the result that certain kinds of flat ear-rings will not

LONDON SATURDAY DECEMBER 23 1944

THE SUPPLY OF BODIES FOR DISSECTION: A HISTORICAL REVIEW*

BY

NEVILLE M. GOODMAN, M.D.

The subject falls naturally into three periods from the Middle Ages until the revival of dissection as part of the general training of medical students in the mid eighteenth century, from then until the passing of the Anatomy Act of 1832, and from 1832 until the present time

First Period

The first date of importance is 1231, when the Emperor Frederick II decreed that a human dissection should be performed at Salerno at least once in five years, but, although dissection was legalized in various parts of the empire in the 13th and 14th centuries, no statutory requirement seems to have been made to provide subjects until, in 1387, we find that the Statutes of the University of Florence request the authorities to see to the delivery of the bodies of three alien criminals each year for this purpose. The connexion between dissection and the punishment of crime was to last for 400 years.

In England and Wales the claims of anatomical dissection were recognized by the Charter given in 1540 by Henry VIII to the United Company of Barbers and Surgeons, which enacted that "the sayd masters or governours of the mistery and communitie of barbers and surgeons of Londõ & their successours yerely for ever after their sad discrecions at their free liberte and pleasure shal and maie have and take without contradiction foure persons condemned adjudged and put to deathe for feloni by the due order of the Kynges lawe of this realme for anatomies and so on

Scotland had been somewhat earlier in the field, the Town Council of Edinburgh having given in 1505 the Incorporation of Surgeons and Barbers once a year a condemned man after he be dead, to make anatomy of, wherethrough we may have experience to instruct others. And we shall do suffrage for the soul." In 1694 this grant was extended to include those bodies that dye in the correction-house; the bodies of fundlings who dye betwixt the tyme that they are weaned and their being put to schools or trades, also the dead bodies of such that are sufflet in the birth, which are exposed, and have none to owne them, as also the dead bodies of such as are felo de se, likewise the bodies of such as are put to death by sentence of the magistrat." This was granted subject to dissections being made only in the winter months and the intestines being buried within 48 hours and the rest within ten days. Although in Ireland no specific provision for anatomical subjects seems to have been made, eight persons are mentioned as Readers of Anatomy in the Charter to the Barbers, Surgeons, Apothecaries, and Periwig Makers of 1687. In France by the middle of the 17th century, dissection was practised so openly that Moliere makes a lover ask his mistress to come and see the dissection of a woman, provoking the maid's comment that "some people take their mistresses to a comedy, but to take them to a dissection is far more gallant!"

Here, the official arrangements for dissection soon proved inadequate, and by the first half of the 18th century "private anatomies" were becoming so common that it was clear that the attempts to put them down were hopeless, already the prevalence of body-snatching had led to riots in Edinburgh in

1725 and 1742. In 1752 the official supply was somewhat augmented by an Act (25 George II, Cap 37) which gave the bodies of murderers executed in London and Middlesex to the Surgeons' Company, and those of murderers executed outside this area might be given to local surgeons chosen by the judge or hung in chains at his discretion.

The revival of anatomy about 1750 under the Hunters in London and the Monros in Edinburgh rapidly increased the number of students and still more the demand for bodies, since formal demonstration by the lecturer no longer sufficed and students carried out many dissections for themselves. The number of medical students in Edinburgh was 57 in 1720, about 340 in 1780-90 and over 400 after 1800. In London the number of students of anatomy was 300 in 1798 and 1 000 in 1823.

Second Period: The Resurrectionists

This brings us to our second period—the Golden Age of the Resurrectionists. These were of two types the students themselves, often led by the professors' assistants, and professional body-snatchers, who worked at first singly or in pairs but later were organized into rival gangs. The professional body-snatchers depended mainly on disinterment, but used other tricks such as impersonation of relatives and stealing before burial. At first prosecutions were rare—indeed, the law on the subject was doubtful and the body-snatchers themselves were convinced that they could not be indicted unless they removed the grave clothes or a portion of the coffin—but in *Rex v. Lynn* in 1788 the King's Bench decided it to be a misdemeanour to carry away a dead body from a churchyard even for dissection, as being an offence *contra bonos mores* and common decency, and it was later decided by the courts that a person would be indictable if he was a party to the non-interment as well as to the disinterment of a dead body (*Rex v. Young* and *Rex v. Cundick*).

With the increase of the traffic, more frequent and open disinterment led to public odium, and the extraordinary state of affairs is best described in the sober words of the Report of the Parliamentary Select Committee on Anatomy of 1828:

"In proportion as the public became vigilant, the laws relating to sepulture were interpreted and executed with increasing rigour and as the price of subjects rose with the difficulty of obtaining them, the premium for breaking the laws increased with the penalty. The exhumations increased in number, and, being now treated as criminals, became of a more desperate and degraded character. The parties of daring men who now took to raising bodies, did it happen (as was frequently the case) that, while in pursuit of the same spoil they fell in one with another, actuated by vindictive feeling, and regardless of the caution and secrecy on which the successful continuance of their hazardous occupation must depend, had contests in the places of sepulture—left the graves open to public gaze, or gave information to magistrates, or the relatives of the disinterred, against their rivals." The public were excited against the teachers of anatomy by these outrageous acts, "and this to such a degree, that of late, in many cases, individuals, out of solicitude to guard the dead, have taken upon themselves to dispense with the laws of their country, and have fired upon parties attempting disinterment."

By 1820 the matter had become a public scandal. In 1828 of 800 students in London, about 500 actually dissected. Since the optimum number of subjects per student was then said to be three—two for dissection and one for operative surgery—

* Abridged from an Arms and Gale Lecture, 1944

about 1,500 bodies were annually required. Students were resorting to Paris, Dublin, and other foreign schools. Sir Astley Cooper stated to the Select Committee in 1828 that about 450 subjects were actually dissected in the London schools in one season. The price was 8 to 10 guineas, and had been as high as 16 guineas, as compared with 1 to 2 guineas thirty years previously. The state of public opinion was such that, according to Sir Astley Cooper, there was practically no chance of obtaining bodies from London burial grounds by disinterment, and the chief source of supply was importation from abroad, mainly from Dublin. These might be seized by the Customs if detected, and were often so putrefied as to be unfit for use. An ingenious ex-naval captain in Dublin not only organized the export of bodies from that city but raised a public fund to pay watchers to prevent exhumation; with the fund he paid his own agents, ostensibly as watchers but actually as resurrectionists. In Edinburgh the situation was even worse. Well-to-do persons hired watchers with loaded blunderbusses at 6d. a night, with free liquor, to guard the graves of relatives until putrefaction was too far advanced for the bodies to be worth exhuming, and I have seen mort safes—iron cages to prevent exhumation—still existing in graveyards more than fifty miles from Edinburgh.

I wish that space allowed me to quote more of the macabre evidence of the surgeons, magistrates, police officers, and resurrection men who appeared before the Select Committee. A resurrectionist—probably the notorious Ben Crouch—admitted to having made a complete corner in the supply for London between 1809 and 1813. According to his book, in 1890 "the number in England was 305 adults and 44 small subjects under three feet; but the same year there were 37 for Edinburgh and 18 we had on hand that were never used at all." Other matters dealt with in the evidence included the extraction of teeth as a profitable side-line; the importation of subjects from Ireland; the attitude of Home Secretaries—Robert Peel and the Marquis of Lansdowne—and of the police; and the easier position and arrangements made for subjects in Dublin, Paris, Göttingen, and Italy.

Many petitions had been received by Parliament, uniformly praying for an amendment of the existing law. One from the Royal College of Surgeons pointed out that they had a legal duty to examine students, especially as regards surgeons for the Army and Navy. For this purpose dissection was necessary. But the Regulations of the College on this point tended to encourage violation of the law and establish "in the procurers of dead bodies a set of men living by practices which are revolting to the feelings of Society, exposed to the hatred and contempt of those around them, and likely, by the joint operation of these causes, to become trained and gradually habituated to the commission of still greater crimes": the law

on Anatomy, already referred to, under the chairmanship of Mr. Henry Warburton, M.P. The Select Committee began its sittings on April 22, 1828, and reported on July 22. Its report did not make specific recommendations, but strongly urged legislative action. At this time Parliament was intensely preoccupied with debates on the repeal of the Test and Corporation Acts and with the state of Ireland consequent on the election of O'Connell for Co. Clare. Nevertheless, its obligations with regard to anatomical supply were brought unexpectedly and forcibly to the notice of the whole nation by the discovery of the sixteen murders of Burke and Hare in Edinburgh, the details of which are too well known to recall here. Suffice it to say that the murders created intense popular excitement and indignation; ruined, in Dr. Knox, the country's leading teacher of anatomy; and gave a new word to the language.

On April 4, 1829, the Catholic Relief Bill passed the Lords, and on the 7th Mr. Warburton moved for a Select Committee to give effect to the recommendations of the Committee on Anatomy of the previous year. As a result, Mr. Warburton's first "Bill for preventing the unlawful disinterment of human bodies, and for regulating Schools of Anatomy," was introduced on May 5. The main features of the Bill were, broadly, those embodied in the Act of 1832—viz., the licensing and control of places and persons for carrying on human dissection; the legalization of bequests for dissection purposes; and the handing over for dissection of bodies of persons dying in prisons, hospitals, and workhouses, if unclaimed within 72 hours, to licensees, who were responsible for burial and the keeping of records. The Bill also laid down specific penalties for disinterment. But it contained a number of features which caused strong opposition, and it also failed to repeal the clause of the 1752 Bill which gave up the bodies of murderers for dissection—an amendment to this effect being defeated by 40 votes to 8. The Royal College of Surgeons petitioned against the Bill on the ground that the appointment of seven Commissioners, of whom a majority were not to be physicians, surgeons, or apothecaries, to control medical schools and places of dissection, would infringe the privileges of the College. The proprietors of private anatomy schools were afraid that the phrasing of the Bill would lead to their extinction, and the *Lancet* supported the opposition because it feared an adverse effect on the study of anatomy outside London and the Universities. Also the Bill did not apply to Ireland, and it was thought that it might increase the traffic in human bodies from that country. The Bill had a second reading in the Commons, but was dropped on June 5, 1829, in the Lords, although its principles received general support.

Nothing more was done in the following 12 months, and on June 26, 1830, George IV died and Parliament was dissolved. In November, following the elections, the long Tory reign of

first Bill of 1829, but most of the features which had roused the greatest opposition were removed in committee. The preamble may be quoted.

"Whereas a Knowledge of the Causes and Nature of sundry Diseases which affect the Body, and of the best Methods of treating and curing such Diseases, and of healing and repairing divers Wounds and Injuries to which the Human Frame is liable, cannot be acquired without the Aid of Anatomical Examination: And whereas the legal Supply of Human Bodies for such Anatomical Examination is insufficient fully to provide the Means of such Knowledge: And whereas, in order further to supply Human Bodies for such Purposes, divers great and grievous Crimes have been committed, and lately Murder, for the single Object of selling for such Purposes the Bodies of the Persons so murdered: And whereas, therefore, it is highly expedient to give Protection, under certain Regulations, to the Study and Practice of Anatomy, and to prevent, as far as may be, such great and grievous Crimes and Murder as aforesaid: be it therefore enacted . . ."

The Anatomy Act of 1832

The substance of the Act may be summarized as follows: Clause I gives power to the Secretary of State for the Home Department and the Chief Secretary for Ireland to grant licences to practise anatomy to qualified medical practitioners, teachers of anatomy, medicine, or surgery, and students attending schools of anatomy, upon application countersigned by two Justices of the Peace. Clauses II and III give the Secretary of State power to appoint "not fewer than Three Persons to be Inspectors of Places where Anatomy is carried on," and to appoint them to districts and lay down their duties. Quarterly returns of bodies removed for anatomical purposes must be made by the Inspectors.

The most important clause is the VIIth, which gives power to persons having the lawful custody of a body to allow it to be dissected in certain circumstances and under certain conditions: from this clause 97% of our present supply is derived—i.e., from unclaimed bodies in the custody of local authorities. This power to permit the anatomical dissection of a body is overridden (1) if the person when living expressed in writing or in the presence of two witnesses his wish not to be dissected, or (2) if the husband, wife, or any known relative of the deceased objects. Clause VIII deals with so-called "bequests"—as there is no legal property in a body, the term is not accurate: it authorizes those having custody of the body of a person who during life directed that an anatomical examination should be made of his body after death, to have this done, again unless the husband, wife, "nearest known relative or any One or more of such person's nearest known Relatives, being of Kin in the same Degree," objects.

Bodies must not be removed for anatomical examination until 48 hours after death and 24 hours after notice has been given to the Inspector, and must be accompanied by a medical certificate of the cause of death. Persons licensed as above to receive bodies for dissection must transmit the particulars and the medical certificate to the Inspector and keep a register (Clauses X and XI). One week's notice must be given to the Secretary of State of places where anatomy is taught or bodies are received for dissection (Clause XII). Bodies must be removed in a "decent coffin or shell," interred with the appropriate religious rites, and a certificate of interment sent to the Inspector within six weeks (XIII). Nothing in the Act is to interfere with necropsies directed by a competent legal authority (XV). The Act directing the bodies of murderers to be dissected is repealed (XVI). Punishments for offences against the Act are laid down as a maximum of three months' imprisonment or a fine not exceeding £50.

The Act was immediately and completely successful in bringing body-snatching to an end. Dr. James Somerville, the first Inspector appointed for England and Wales under the Act, gave evidence before the Parliamentary Select Committee on Medical Education in April, 1834—20 months after the Act's coming into force. He stated that exhumation had entirely ceased: prices of subjects were greatly reduced, and they were obtained in a much fresher condition. In the first year after the passing of the Act 600 subjects were supplied to the London schools, as compared with his estimate of about 300 previously. There were temporary declines in supply, Dr. Somerville stated, through "the extraordinary mildness of the season" causing

a lower death rate following the extraordinary previous mortality from cholera and "the late influenza"; also because of the "exceptional diffusion of comfort" among the working classes. Both these causes are liable to cause shortages to-day. In Scotland the success of the Act had not been so instantaneous, but difficulties had been smoothed by the Inspector for Scotland, Dr. Craigie. The Return of Licences under the Act at the time showed 8 hospital medical schools and 8 private schools in London and 16 hospitals and private schools in the Provinces; in addition 19 persons in the Provinces were licensed to practise anatomy for their own information or that of their private pupils.

Legal and Administrative Changes since 1832

Before discussing the supply position from 1832 to the present time, certain legal and administrative changes since the passing of the Act must be mentioned. The Amending Act of 1871 (34 Vict., Cap. 16) merely gave power to the Secretary of State to vary, by Order, the period within which the certificate of interment must be sent to the Inspector of Anatomy—i.e., to vary the time within which the dissected subject must be buried. A change was desirable as the result of improved methods of preserving bodies, together with a gradual fall in the supply in relation to the number of students. The first Order in 1871 extended the period from six weeks to six months. At various dates the period was further extended, and in 1940 a similar Order to that of the last war was made for England and Wales—i.e., at the present time the period during which a body may be retained for dissection is two years.

The functions of the Home Office under the Anatomy Acts were transferred in 1919 to the Ministry of Health. When the Local Government Act of 1929 came into force a circular was issued transferring the functions of the Boards of Guardians under the Anatomy Acts to the Councils of the appropriate local authorities—i.e., to the Councils of Counties and County Boroughs.

Certain changes in the appointments and duties of the Inspectors of Anatomy must also be noted. Dr. James Somerville was Inspector for England and Wales from 1832 until 1842, when separate Inspectors were appointed for London and for the Provinces. In 1921 a single Inspector, Dr. Alexander Macphail, was appointed for the whole of England and Wales, and in 1939 Prof. Henderson, his successor and the present Inspector of Anatomy—now serving with the Royal Navy—was appointed Inspector for Scotland also. Originally the Inspectors of Anatomy were concerned with the administration of the Anatomy Acts and not with questions of supply. In 1921, however, when the supply position was extremely serious, the Minister of Health, Lord Addison—himself an anatomist—agreed that Dr. Macphail should be appointed as Inspector of Anatomy and also as a whole-time medical officer on the staff of the Ministry of Health, and should concern himself with questions of supply. Since then the Inspector has held what might be described as a watching brief over the supply of bodies for dissection. In agreement with the professors of anatomy concerned, he opens up new sources by approaching local authorities to give their sanction to co-operation in the work of the Anatomy Acts; stimulates existing sources by correspondence and visits; corresponds with other Government Departments on matters which have given rise to difficulties or disputes; and so on. For London, the Inspector has agreed to take the more direct responsibility of allocating supplies to the different schools, in co-operation with the London Committee of Licensed Teachers of Anatomy, whose meetings he attends by invitation. In Scotland, the Inspector attends the statutory Annual Meeting of the Edinburgh Anatomical Committee, the Glasgow Institute of Anatomy, and the Aberdeen Funerary Committee. His statutory duties under the Anatomy Acts include occasional visits of inspection to the medical schools and the supervision of the work performed by the Clerks to the Anatomy Offices in London and Edinburgh.

Turning to supply, reasonably correct and comprehensive figures are fortunately available to show the variations in supply in relation to the number of medical students from 1832 to the present time.

Let us now examine the nature of these elements in the case of the radiant-heat cradle. They are, first, the lamps, which emit radiation of a temperature of about $1,800^{\circ}\text{C}$. (carbon filaments), and which may be considered as point sources. Not all their radiation, however, arrives at the skin of the patient, because the glass envelopes of the bulbs absorb all wave-lengths greater than about 3μ . The absorbed fraction amounts to about one-third of the total radiation emitted by the filaments, and heats the glass envelopes to a temperature of about 100°C . Thus the envelopes in their turn become sources of radiation; but since their temperature is very much lower than that of the filaments, the energy distribution of the radiation emitted by them is quite different from that of the absorbed radiation. Finally, the metal background of the cradle is also heated by radiation from the lamps to a temperature of about 120°C ., and therefore it, too, acts as a radiator, which, because of its large surface, plays a very important part in producing the flux received on the skin of the patient (Brown, Evans, and Mendlesohn, 1943). If the background is polished the problem is further complicated by reflection of part of the radiation.

Another difficulty, and one of great importance for the clinician, is introduced by the fact that the heating up of the envelopes and the background is a gradual process, which may take as long as several hours. As we shall see, at the end of this time the patient is receiving *three times* as much radiant energy every minute as when the cradle was first switched on. Although we selected the particular example of the cradle because we had studied it closely in previous work, the same problem of complexity presents itself in connexion with practically any form of clinical treatment lamp.

Computation

The difficulties stressed above will make it clear that a numerical computation of the radiation flux received by the patient is a complicated procedure which, even in the simplest cases, requires considerable mathematical skill and laborious numerical calculation. We have in fact carried out such computations for the radiation flux received on a horizontal plane stretching across the cradle at its widest part—i.e., at 7 in. above the base, or roughly the height of the ventral surface of the patient. The results of these calculations, which are shown in Fig. 3 (B) and Fig. 4 (B), will be discussed below. The mathematical details, which are of a somewhat complex character, will be published elsewhere. In contrast, therefore, to x-ray work, computation cannot be advised as a feasible means for the clinician of estimating dosage of radiant heat. Each separate case constitutes quite a considerable problem of mathematical physics, and any error in calculation, or the neglect of any contributing factor, might easily result in a dangerously incorrect estimate of dosage.

Direct Measurement of Radiation Flux

Our efforts will therefore be directed towards the development of an instrument which can be placed at a position which the patient's skin will occupy, and which directly measures the radiation flux. The fact that such an instrument—for which we should like to propose the general name of thermo-radiometer—does not exist serves as an indication that certain difficulties stand in the way of its development. A thermo-radiometer must record the flux of radiant energy received throughout the whole range of wave-lengths emitted by the treatment source. The radiant energy arriving at the receiver surface of the radiometer must be converted into heat, the quantity of which can then be determined by one of several methods. This means that the instrument must register only energy received by radiation, and must not register energy received in any other way. But under any treatment source the air may be warmed, and therefore heat is apt to be transferred to the receiver surface not only by radiation but also by heat conduction through the air.* In scientific determinations

* Practically no quantitative information is available on the question of how great this conduction may be. Certainly it is not related in any simple way to the quantity of heat received by radiation. It should be possible to devise a simple method for determining the quantity of heat received by the skin through air conduction, and the results would be of interest to the physician; but the whole question is a very complex one, and is beyond the scope of a discussion of heat transfer by radiation.

of infra-red radiation this difficulty is often overcome by enclosing the receiver surface in an evacuated envelope, and this method has also been used in attempts to determine radiation flux for medical purposes.

The method is, however, limited by the fact that no material suitable for the construction of the vacuum container is known which is uniformly transparent throughout the whole spectral range. A glass envelope, for instance, as used by Mayneord and Tulley in some of their work, is quite opaque for wave-lengths greater than $3\text{--}3.5\mu$ —a fact which was pointed out by these authors. How seriously this limitation can affect the dosage based on the readings of such an instrument is clearly shown in the case of the cradle, where all the radiation flux coming from the envelopes of the lamps and from the metal background is stopped before it reaches the recording surface, because it is all in wave-lengths greater than 3μ . This means that, although at the beginning of a treatment the patient may be receiving something like the flux indicated by the reading of the instrument, after a lapse of time he will actually be receiving three times as much, though there will have been little or no change in the reading. The acceptance of such readings at their face value therefore introduces a serious danger of overdose.

We have accordingly attacked the problem in a different way. Instead of excluding heat conduction we have employed a differential arrangement in which the energy received by two surfaces is compared. Only one of these surfaces is exposed to the radiation from the treatment source, while both of them receive heat by conduction through the air. Since the distance between the two surfaces is small, the air-surrounding them has the same temperature, and the amount of heat received by conduction is the same for both, and cancels out, leaving a direct indication of the radiation flux—i.e., of the quantity which we wish to measure. The physical method by which we determine the amount of heat received by the surface must

FIG. 2a.—Diagram showing thermo-radiometer connected with millivoltmeter.

FIG. 2b.—Diagram of the thermo-radiometer.

employ some sort of calorimeter. A primary method, for instance, consists in measuring the rise in temperature of a copper block of given weight in a given time. We have indeed used such an arrangement, comparing the energy received by two such copper blocks, the blackened surface of one of which was exposed to the radiation. Observations with such a thermo-radiometer are very useful for the determination of absolute values of radiation flux, but are too time-consuming for clinical practice.

We therefore propose for general use a simpler arrangement (Figs. 2a and 2b), having two receiver plates, R_1 and R_2 , with blackened surfaces, the temperature difference between which is measured by means of a set of thermocouples attached to their reverse faces. R_1 is exposed to the radiation flux to be measured, whereas R_2 is screened from this radiation by the baffle, B . In order to give a constant flux with which the radiation to be measured may be compared, R_2 is placed before a metal screen, A , which is maintained at constant (room) temperature.

When the instrument is used, R_1 is placed in the radiation field at the position which would be occupied by the skin of the patient. R_2 receives the radiation flux which the patient will receive, and R_2 receives a standard flux from A . Both, however, are exposed to the same air conduction. The temperature difference between R_1 and R_2 rapidly becomes steady, and this difference depends only on the flux falling on R_1 , provided the flux on R_2 is kept constant.

The instrument must be calibrated against known radiation fluxes (which may be determined by the primary calorimetric method described above, or otherwise), but, once this has been done, the scale of the millivoltmeter M , can be graduated directly in units of flux (gramme calories per square centimetre per minute). The physician can therefore read off at a glance the flux which the patient will receive on any part of his skin, simply by placing the little instrument in the position which that part of the skin will occupy.

We have constructed such an instrument and have checked its readings against the flux received from well-defined radiation sources, and by comparison with the primary calorimeter. The technical details of this work will be published elsewhere.

Using this instrument we have measured the radiation flux in radiant-heat cradles. The results, which are of considerable significance for the clinical use of these cradles, are shown in Figs. 3 (a) and 4 (a). Each figure is a map of a horizontal plane 7 in. above the base of the cradle and the results are given in the form of a series of "contour lines" along each of which the radiation flux is constant. At any point on the curve marked "1.5," for example the flux is 1.5 calories per square centimetre per minute, and at any point between the curves marked "1.5" and "1.6" the flux is intermediate between these two values, and so on. Each map is divided into two halves: the left-hand halves (a) show the values actually measured with our instrument while the right-hand halves (b) show the values calculated as mentioned above.

FIG. 3—Distribution of radiation flux under standard heat cradle with blackened background. The flux is that due to the lamps plus that due to the background. Numerals on contour lines give the amount of radiant energy in calories per sq. cm. received in each minute on a plane 7 in. above base of cradle. a=measured values, b=calculated values. Positions of lamps above plane are represented by circles.

Fig. 3 refers to an ordinary cradle with a blackened background, and the flux at each point is therefore the sum of that due to the lamps and that due to the heated background. In Fig. 4 the flux due to the lamps only is shown; experimentally, this was secured by cooling the metal background. Thus Fig. 4 shows the flux

received by the patient immediately after switching on and before the background has had time to heat up, while Fig. 3 shows the very much greater flux received by the patient after the background has had time to heat up and become a source of radiation on its own. The agreement between the measured and calculated values is surprisingly good, and indicates the general correctness both of our line of theoretical reasoning and of our methods of measurement.

A comparison of Figs. 3 and 4 shows that during the course of treatment the flux received by the patient may increase threefold—a fact which brings home the serious danger of overdosage which

FIG. 4—Distribution of radiation flux under standard heat cradle with blackened background. Background cooled. Flux due to lamps alone. a=measured values, b=calculated values.

may be incurred if the increase of the power of the source with time is not taken into consideration. It may be remarked that the results of Fig. 4 (no radiation from the background) are very similar to those of Mayneord and Tully (1943), who excluded the long-wave radiation from the background by the glass envelope of their radiometer.

Some other investigations (results not shown) are of interest. The results of Figs. 3 and 4 refer to the case when the cradle is blackened but the bulbs are not shielded, in contrast to the conditions used in work previously described (Brown, Evans, and Mendelssohn, 1943). In one of the additional investigations the flux was determined with the background left polished and kept cool, and with the bulbs unshielded. The conditions were exactly the same as those for the results of Fig. 4, except that rays from the lamps were reflected from the metal background. The results were almost exactly the same as those shown in Fig. 4, which means that the reflection of rays from the polished background is of very little importance in producing the distribution of flux received by the patient.

We also determined the flux in a cradle in which the background was blackened and not cooled, and in which the lamps were covered with thin metal shields. The average value for the flux in this case was about 1 calorie per square centimetre per minute, and the flux was extremely uniform all over the cradle area.

All these results and particularly the preponderant part played by the radiation from the cradle background, represent a gratifying confirmation of our first rough analysis of the action of heat cradles.

Conclusion

The thermo-radiometer used by us is essentially a laboratory instrument, but it holds out good prospect for development into a simple radiation-flux indicator for clinical use. When this problem of accurate estimation of total flux has been solved the next step must be to devise an instrument capable of differentiating flux received by the patient in different wavelengths—i.e., an instrument capable of assessing the quality of radiation.

Meanwhile, a great deal can be done by an accurate determination of the total radiation flux received under various conditions from standard treatment lamps, and thus to ensure

more reproducible and better-defined conditions of treatment by infra-red rays. There remains, of course, the great and complex problem of the physiological action of heat radiation. Here again the position is much more difficult than in the case of x rays. Whereas x rays are more or less uniformly absorbed by the tissues, in which they produce chemical changes, the action of infra-red rays results mainly in an increase in temperature produced near the surface of the skin, which is counteracted by perspiration and by dissipation of the local increase in temperature by the circulation. While a certain amount of information as to the penetration of infra-red radiation exists, little is known about the specific action of heat radiation under clinical conditions. As has been pointed out before (Brown and Mendelssohn, 1944), the physiological action of a given type of heat radiation is likely to be quite different in local and in general administration. The greatest need is for clinical observations of the effects of infra-red radiation administered in known quantities and under well-defined conditions, and we hope that the considerations advanced in this paper will aid the clinician in establishing conditions of treatment which will provide a sound physical basis for the study of clinical observations.

Summary

The physical factors involved in the clinical application of radiant heat have been enumerated and discussed. Computation of dosage based on the consideration of the nature of the treatment source is liable to grave error and should be discouraged. Treatment should be based on the direct measurement of radiation flux—i.e., the amount of radiant energy received on the surface of the patient's skin. The methods by which such measurements may be made have been discussed, and one particular radiometer has been described and recommended for clinical use.

Dangerous overdosage may be caused by: (a) neglect of the fact that the radiation from almost all treatment sources increases during the time of application; (b) attempts to determine the flux received by the patient with unsuitable radiometers which yield results far below the true values.

We should like to thank Prof. L. J. WITTS for his interest and suggestions, and for the provision of experimental facilities during part of this investigation.

RADICAL OPERATION FOR VARICOSE VEINS

BY

HAROLD DODD, Ch.M., F.R.C.S.

Surgeon to King George Hospital, Ilford, and to Royal Hospital, Richmond

To call an operation for varicose veins radical is a substantial claim, especially when the ingenious and occasionally heroic procedures of the past are recalled—e.g., multiple ligatures and excisions, the Trendelenburg operation with and without excision of the prominent veins, the stripping operation, injection therapy, etc. Since 1930 the operation of simultaneous ligature and injection in various forms has been developed and reported (Dodd and Oldham, 1940; Dickson Wright, 1940). It started in 1932, and this article details the position after 800 operations which a follow-up has shown to merit the term "radical." Since 1939 modified procedures have been described which give good immediate results, but, in my experience and that of others, recurrence takes place in three months to three years and these easier methods are not advised (Russell, 1941).

The radical operation for varicose veins premisses several factors. First the veins must be varicose—that is, they must be distinguished from compensatory veins which have developed in response to thrombosis of the deep conduits. Then, having decided that the veins are varicose, the type must be diagnosed, so that the correct radical measure can be chosen. There are at least seven varieties of varicose veins which require operation to cure—most of the remainder will respond to efficient injections. The types of varicose veins are diagnosed as follows, depending on incompetence of the valves in or at:

- (1) the termination of the great saphenous vein; (2) the termination of the external saphenous vein; (3) the internal and the external saphenous veins coincidentally; (4) the communicating veins between the deep and superficial venous systems of the leg (which normally allow blood to flow inwards); (5) the communicating veins between the deep and superficial venous systems, plus (1); (6) the communicating veins between the deep and superficial venous systems, plus (2); (7) the communicating veins, plus (3).

The radical operation consists in the permanent obliteration of the varicose veins. It is achieved by a combination of ligatures and division at the termination of the internal or external saphenous veins or of the communicating veins, and thrombosis and sclerosis of the varices by injection of an effective and adequate amount of sclerosing agent at the same time. These two factors—i.e., the agent and its volume—are determined by the grossness of the veins to be destroyed.

Radical Operation for Varicosity of Internal Saphenous Vein

This is the commonest presentation, and the plan to be detailed often suffices for the occasional associated incompetence of the communicating veins, particularly those in the thigh.

The Anaesthetic.—A local or general anaesthetic is admirable; a spinal gives pleasantly empty veins and the patient stops in bed for 24 hours. In my practice patients get up the night of the operation, and thereafter morning and evening for lengthening periods, the object being to avoid pulmonary embolism and to keep up muscle power.

The operation necessitates incisions in the groin and at the internal malleolus at the ankle. The grossest veins require a third ligature, injection, and division above the knee. The veins are exposed, tied, and divided, and 20 to 40 c.cm. of 30% saline is injected downwards at the groin and upwards at the ankle. The result is a firm sclerosis of the internal saphenous system, and in some cases of varicose veins in the external saphenous area as well. The thrombosis is palpable before the patient leaves the operating-table, so that the adequacy of the operation is apparent.

Technique of the Operation

The Landmark of the Incision.—The incision runs 1/4 in. below and parallel to the natural fold of the groin. It is 2 to 3 in. long, according to the obesity of the patient. Its centre lies where a line dropped from the pubic spine at right angles to the fold of the groin intersects the incision. The location of the internal saphenous vein is somewhat variable, but this exposure leads immediately to it. The centre of each lip of the wound is seized and forcibly elevated and retracted. This stretches the subcutaneous tissue and makes it possible to cut steadily through the two layers of subcutaneous fascia to expose the vein. The internal saphenous vein—recognized by its large size—is dissected "nude" with the scalpel until its three upper and occasionally one or two downward branches are revealed and also until the inward turn of the main trunk to join the deep femoral vein is defined.

Saphena varices are notoriously friable and are handled fondly like china. The branches are tied and divided between ligatures. The common femoral vein is exposed sufficiently to ensure that the lower part is patent: the operation is abandoned if it isn't, for then the internal saphenous vein must be compensatory. The end of the saphena magna at its union with the femoral vein is tied with stout thread: to tie it distal to this point leaves a cul-de-sac of vein in which a thrombus can form, and pass into the main venous system, with undesirable pulmonary embolism.

An Abnormality.—Occasionally what appears to be the internal saphenous vein is small; this stimulates the search for a duplicate vessel which may lie underneath separated by a layer of fat or occasionally parallel in the same plane of fascia. The common femoral vein, which may be mistaken for it, is recognized by its size, its straightness, the depth at which it lies, and the pulsation of the femoral artery adjoining it. I have once tied and injected the femoral vein, and on two other occasions have had the ligature around it, discovering the mistake only just in time. A good exposure is the best preventive.

The great saphenous vein collapses on ligature, as its content is mainly a regurgitation from the femoral vein

The Injection—The distal portion of the vein is injected with 20 ccm of 30% saline, making sure that the fluid does go into the lumen and that it is not put into the deep tissues, which results in gross sloughing and delayed healing. A less effective alternative is 5 to 10 ccm of ethamolin. When injecting some veins they dilate and the sclerosing fluid sprays out alongside of the needle, indicating that the terminal valve in the collapsed vein has become competent. In this event the technique is as follows:

The lower end of the exposed vein is clipped with a haemostat. Another ligature is passed loosely round the centre of the exposed vessel. The vein is half divided by a scalpel between the two ligatures, and an olive-headed needle or ureteric catheter is threaded into the vessel. When the head is beyond the lower ligature, this is pulled tight to avoid bleeding, and the forceps is removed. The long needle or catheter is introduced gently down the internal saphenous vein. These instruments hitch occasionally on the valves, but manipulation disengages them and allows 10 to 18 in. of the vein to be traversed. Handling should be dainty, to avoid poking the instrument through the venous wall, when gross sloughing occurs. The concentrated saline (30%) is injected through the olive-headed needle (it fits a Record syringe) or ureteric catheter, slowly withdrawing it while doing so and avoiding leakage of the sclerosing agent from the vein. If the anaesthetic is local infiltration a painful spasm follows. The needle or catheter is now removed and the lower ligature tied.

Transfixion Stitch—When the internal saphenous vein is divided there is no valve between it and the right side of the heart, so that a torrential haemorrhage follows if the proximal ligature slips. When this happened once, seven pints of blood were required to restore the loss. This danger is minimized by a second tie, transfixing the stump with fine thread in the same way that a hernial sac is secured. The wound is cleaned especially when it has been soiled with the injection, the dead space is obliterated, and the skin is closed accurately and a pressure dressing applied.

Ligature of Internal Saphenous Vein at the Ankle

The internal saphenous vein at the ankle lies in a groove at the anterior border of the internal malleolus intimately bound to the deep fascia. It is important to find the great saphenous vein and not a large superficial radicle. An incision 1 in. long is made over the front edge of the internal malleolus, and the lips of the wound are opened and elevated. In some females fat overlies the vein, but usually it is visible through the deep fascia and is picked up, cleaned, and tied at its lower end. A loose ligature is passed round the upper end. The vein is half cut through transversely and the olive-headed needle or ureteric catheter is inserted upwards very gently. Sometimes the ureteric catheter will pass when the needle won't, and vice versa. They frequently hitch where a large communicating vein joins. The delicate introduction is essential otherwise the needle or catheter may be thrust through the wall of the inelastic vein and the sclerosing fluid be inserted into the subcutaneous tissue causing a huge slough of the skin, fat and deep fascia that requires months to heal. The catheter or needle is withdrawn during the introduction of 20 to 30 ccm of 30% saline. Soiling of the wound must be avoided. The upper ligature is tied and the vessel divided. The skin is sutured accurately, it unites slowly in this area, especially if pigmented or eczematous or ulcerated.

The Dressing—A pressure dressing is put on both wounds. Skill is required, and asepsis must be good, for suppurative and dermatitis will incapacitate otherwise fit men and women for weeks or even months.

Ligature above the Knee

When saline 30% is used the varices are palpably thrombosed at the end of the operation. Should those about the knee not be solid, a third ligature of the internal saphenous vein above the knee is required. The vessel is exposed on the antero-internal aspect a hand's breadth above the joint line, and a ligature is applied. If the upper section is solid nothing further is necessary, but if it is fluid 5 ccm of saline 30% will make sclerosis certain. Below the tie 5 to 15 ccm of the hypertonic saline is put in it either through a hypodermic needle or through the olive-headed needle or catheter, managed

as before. Then the vessel is again ligatured and divided. The wound is closed.

Ligature of External Saphenous Vein

The Anatomy—The external or short saphenous vein perforates the deep fascia about the lower part of the popliteal space and runs under it until it reaches approximately the bend of the knee-joint, where it turns in deeply and joins the popliteal vein, usually 1/2 to 1 in higher. Gray's *Anatomy* points out that "the mode of ending of the short saphenous vein is subject to considerable variations. It may join the long saphenous vein in the upper one-third of the thigh or may divide into two branches, one of which joins the long saphenous vein, the other the popliteal vein or the deep posterior veins of the thigh. Occasionally it ends below the level of the knee-joint, in the long saphenous vein or in the deep muscular veins of the calf."

Technique of Operation—The patient lies on the face. Originally the incision was longitudinally over the line of the vein and was extended up or down as required, but this often heals indifferently, sometimes with a thickened and sensitive scar. The incision made in the central transverse crease behind the knee is better. A sandbag under the foot produces a slight laxity of the otherwise tight gastrocnemius muscles. The incision is deepened through the deep fascia. The external saphenous vein lies surrounded by fat in the groove between the inner and outer heads of the gastrocnemius. It may be duplicated or triplicated, and the sural branches of the internal popliteal nerve may be closely associated. A deep dissection is required, and the successful complete exposure, ligature, injection, and division can be a major surgical exercise. The union with the popliteal vein must be exposed and the associated branches divided between ligatures. The vessel is ligatured and injected similarly to the internal saphenous vein in the groin giving meticulous attention to technique. No further ligature or injection is needed for the external saphenous drainage area.

Incompetent Communicating Veins

Occasionally the communicating veins between the superficial and deep systems are so gross as to require deliberate exposure and division of the connexion and repair of the considerable defect in the deep fascia. These points usually lie at the lower inner third of the thigh and at the leg on the inner surface. They are located by palpation with the help of the finger when the elastic varix and the hole in the deep fascia are felt or after emptying the veins by moving two tourniquets closer together on the limbs and watching the vessels fill up.

In the average case of incompetent communicating veins ligature and injection at the groin and ankle or of the external popliteal vein behind the knee suffice to obliterate them. In the lower third of the leg the inefficient communicating vein may be so large and the pressure in it so great that direct attack is required. In fact, the already described procedure by obliterating a large part of the superficial venous system has the effect of increasing the content of the deep veins and thereby the pressure in the communicating veins. The clinical result in large communicating veins is more swelling and pain in the lower third of the leg than before the operation, which may raise the suspicion of obliterated deep veins. It is usually this which explains the recurrences after the operation. A hint of a marked communicating vein of the leg is given by pigmented skin, oedema, or ulcer in the lower inner third of the leg.

The Remedy—The treatment of the communicating veins consists in finding them, dividing them between ligatures, and closing the hole in the deep fascia. They are located in one of two places on the inner surface of the leg—either 2 to 3 in. above the tip of the internal malleolus or at the junction of the middle and lower thirds of the leg. Their position is determined by palpating systematically over the skin, when elastic sensation and a defect feeling like a button-hole in the deep fascia are found. One or two demonstrations soon give the peculiar experience. The incision is made vertically over the area. There are usually a few overlying small varices, and bleeding is copious. The deep fascia is exposed and the penetrating vein will be located coming off at an unexpected

angle. It is divided between ligatures, and the slit in the deep fascia is closed. The skin in these conditions heals poorly; it is often eczematous, or there may be adjoining ulceration. One stitch and a firm pressure dressing only are required, and patients stop in bed until healed, getting up morning and evening for lengthening periods. The results are excellent.

The communicating veins in the lower third of the thigh seldom call for direct attack, and are settled either by incision, ligature, and injection of the groin or by a similar procedure to the internal saphenous vein, 3 to 4 in. above the knee on its antero-internal surface.

Subsequent Injections.—In the majority of cases no further treatment is required, but occasionally small areas of veins remain patent, and these respond to immediate injection by ethamolin or quinine and urethane, 2 to 5 c.cm. of each. Sodium chloride 30% is not used for ordinary injection because gross sloughing follows if a few drops leak outside the vein.

Conclusion

The radical operation for varicose veins depends on the pathology and diagnosis of the varicosities. There are two types of varicosities: those due to loss of elasticity of the internal and external saphenous venous system with incompetence of the valve guarding their terminations, putting the superficial veins in direct communication with the right side of the heart, and those due to enlargement of the communicating veins between the deep and superficial venous systems—these are mainly at the lower third of the thigh and leg.

There are seven main diagnoses made up of combinations of these.

Up to five small but essential operations are required to cure the varicose veins in a limb.

SULPHONAMIDE ALLERGY

THE PERSISTENCE OF DESENSITIZATION

BY

R. G. PARK, M.B., M.R.C.P.

Major, N.Z. Medical Corps

(From a Military Hospital in the Middle East)

There are two types of allergic sensitivity which can arise during sulphonamide therapy—according to whether the drug is taken internally or is applied to the skin. The internal type may take many different clinical forms, of which fever, morbilliform erythema, and leucocytosis are the commonest features. In the cutaneous type the reaction is an eczematous dermatitis. In either case violent reactions are apt to follow administration by mouth, and one question which comes up is, Can these people be desensitized as a safeguard for the future?

The answer is that they can. Schlesinger and Mitchell (1938) reported that cases of sulphanilamide fever and rash cleared up in three or four days even though the drug was continued, and that one such case was followed up two months later and found to be insensitive. In 1942 Erskine stated that allergic cases could be desensitized either by keeping on with full doses the time of the reaction or by giving ascending doses at a later date. In a previous report (Park, 1944) on a patient who developed sulphapyridine neutropenia and was still sensitive after three months, details of a successful desensitization were given.

In the eczematous type desensitization was introduced by Tate in 1943 (personal communication), either at the expense of a severe reaction by full doses over about four days or by smaller doses for about three weeks, causing milder reactions.

Methods Used

My experience over the last 18 months has been that desensitization has been consistently successful in these allergic

states. The drug has been given in all cases by mouth, in four or five divided doses per day—enough to keep up a fairly constant level in the blood stream. Beginning with an amount too small to cause a reaction, the dose is doubled each day until a mild reaction appears. It is then kept the same until all symptoms have subsided, when it is again increased.

The two forms of allergy differ sharply in their response to desensitization. In the internal type, in which the first sign of a reaction is a rise in temperature, it is usually possible to start with 0.1 g. at each dose, doubling up daily to reach 1 g. in four or five days. More sensitive cases, such as the one reported below, take longer; the most sensitive one yet encountered had to start with 0.005 g. and took nine weeks to work up to 1 g. In the eczemas this high degree of sensitivity is the rule. The average case takes about six weeks to desensitize if the dosage is kept below reaction level.

The next question which springs to the mind is, How long does this benefit last? Does the allergic state return in the way that it does each season after hay-fever desensitization, or is it permanent? This question has not been answered up till now, and it is only from its answer that we can learn whether this desensitization to sulphonamides is really worth while. The following case is reported as a single pointer to the possible solution of this problem.

Case Report

Sapper X., aged 40, began treatment for chancroid with sulphanilamide on July 21, 1943, taking 1 g. four times a day. On the sixth day his temperature rose to 103° F. and he developed a general morbilliform erythema, showing no tendency to photosensitivity. It was slightly irritable. He complained of pains in the knees and other joints, but there were no objective findings. The drug was stopped at once. He gave a history of having received sulphapyridine for pneumonia six months previously without any reaction. On successive days his temperature reached peaks of 103°, 101.6°, and 100° F. A leucocyte count showed a total of 10,000. From July 30 onwards he was afebrile. On Aug. 8 he was put on divided doses of 1 g. of sulphapyridine. A few hours after the first dose he developed a temperature of 101° F. and further joint pains, but no rash. The fever lasted 48 hours.

Desensitization with sulphanilamide was started on Aug. 8 with four doses per day of 0.125 g. After two doses, however, he again reacted with a fever up to 102° F., a recurrence of the rash, and further joint pains. The drug was stopped and his symptoms subsided. Sulphanilamide was continued as follows:

Date	Doses per Day	Amount (g.)	Result
Aug. 11	4	0.02	No reaction
12	4	0.04	" "
13	4	0.08	" "
14	4	0.125	Fever of 99.6°
15	3	0.125	" " 101.6°
16	Nil		Still febrile
17	"		Almost afebrile
18	"		Afebrile
19	"		"
20-22	4	0.02	No reaction
23-24	4	0.04	" "
25-26	4	0.08	" "
27-28	4	0.04	Mild reaction
29-30	4	0.06	No reaction
Aug 31-Sept. 2	4	0.08	" "
Sept. 3-5	4	0.125	" "
6-11	4	0.15	" "
12-14	4	0.19	" "
15-16	4	0.4	" "
17	4	0.5	" "
18	4	0.6	" "
19	4	0.75	" "
20	4	0.9	" "
21	4	1.0	" "

He was discharged from hospital and nothing more was seen of him until Sept. 1, 1944, when he reported at the V.D. Dept. to have a routine injection for syphilis, which he had contracted in the meantime. He gave the story that in June, 1944, he developed a sore on his penis. At this time he was given sulphanilamide in seven doses of 1 g. over two days. This caused a febrile reaction accompanied by a recurrence of his previous symptoms, subsiding in two or three days. A diagnosis of syphilis was then made, and from that time he had been receiving weekly N.A.B. and bismuth.

He was brought in for further investigation and given the following drugs:

Sept. 3,	sulphathiazole,	1 dose of 1 g.
" 4,	"	4 doses of 1 g.
" 6,	sulphapyridine,	1 dose of 1 g.
" 7,	"	4 doses of 1 g.

No reactions to the above were seen. On Sept. 9 a dose of 1 g of sulphanilamide was given, and caused a pyrexia up to 100° F., with the same pains in the joints. This was confirmed by a similar reaction the next day to a dose of 2 g. On Sept. 12, 13, and 14 single doses of 3 g each of sulphapyridine, sulphathiazole, and sulphanilic acid respectively were given, with no reactions. At this stage he had to leave hospital urgently for other reasons, and it was not possible to give him any further desensitization.

Discussion

To sum up this patient developed a highly allergic state during sulphanilamide therapy, so that he reacted to as little as 0.25 g with a sharp pyrexia. He was also allergic to sulphapyridine in a lesser degree, with a milder reaction to a dose of 1 g. Desensitization took six weeks, but succeeded in working him up to full doses without reaction. Nine months later he apparently had a reaction to further full doses.

Reinvestigation one year after desensitization showed mild reactions to doses of 1 g and 2 g of sulphanilamide, but none at all to doses up to 3 g of other sulphonamides. His allergy had therefore partially returned, but only to a fraction of its original level.

If we may be allowed to theorize on the possible immunological mechanisms underlying this and other drug allergies, the following working hypothesis would fit the facts as they are at present known. In some people sulphonamides stimulate the formation of antibodies. These will then unite with future doses of the drug to cause allergic reactions. Their formation goes on after the drug has been stopped, but gradually tapers off and finally stops. Small desensitizing doses will use up these antibodies and abolish the allergic state. If desensitization is carried out before they cease to be formed, the allergy may partly recur, but if an interval is allowed to elapse before starting desensitization it may be expected to be permanent. It now remains for this hypothesis to be tested in practice.

Summary

Desensitization to sulphonamides has been a consistent success by the method described.

An opportunity of following up a desensitized case showed that allergy had returned after one year to only a fraction of its former level.

There is theoretical reason to believe that if such cases are left for a time before being desensitized the benefit may be permanent.

I wish to thank the Director of Medical Services, 2 N.Z.E.F., for permission to publish this report.

PENICILLIN IN CIVILIAN PRACTICE

BY

H. B. MAY, M.R.C.P.

Assistant Director, Hale Clinical Laboratories, London Hospital

Supplies of British-made penicillin have now been available for civilian use for three months, being distributed by the Ministry of Health to the Deans of Medical Schools and, through them to their own and associated hospitals. An indication of the types of case which have received penicillin from one centre might be considered to be of general interest.

Forty million units of penicillin a month were allotted to this centre, and the administrative heads of 43 hospitals were circulated but, largely owing to the publicity given in the Press to the fact that supplies were limited, the amount asked for in the first month was only 3 million units, in the second month it rose to 13.5 million units, and in the third month to 22 million units. No request for penicillin was refused in cases in which the infection was caused or was probably caused by a sensitive organism, and systemic treatment when needed was as a rule started before full laboratory investigations had been carried out, although in cases in which local treatment was indicated penicillin was usually withheld until a sensitive organism had been isolated. It was suggested that for systemic treatment the penicillin should be given as a continuous intramuscular drip, using 100,000 units a day dissolved in a pint of

saline and administered into the outer side of the thigh. In each case 5 days' supply was provided.

Conditions Treated

Cases receiving penicillin comprised 15 of osteomyelitis, 5 of staphylococcal pyaemia, 2 of brain abscess, 2 of sulphonamide-resistant gonorrhoea, and 1 case each of staphylococcal orbital cellulitis, staphylococcal jugular phlebitis after mastoidectomy, streptococcal puerperal septicaemia, septic abortion, actinomycosis, pneumococcal meningitis, staphylococcal meningitis, salpingitis of undetermined aetiology not reacting to sulphonamides, generalized staphylococcal pyoderma, post-operative pneumonia of doubtful aetiology not reacting to sulphonamides, staphylococcal pericarditis, suppurative pneumonitis with multiple small abscesses demonstrated in radiographs of the chest (this patient subsequently had a pneumonectomy performed with success), and a case of severe human bite which showed a mixed flora, including *Staph. pyogenes*, *F. fusiformis* and an anaerobic streptococcus.

Local treatment was employed alone in 50 cases of staphylococcal skin infection, mainly *syccosis barbae*, 20 cases of staphylococcal infections of the hand, 5 cases of staphylococcal or pneumococcal conjunctivitis, 4 cases of pneumonectomy or lobectomy to prevent post-operative empyema, 4 cases of empyema—one being a case of tuberculous empyema with an associated staphylococcal infection—2 cases of staphylococcal carbuncle, and 1 case each of infected gangrene of the foot, streptococcal arthritis of the shoulder-joint, and generalized peritonitis secondary to a perforated gangrenous appendix.

Results

A number of these cases will no doubt be reported in detail by individual clinicians, but certain general conclusions emerge from the series as a whole. The results of penicillin treatment have confirmed the findings of earlier clinical trials: very serious staphylococcal infections, such as meningitis and pyaemia with a high colony count in the blood culture, have been cured, but two patients with multiple lung abscesses died. In very early cases of osteomyelitis it was possible to bring about apparent cure without operative intervention, but in those seen late in the disease penicillin seemed to have disappointingly little effect. It is therefore more than ever necessary for practitioners to get cases of osteomyelitis into hospital at the earliest possible moment. The cases in which the bacteriology was unknown—viz., those of salpingitis, post-operative pneumonia, and septic abortion—all did badly, as would be expected the result of the administration of penicillin without bacteriological control is likely to prove unsatisfactory. The case of human bite improved rapidly under general and local penicillin treatment. The patient was a negro who had been bitten on the thumb by a negro, and as Boland (1941) showed these bites carry a high morbidity rate due to spreading cellulitis. In this case the patient was treated with injections of 20,000 units every three hours and with local penicillin cream, the inflammation remained localized, and she was discharged from hospital in 27 days. One patient complained of considerable local pain when being treated with a continuous intramuscular drip, it was noted that blood concentrations of penicillin were lower than usual, and at necropsy there was evidence of considerable muscle damage.

Systemic Treatment—The number of patients for whom penicillin was requested for systemic use was the same in the second and the third months in which supplies were available although in the latter, owing to increasing supplies, greater individual doses were prescribed. It is probable, therefore, that, although spectacularly successful in suitable cases, the number of patients in hospitals needing systemic penicillin is by no means large, and the total quantity which will be used even when supplies are freely purchasable will be smaller than many of us expected.

Local Application—The general practitioner will find local penicillin treatment of great value in suitable cases of conjunctivitis and staphylococcal skin diseases. For conjunctival instillation the solution of 1,000 units per c.c.m. is less painful than the application of penicillin cream, but for *syccosis* the lotion was less effective than the cream, this was prepared according to the formula of Clark *et al.* (1943), and results from

all hospitals have been excellent. For infections of the hand the instillation of the solution at a concentration of 1,000 units per c.cm. seemed to be more effective than the cream; but dressings have to be done more often, and were more painful. Small boils were successfully aborted in 24 hours by injecting 0.1 c.cm. of a strong solution of 10,000 units per c.cm. into the boil; the treatment, however, is painful, and not more than 0.1 c.cm. should be injected at a time. Local application uses up comparatively small quantities of penicillin.

Comment

Penicillin cream is certain to be used very widely in civilian practice, and the difficulty that practitioners and pharmacists have encountered was largely in the preparation of the sterile lanette wax and castor-oil base, which has to be autoclaved. This can, however, be prepared in bulk, and will keep indefinitely; when needed, the appropriate amount can be melted, cooled to 60° C., and the penicillin solution added to make a final concentration of 200 units per gramme.

It would be a great advantage if supplies of sterile cream base were available from a central store so that pharmacists and practitioners in small hospitals could make up their own penicillin cream as they needed it. A self-sterilizing cream would be very desirable, but until this is available it is essential that practitioners supplying patients with penicillin cream for application at home to a skin lesion should be careful to provide them with precise instructions on how to remove the cream from the jar with reasonably sterile precautions. We have found it satisfactory to tell patients to immerse the blade of a metal-handled table-knife in boiling water for five minutes and then cool it under a freely running cold tap; the cream is removed without delay, and the knife is not replaced in the jar without resterilizing. The tablets of penicillin proved to be easier to handle and more economical in use than the ampoules in which American and Canadian penicillin is dispensed. If in the future British penicillin is to be sold in ampoules it would be of considerable advantage if the glass used were soft enough to be cracked without considerable effort or, better still, if the substance could be dried in a bottle or ampoule with a rubber seal in order that the reconstituted solution could be removed in small quantities with a syringe and needle.

Summary

The types of case in which penicillin is likely to be of value in civilian practice are indicated by the conditions treated in the first three months in which British penicillin was freely available.

The general practitioner will probably use penicillin cream locally more often than any other preparation of the substance.

Sterilized penicillin cream base should be available to practitioners and pharmacists, who will then be quite capable of making up the cream from penicillin tablets.

With adequate instruction patients can carry out treatment of skin conditions with penicillin cream quite successfully in their own homes.

The consumption of penicillin is largely conditioned by the number of cases needing systemic treatment, and this was smaller than was anticipated.

The third annual report of the North-Eastern Regional Hospitals Advisory Council contains as an appendix a report by Prof. J. C. on the Durham University department of child health at Royal Victoria Infirmary, Newcastle-upon-Tyne, which opened up in 1943. The main work of the children's clinic is the medical consultation service provided each afternoon in sessions held by experienced children's specialists. In collaboration with the health department of the Newcastle City Council a child welfare clinic was placed in the new department and opened in May last to serve as a training centre for doctors and nurses taking up this work. The main in-patient clinical work of the department is carried out in the children's wards of the Royal Victoria Infirmary, with additional wards in the Babies' Hospital. The teaching of undergraduate students in child health and clinical paediatrics is now established. It is intended that research shall become one of the chief features of the department's activities; already several important lines of research are being pursued.

Medical Memoranda

A Case of Exomphalos complicated by Acute Intestinal Obstruction

The following notes of a case of exomphalos which has come under my care may prove of interest.

CASE REPORT

At noon on Dec. 14, 1943, I was called to a ward where a Munyarwanda woman had just given birth to a male child with exomphalos. The proximal portion of the cord was in the form of a bag covered with translucent amniotic membrane. It was about the size and shape of a large lemon, and through the membrane covering coils of small intestine could easily be made out. The sac was attached to the abdomen by a skin-covered pedicle 1 in. in length and 1 in. in diameter. In all other respects the infant appeared normal and strong. The cord was ligated and severed distal to the sac.

At 3 p.m., three hours after birth, I performed an operation. Naturally the question of the most suitable anaesthetic arose. Langton Hewer states that in acute abdominal conditions in young children the techniques involving local and spinal blocks show a higher mortality than general anaesthesia. Lambert Rogers (1941) operated upon a very severe case of exomphalos 20 minutes after the birth of a baby. In this case the operation was so near the birth that he felt it might be considered a mere prolongation of normal birth trauma, and consequently used no anaesthetic. The child suffered no shock, respiratory distress, or other complication. Three hours was perhaps too long after birth to consider a severe operation as a prolongation of the physiological process of birth. Carman (1941), after operating on a 4-day-old baby for strangulated hernia, reported favourably on ether and oxygen as the anaesthetic agent, after premedication with atropine 1/200 gr. I had no ether or oxygen available. However, Ley (1942), in reporting a successful operation in a case of severe exomphalos on a baby 10 hours old, stressed the value of pure chloroform anaesthesia for abdominal sections in very young children. Accordingly I instructed my comparatively inexperienced native orderly to administer pure chloroform.

A transverse incision was made, as in Mayo's operation for umbilical hernia, through the skin and subcutaneous tissue. The inner layers of the neck of the sac consisted of tense, tight fibrous tissue, and so the superior-anterior surface of the sac itself was incised and the sac opened. It was seen to contain almost the whole of the small intestine, the coils of which were very congested indeed, and I was in doubt whether one of the coils was viable or not. The umbilical vessels were found on the inferior wall of the sac; these were carefully ligated and tied, and the sac was then opened completely. As the opening through the neck was so tight it was obviously impossible to attempt the return of the bowel through it. The fibrous ring was therefore cut. At this stage, the anaesthesia being light, the child strained and almost the rest of the bowel prolapsed. The normal pink colour of the freshly prolapsed coils was in marked contrast to those already seen. There was a distinct compression ring on the two coils which had been constricted in the neck.

Smellie, in Ley's case, was compelled to use "deep chloroform anaesthesia." As it was found impossible to replace the intestines under light anaesthesia I instructed the orderly to push the chloroform. This was done; but very soon, in spite of the constant use of towels wrung out in hot saline, the child became cold and clammy and its breathing very intermittent and gasping, like that of a baby just born with asphyxia neonatorum. I did not think it could survive the rest of the operation. With difficulty the bowel was replaced. The abdomen was closed with one purse-string suture through the peritoneum and fascia, and the skin with interrupted silkwool-gut sutures. The apparently moribund child was returned to the ward wrapped in cotton-wool, surrounded with hot-water bottles, and placed with its head low down. The operation had lasted about 1½ hours.

To my amazement the child rapidly recovered. That night it vomited only once. It almost immediately started taking the breast, passed water normally the first night, and had a normal action of the bowels the second night. With the exception of slight sepsis of the wound, which rapidly responded to fomentations and sulph-anilamide powder, it made a complete and speedy recovery. The weight of the baby was 6 lb.

DISCUSSION

Exomphalos, when a true sac is present, is a very rare condition, with a high mortality rate; but the above case, and more especially those reported by Lambert Rogers (1941) and Ley (1942), show that even marked degrees of this abnormality are viable if submitted to operation at once. Sheldon (1936) states: "Operative treatment is usually required, but, in the absence of intestinal obstruction, conservative treatment, by simply protecting the sac from injury, has been followed by slow natural repair." Intestinal obstruction is always a serious condition, and the younger the patient the more serious it is. Therefore a conservative treatment which awaits the signs of

obstruction seems one that is likely to deprive the infant of that chance of survival which surgery can give it. A further reason against expectant treatment is, as McGavin and Choyce (1932) pointed out, that the vascular amniotic membranes slough and rupture, leading to a fetitious ectopia of the viscera and resultant death from shock or sepsis.

Brailsford (1939) has drawn attention to the possibility of diagnosing antenatally several of the severe forms of congenital deformity by a radiograph of the foetus. In a case of exomphalos he noticed a marked shortening of the spinal column. In the present case, in Lambert Rogers's, and apparently in Ley's, no such shortening was present, so that the absence of shortening in a foetal radiograph certainly does not indicate an absence of this deformity.

I would like to pay tribute to the splendid anaesthesia given by my native boy and, in doing so, to state what fine anaesthetists and nurses our comparatively uneducated Banjaraunda boys make. With their services as anaesthetists and assistants there are very few surgical procedures which we are unable to tackle in our hilly and primitive hospital.

Muscle Spasm apparently due to Lack of Sodium Chloride

The following report may help other doctors who have to deal with a similar case.

CASE REPORT

At 12.15 a.m. on Aug. 10 after a week of increasingly hot weather culminating in an extremely hot day and night, I saw a boy of 17 years with the following history and condition. He had gone to bed at 10.30 p.m. on Aug. 9 feeling weak and poorly, and, like everyone that night, sweating freely. At about 11 p.m. he began to have "pins and needles" first in the arms, later also in his legs and face, followed in about ten minutes by a mild attack of cramp in each biceps humerus lasting a moment or so and passing off. Some ten minutes later another attack of cramp involving more flexor muscles occurred, passed off, and so on, each attack being worse and involving more muscles, the "pins and needles" persisting throughout.

When I saw him he was just going into a spasm, which lasted 3½ minutes and at its peak was as follows. The arms were tightly folded as in a swimmer's photograph, fingers clawed, legs in the frog position, head flexed, trunk slightly flexed, face screwed up with pain but not a risus sardonius, copious sweating, respirations the incredible rate of 50 per minute, pulse forcible and 90 per minute. It was quite impossible to straighten even the fingers.

The spasm left him utterly relaxed and exhausted, temperature 96.4°F, "pins and needles" present and strong, mind clear throughout. Tetanus and tetany were ruled out, no abnormal signs in chest or abdomen, no rash. Direct questioning elicited "Yes" to "Do you sweat a lot?" and "Do you dislike table salt?" Three teaspoonfuls of sodium chloride in one third of a pint of warm water was given, and, interestingly, he volunteered that it tasted good, nor was there any nausea. Three minutes later another attack started, but less violent and long. Another drink of two teaspoonfuls to one third of a pint was given, which, he said, tasted a bit strong. Within 1½ minutes of the first drink the "pins and needles" had begun to go and within 30 minutes had gone. He felt hungry; temperature 97.6°F. I left him eating two huge "doorsteps" of bread and margarine.

Later that day I visited him, he was up, had no physical signs of anything abnormal in the chest, temperature 98°F, and he said he had an appetite for the first time in three weeks.

COMMENT

One must decide, was it an acute shortage of sodium chloride in the blood giving rise to cramp of a most unusual violence and cured by the strong saline draught, or was it something else which had reached its peak as I arrived and went off despite the treatment? I think the former, but unfortunately I did not taste his sweat (it might have been saltless), nor do conditions in a council house encourage taking blood for a sodium chloride estimation when the nearest laboratory is sixteen miles away. There can be no doubt that had the condition not cleared up his heart would not have stood up to the strain for more than another six or seven hours. Also why does this sort of cramp and athlete's cramp always affect the flexor muscles?

Reviews

NEUROSYPHILIS

The Management of Neurosyphilis. By Bernhard Dattner, M.D., Jur.D. with the collaboration of Evan W. Thomas M.D. and Gertrude Wexler M.D. Foreword by Joseph Earle Moore M.D. (Pp. 398. \$5.50 or 25s.) New York: Grune and Stratton, London: William Heinemann, 1944.

Dr. Dattner, formerly assistant in the Vienna clinic of Wagner-Jauregg, has written a useful and much-needed book. His subject is one that is common to syphilology, neurology, and psychiatry, and it is good to find it treated as an all-round problem of its own and not one-sidedly as an incidental topic in one of the three major specialities.

The book is well documented, the findings of other workers are culled from far and wide, and useful personal observations are included. There is no rushing at conclusions, and controversial problems are squarely faced. We are glad to see the author's insistence on the importance of spinal-fluid findings in diagnosis and during the early stages of syphilis, and he puts the matter of therapeutic results in true perspective when he stresses negative serology and longevity—and not clinical improvements—as the chief criteria for estimating the efficacy of particular treatments.

One might disagree with certain statements—e.g., that a post-malarial fluid once negative remains so—but these are only minor matters. One criticism that must be made, however, is that little or no space is devoted to flocculation tests. It is high time that the Wassermann were dislodged from its preferential position, and a reference to the greater sensitivity of the Meinicke, Muller, and Kahn tests (to mention a few) would have been welcome; it would, incidentally, have had an important bearing upon the question of the frequency of negative serology after treatment and also upon the likelihood of finding negative blood results in cases of untreated meningo-vascular syphilis. Moreover the inclusion of the flocculation tests might have led to a consideration of the all-too-neglected problem of standards of cure—standards of satisfactory progress (beyond which intensive treatment is no longer necessary) which will never be established until we are all agreed as to which tests we will accept.

The book is a timely one clearly and capably written, and it can be confidently recommended to all concerned in the recognition and treatment of neurosyphilis.

SURGERY FOR STUDENTS

Surgery: A Textbook for Students. By Charles Aubrey Pannett, M.D. F.R.C.S. (Pp. 740, illustrated 35s.) London: Hodder and Stoughton, 1944.

With the sentiments Prof. Pannett expresses in his preface the majority of surgeons, and, we hope, all surgical examiners, will agree. The gist of the matter is that he believes a textbook for undergraduate students should be the product of a single author, since "it does not seem fair to expect the student to have more exact knowledge than his examiner possesses, or to have read a series of monographs by experts." The specialist may have acquired special facility in technique by confining his work within narrow limits, "but the facts of the specialty and the principles on which he works are within the compass of the general surgeon's wit." The object of the book is "to present the facts of general surgery in as few words as possible"—a very desirable aim in these days of prolixity.

In the application of these principles, however, we cannot help feeling that the author has not been entirely successful. In large portions of the book the condensation has been overdone, which has made it a guide more suited to the nurse or medical auxiliary than to the medical student. It will be accepted, too, that the greater the conciseness the more the need for extreme accuracy, and in this the book unfortunately falls short of expectations. We are, of course, not criticizing legitimate expressions of opinion, but factual statements, as the following examples will show. "The brilliant discovery by Mechnikoff of arspenamine" although one of the numerous synonyms for "606" is "Ehrlich-Hata compound", "the secretion of testosterone by the spermatogenic cells": true, it has been

PHEMITONE-BOOTS

ANTI-EPILEPTIC

Phemitone is a barbituric acid derivative related to phenobarbitone for the treatment of all forms of epilepsy. Phemitone is non-toxic in therapeutic doses and is most effective in severe cases of epilepsy. It reduces the frequency of major seizures and, as it has a lower hypnotic action than phenobarbitone, the patient's mental condition is usually improved. The average dose is 3 gr. twice or thrice daily.

Vitamin B Therapy

Each tablet contains:
Aneurine 1 mg. (320 International Units B.P.),
riboflavin 1 mg. (equal to 400 to 500 Sherman-Bourquin Units) and nicotinic acid amide (P.P. factor) 15 mg.

Packings: Bottles of 25, 100 and 500.

'Benerva' Compound tablets combine in one single preparation the properties of the three best-known and most active constituents of the vitamin B complex. In the few food-stuffs rich in the complex the different factors vary within wide limits; in 'Benerva' Compound tablets aneurine, riboflavin and nicotinic acid amide are presented in constant proportions and comparatively large doses.

'BENERVA' COMPOUND

'Benerva' Compound tablets have been successfully employed in such conditions as chronic gastro-intestinal disturbances; anorexia, frequent tiredness, both mental and physical; various dermatoses; certain ocular diseases; nervous disorders; neuritis; glossitis; cheilosis and in certain pathological symptoms of senility.

PENICILLIN IN SYPHILIS

It is now a year since the first announcement that penicillin has an action on syphilis. Further information has been awaited with deep interest, because the successful outcome of clinical trials would mean a complete revolution in the treatment of this disease and a far greater likelihood of its ultimate extermination. These hopes are based on the fact that penicillin is for all practical purposes non-toxic; so that a single course lasting about a week, and free from the dangers of intensive arsenotherapy, may prove to be all that is needed to effect cure. The main drawback is that administration has to be continued day and night, and therefore requires admission to hospital. The necessity for continuous treatment presents less difficulty in the armed Forces, and the advantage to them of being able to return a man to duty after so short a period of treatment is paralleled only by the corresponding advantage already secured by the penicillin treatment of gonorrhoea.

Study of the penicillin treatment of syphilis has been pursued extensively and with great vigour and thoroughness in the United States on a plan laid down by the National Research Council, and a series of three reports¹ has now appeared which represent experience at a large number of centres. All the authors are agreed that penicillin treatment causes rapid disappearance of *T. pallida*—usually within less than 24 hours—and rapid healing of primary and secondary lesions. Herxheimer reactions are common, although naturally of little account in superficial lesions. It is also the general experience that all serological tests for syphilis pass through a stage of diminishing positiveness to become negative in a majority of cases usually within 3 months. In a large proportion they have remained negative so far as observation has yet gone; others have shown a tendency to the redevelopment of positive reactions. J. F. Mahoney and his colleagues give examples in the first paper of different types of serological history, as revealed by the performance of ten different tests on as many as twenty or more occasions. They also report the results to date in 100 patients, 4 of whom were the first to be treated; 3 of these have remained clinically well and serologically negative; the fourth has a recurrence probably due to reinfection.

Mahoney, J. E. Moore, Commander W. Schwartz, and Lieut.-Col. T. Sternberg are the authors of a second paper which is based on the work at twenty-three centres, Service and civilian, where 1,587 cases have been treated, 1,418 of which are suitable for analysis. Treatment at all these centres followed a plan, all patients being given 3-hourly intramuscular injections for 7½ days; they were divided

into 4 groups in which the individual dose was 1,000, 5,000, 10,000, or 20,000 units. Even the smallest dose caused disappearance of *T. pallida* and healing of lesions, but the smaller the dose the less often did serological tests become negative and the more frequent was relapse. The largest dose employed is therefore now considered the minimum necessary. Slightly better results than any obtained with penicillin alone followed the administration of either 60,000 or 300,000 units of penicillin in all, together with a subcurative dose (320 mg.) of mapharsen. There is clear evidence that the earlier treatment is begun the more certain is its effect. Among patients treated with penicillin alone the frequency of relapse in sero-negative primary syphilis was 3.2%, while in sero-positive primary it was 5% and in secondary 9.8%. In view of this finding it is not surprising that the results of treating late syphilis, which are described by J. H. Stokes *et al.* in the third of these papers, are much more equivocal. Among 182 cases, of which 122 had neurosyphilis, the proportion in which serological tests became actually negative was only 10%, though some reduction in positiveness occurred in about 50%. Clinical improvement and spinal-fluid changes corresponded, about half the patients improving definitely, a few strikingly, and the remainder little or not at all. Herxheimer reactions occurred in 20% and are considered to call for cautious early dosage. The effect on gummata of the skin and bones is more encouraging; these disappear with almost unfailing regularity after only moderate dosage.

It is impossible fully to assess the significance of these findings, in spite of their massive scale and elaborate control, if only because in syphilis time alone can tell. A continued hope that a full single course will cure the disease in the primary stage seems justified, and results may be bettered by improved methods of dosage and administration. It is noteworthy that all these patients were treated by spaced intramuscular injections, and there is no mention anywhere of blood estimations to determine whether an adequate concentration was maintained in the blood throughout the intervals between injections. No one knows what an adequate concentration actually is for attacking *T. pallida*, but it is well known that the concentration falls to a very low level between individual injections. According to I. W. J. McAdam, J. P. Duguid, and S. W. Challinor,² to keep the blood continuously bacteriostatic for *Staph. aureus* the daily dose required if given 2-hourly is 120,000 units, if 3-hourly 200,000 units, and if 4-hourly 600,000 units. The same effect can be achieved by giving only 100,000 units by continuous intramuscular drip, and this on general principles would appear to be the method of choice for treating syphilis.

It is a remarkable fact that both principal forms of venereal disease should prove to be amenable to the same drug. To the thoughtless it might even appear highly convenient, in that if necessary two birds can be killed with one stone. Owing to the different times of appearance of the two diseases it is in fact occasionally a grave drawback. C. R. Wise and D. M. Pillsbury³ mention two cases in which the treatment of gonorrhoea with 100,000

¹ *Lancet*, 1944, 2, 336.² *Brit. J. Surg.*, Special Issue, "Penicillin in Warfare," 1944, p. 214.³ *J. Amer. med. Ass.*, 1944, 128, 63, 67, 73.

units of penicillin apparently suppressed a coincident syphilitic infection, which became manifest only on the delayed appearance of secondary lesions. This possibility is perhaps an argument in favour of treating gonorrhoea initially with sulphonamides.

PREVENTION OF PROSTITUTION

The League of Nations has done much useful work on the rehabilitation of adult prostitutes.¹ Its advisory committee on social questions, recognizing that rehabilitation is inevitably more difficult and less effective than prevention, has since 1938 been collaborating with the International Labour Office in a study of how to prevent prostitution, especially in minors.² The causes which lead women into prostitution can be divided, it says, into two main categories—one social and the other individual. At all events before the present war social causes alone were rarely determinant unless they were linked up with predisposing characteristics. The more important of these are weak character, poor mental equipment, and grave physical disability; less important are an oversexed constitution or inherent depravity. Predisposition to such a way of life is apparently very rare—6 to 10%—and these women are psychopathic. The chief social causes are disintegration of family ties or separation of the adolescent from the shelter of the family; faulty education and upbringing; slums, want, and, in some occupations, insufficient social protection against risks due to the environment, the temptations or conditions of life which it entails. Every improvement in the social and economic status of women is likely to strengthen the resistance of the individual woman to the hire of her body. Other things being equal, the percentage of full-time prostitutes decreases with the improvement of social services protecting the weak. The increasing opportunities for women to make lives of their own have preserved many from becoming prostitutes, but an even more important factor has been the development of social insurance and its progressive extension among women workers. Unemployment insurance bridges over dangerous periods of great material embarrassment by intervening at the critical moment, which is largely important in a marginal case—that of a woman whose resistance to financial temptation has already been weakened. The removal of financial insecurity is a powerful protective factor. In feminine occupations in which social protection is neglected the percentage of prostitutes is greater than in fully protected occupations. Organizations and social protection are vitally important in such occupations as domestic service and catering, and in night clubs and music-halls. Measures that improve the standard of living, and specially housing, tend to reduce prostitution.

Social preventive action may well include the protection of young workers when they are placed in employment. Other social measures intended to organize protection against risks arising out of the surroundings of the work may be negative, prohibiting the employment of young persons in work where the risks are serious; or positive,

organizing supervision over young people and helping them to overcome the difficulties arising out of their work. The organization of the occupation itself, and the adoption of rules devised for raising its standards, may protect against demoralization. Measures of this kind seem to be particularly suitable for overcoming the risks in domestic service.

The committee holds that insufficient attention has been paid to the demand for prostitutes. To reduce the demand would lead to a reduction of the supply. The first effect would be a temporary or permanent fall in the earnings from prostitution. Among prostitutes the part played by bad company, and especially by *souteneurs*, is infinitely greater than in any normal group of women. If the law is strict and is applied with the utmost severity, all forms of the *souteneur's* activities can be checked. For such suppression, however, a powerful and active public opinion is needed. One difficulty in this line of attack is that in regulationist countries brothel-keepers are recognized or tolerated, and therefore immune from legislation directed against the *souteneur*. The punishment of adult prostitutes for offences connected with prostitution is entirely useless and even dangerous. Imprisonment of women who are on the brink of prostitution makes them even more conscious that they are already outcasts, and makes their return to normal life infinitely more difficult. Fines merely incite to prostitution as a means of raising the money. Certain experiments carried out in the Scandinavian countries aim, without punishment, at deterring women from continuing to prostitute themselves. The principal innovations consist in the psychiatric examination of prostitutes, the treatment of those found to be feeble-minded, and the use of probation. Such methods, it is suggested, would take off the streets a large number of women who go on them because of poverty. Probation should prove a powerful deterrent to a woman who has not yet entirely lost her self-respect. One highly significant development is the recent advance in the treatment of gonorrhoea. This has much reduced the fear of disease and therefore tends to increase the demand for prostitutes. Future appeal to men will have to be based less on physical danger and more on moral grounds.

One of the chief individual as distinct from social causes of prostitution is slight mental abnormality. The great majority of prostitutes are borderline cases. Difficult mentally defective children should be more surely detected while they are at school and be adequately educated. Incapables should be protected from those realities of life that are too difficult for them. Again, many women are forced to prostitution by chronic physical disease which incapacitates them for normal work. The remedy is compulsory health and sickness insurance. Social services can contribute by helping women who have contracted venereal disease before they fall into prostitution by putting them in touch with voluntary organizations and with official and non-official help during treatment and after cure. Societies should avoid forcing women who are merely promiscuous into professional prostitution. Police raids on places of amusement are often followed by the indiscriminate detention of prostitutes and non-prostitutes. The latter run a grave risk of losing their employment in consequence; they are prone to have difficulties with their families, and to take

London: Allen and Unwin. (6s.)

to the streets. The authorities in countries which practise regulation and the licensing of brothels tend to force suspected women into the rigid system of registration. The committee declares that minors should never be registered as prostitutes or be allowed to become inmates of licensed houses. Authorities and voluntary organizations should make every effort to warn women about to be registered of the serious consequences of this step, fix a long enough interval between application and the issue of the card, and keep away from their offices souteneurs, brothel-keepers, and the like, who might bring pressure to bear upon applicants. Girls who wish to be struck off the register should be helped and not obstructed. As unmarried mothers fall nearly everywhere under a social stigma, public health and social services should give them financial aid. Efforts should be made to restore them to their families or to place their children in suitable homes, and to find them employment. Such services should be organized in such a way that unmarried mothers do not hesitate to apply to them. Many girls drift into promiscuity and later into prostitution through being suddenly transferred to a strange mode of life. Voluntary organizations, says the committee, should try to enlighten young women by meetings and leaflets. Besides drawing attention to the dangers of large towns, they should impart at least rudimentary knowledge of the means of help that are available. Railway missions especially do much by protecting young girls who have run away, have met doubtful persons on their journey, or are travelling to new places of employment. These services ought to be extended to travel by road, air, and water. Women police can give much protection to minors on the fringe of prostitution by supervising cabarets, night-clubs, suspicious restaurants, and other haunts of prostitutes. In regulating countries they may be able to rescue promiscuous girls before they are caught by the *police des mœurs* and registered. Many prostitutes have started their sexual experience very early, and the severe punishment of sexual offences against children provides a certain safeguard. In some countries the age of consent could be raised without interfering with the liberty of the subject.

In conclusion the committee hopes for a further reduction in prostitution if social progress and preventive measures coincide with the growth of new standards of sexual morality. It looks forward to a period during which there will be a progressive decline by a general increase in individual consciousness of responsibility, by a further development of social services, and by deliberate official effort to lessen its incidence.

PAIN SENSITIVITY IN DYSMENORRHOEA

The many theories put forward to explain dysmenorrhoea have included, according to the fashion of the day, various endocrine disturbances, vitamin deficiencies, and psychological difficulties. The simplest explanation is probably that women who experience dysmenorrhoea are more sensitive to pain than their more fortunate sisters. Haman¹ has produced evidence that this is so by comparing the sensitivity to pain in 100 women with dysmenorrhoea and 100 without, in 100 post-menopausal women, and 100 men. His method of testing pain sensitivity is a simple one

based on pressure pain, using a sensimeter. This is a simple adjustment of a standard Geneva lens measure, an instrument looking like a watch, with three projecting pointed rods, the centre one being movable and projecting beyond the other two. The rods are rested on the proximal phalanx of the thumb, and pressure is applied until it hurts, as the central rod is depressed its movement is recorded on the watch face, so that a reading of individual pain thresholds may be made. Haman publishes means and frequency distribution curves of the results in the four groups. They show no significant differences between the averages of the men, normal women, and post-menopausal women, though the latter had a slightly higher threshold than the others. The dysmenorrhoeic women, however, had a significantly lower average threshold. When divided into two subgroups—those with primary and those with secondary dysmenorrhoea—the first gave a lower average than the second. When the post-menopausal women were divided into those who had had dysmenorrhoea and those who had not, the former showed a lower average threshold than the latter. This does not entirely rule out the possibility that persistent cyclic pain such as is suffered in dysmenorrhoea may lead to a general increase in nerve sensitivity. A clinching demonstration would be to determine the pain threshold in large groups of pre-adolescent girls and see whether dysmenorrhoea was later most frequent among those with the higher thresholds.

SCHEME FOR CANCER TREATMENT

In a discussion at the Radiological Section of the Royal Society of Medicine on post-war organization for cancer treatment (which is reported elsewhere in this number) Mr G F Stebbing mentioned a pamphlet describing an "A B C Scheme for the Organization of Cancer Treatment in London". We have now received a copy of this pamphlet.¹ Dr Malcolm Donaldson's object in publishing it is to persuade the voluntary hospitals in London and the surrounding counties to get together and draw up a scheme to help the local authorities, who are responsible under the Cancer Act for submitting to the Ministry of Health a plan for the organization of cancer treatment in their areas. Because of the scarcity of towns with large populations in the Home Counties and the centralization of many big hospitals in the County of London, it is considered essential in the A B C scheme that the County of London and the six surrounding counties should be regarded as one area. It is suggested that this area, comprising a population of about 12 000 000, should be divided into six sectors or groups. In each of these six sectors the hospitals would be classified as A, or B, or C. Class A hospitals—in most cases teaching hospitals—would have facilities for all methods of treatment, including radiotherapy. Class B hospitals in the County of London, it is considered essential but not radiotherapy, and Class C hospitals would be used for preliminary investigation of suspected cases of cancer. It is further suggested that if there is more than one Class A hospital in one area they should co-operate particularly in respect of radiotherapy, and should elect one of their staff as a 'co-ordinating member'. Again, it is suggested that there might be substations of radiotherapy in some of the larger towns of the Home Counties working in the closest co-operation with the A hospitals and sharing the radiotherapeutic staff. It will be seen that by this A B C scheme there would be large groups of hospitals rather than exactly defined areas, in which the A hospitals and their substations would take on the responsibility for giving radiotherapy to the patients in the B hospitals, the

¹ *Amer J Obstet Gynec* 1944 47, 636

¹ Copies can be obtained from the National Radium Commission, 12, Manchester Square, London, W 1

patients being returned to their original B hospitals for after-care and follow-up. Such a scheme does not deny an A hospital the right to treat patients from elsewhere, or a B hospital to send a patient for special treatment to an A hospital outside its group. It is suggested that there should be a medical organizing committee for each of the six groups, who would be responsible to a Cancer Council consisting of representatives of those local authorities who control the area in which the hospitals are situated. Although in the first place it may be necessary to have a Cancer Council in each sector, later one Cancer Council would probably suffice for the whole seven counties.

HOMELESS CHILDREN

Experience in caring for children bombed out of their homes in this country will help in dealing with the far larger problem of caring for millions of homeless European children. Dr. D. W. Winnicott and Clare Britton, a physician and a psychiatric social worker, took part in the Oxfordshire scheme of setting up evacuation hostels for children who could not settle in billets.¹ They found themselves able to cope with children who came to them with severe symptoms when the illness was temporary and by way of a defence mechanism. Nearly all such children respond well even without individual psychotherapy, and are able to enter home life again. Several hostels form a group directly administered by the county council, and a psychiatrist visits one day a week and directs a whole-time psychiatric social worker in the routine management of the hostels. The grouping of hostels makes possible a certain amount of classification and enables children to be changed from one type of hostel to another without breach of continuity of treatment. Not more than 25 children, the authors think, should be put in one hostel; the ideal number seems to be 12. Also, the hostels should not be so near one another that the children can meet and compare notes; for that matter it is just as well that the staff should not constantly compare their own efforts with those of their neighbours. In practice the psychiatric social worker controls the whole of the work except for maintenance and alteration of buildings. She is in touch with all that each hostel has gone through; she knows which type of case goes best in each hostel, and she can appreciate the difficulties of the staff. She knows each child at every stage, and it is her function to give the children a sense of continuity. Previous training and experience as hostel wardens matter little compared with the ability to assimilate experience and to deal in a genuine, spontaneous way with the events and relationships of life. Wardens are put to such a severe test by the children that only those who are able to be themselves can stand the strain. They must also have a genuine love of children. If a man and wife are appointed this avoids many deficiencies, and many difficulties do not arise. A warden must be willing to stay in the job, for a change of warden means "casualties" among the children. The education of wardens is obviously important. It is part of the work of the psychiatrist and the social worker, and much help is given if wardens have enough confidence in themselves to be able to think along psychological lines and discuss problems with other wardens and experienced people. The subordinate staff present a problem, for, as the children are somewhat antisocial, the management cannot help being dictatorial and the assistants have their initiative much curtailed. Each hostel tries to reproduce as nearly as possible a home environment: a building, food, clothing, human love and understanding; a time-table, schooling; apparatus and ideas leading to rich play and constructive

work; substitute parents and other human relationships. Antisocial, introverted, depressed, distorted, and backward children all need separate and distinct kinds of treatment. The limitations of the experiment are obvious, and perhaps the most serious are that everyone feels the world to be temporary and entrants cannot be selected. Nevertheless, the authors think it has been well worth making. It has shown the difficulties and possibilities of providing substitute homes for children, and proves that residence in a hostel under specialized management can have definite therapeutic value. This conclusion is borne out by a valuable survey of experience under the evacuation scheme just issued by the Ministry of Health and printed in pamphlet form under the title *Hostels for "Difficult Children"* (H.M. Stationery Office; 6d.).

FLUOROSIS IN SOUTH AFRICA

The existence of endemic fluorosis in South Africa was recognized as a serious problem about five years ago. Particularly important areas of fluorosis are at Pilansberg, Warmbaths, the Saltpan region of the Transvaal, and several areas in the Cape Province. Fluorine-bearing rock minerals, and soils are widely distributed, giving rise to domestic waters with toxic levels of fluorine, in places up to 11 parts per million and many having 6 p.p.m. The fluorine concentration in the water of dams, springs, wells and boreholes varies widely according to the rainfall. Characteristic mottling of the teeth drew attention to the existence of the fluorine. It appears that the pattern of the mottling is very variable, from chalky patches to a opaque whiteness of the whole tooth; sometimes, but not invariably, hypoplasia and pitting are severe. Not every one in a "fluorine area" is affected, nor is the extent of the reaction the same in those with fluorosis from drinking water of similar fluorine content. Ockerse¹ believes that the differences are due to the form of fluorine compound present; they are equally likely to be due to dietary factors; for example, a high-calcium diet, especially one that includes milk, probably protects against fluorosis. Staining of the mottled enamel is, of course, recognized in South Africa, but the nature and cause of this stain are unknown. The mixed populations of South Africa make it difficult to investigate the still open question of whether mottling protects against caries. Moreover, it must be recognized that an optimum intake of fluorine might give protection with little or no mottling.²

Of even greater interest than the study of the teeth is the observation that gross skeletal changes occur at about 2 years of age after long exposure, with such symptoms: stiffness of the spine and joints; x-ray examination reveals ossification of the lumbar and thoracic vertebrae, and osteophytic deposits on the radius, ulna, and rib margins; there is also loss of appetite and emaciation. This condition finally incapacitating, resembles that shown by Shortt's cases in India. The whole syndrome is probably comparable to cases of industrial fluorine poisoning. Ockerse's report, which gives details of interest to geologists, dentists and public health workers generally, emphasizes the fact that endemic fluorosis from domestic waters with high fluorine content involves more than severe mottling of the dental enamel; severe damage may be done to the health and welfare of the users. The harmful nature of the water supply in several regions of South Africa has necessitated the use of rain-water.

OBSERVATIONS ON SCABIES AT THE ST. PANCRAS BATHING CENTRE

BY

M. W. GEFFEN, M.R.C.S., L.R.C.P., D.P.H.

Assistant School Medical Officer, L.C.C.; Medical Officer,
St. Pancras Bathing Centre

The prevalence and obstinacy of scabies, and the evident difficulties which many general practitioners have with it, are proffered as excuses for another article on this subject.

I have had the advantage of attending school-children at the St. Pancras Bathing Centre for the L.C.C., and younger children and adults at the same centre for the St. Pancras Borough Council. This has led to the treatment of whole families simultaneously. The intention has been to treat all immediate contacts at the same time as those affected by the disease, with a view to reducing the number of recurrences.

During 1943 the total number of new cases treated among school-children was 1,136, with 5,215 attendances—i.e., approximately 4.5 attendances (not necessarily treatments) per child. Medical examination of adults and pre-school children started only at the beginning of March, the figures for new cases in the last ten months of 1943 being adults 442, pre-school children 201, with a total of 2,138 attendances—an average of 3.3 per patient.

In nearly every case (the exceptions being babies under 1 year old) treatment has been with benzyl benzoate, painted on by trained personnel at the clinic. In a few cases only one application was given, and in a very few three paintings were applied; the great majority had two such treatments, the remaining attendances being for simple baths, observation of progress, treatment of complicating sores, or sometimes for re-assurance about persistent itching or healed spots. It has been established by K. Mellanby and others that one application of benzyl benzoate will cure nearly all cases of scabies. Owing to the difficulty of collecting whole families simultaneously, it has been the practice at the clinic to give two applications at an interval of two or three days. It has been hoped that this would allow contacts and carriers to be disinfested before finally discharging those members of the family who presented themselves earliest.

Despite these precautions of doubling the treatment and persuading contacts to attend, 193 of the 1,136 school-children came back to the clinic with recurrences of scabies—i.e., nearly 17%. It has not been possible to prove that none of these recurrences were relapses, but the lapse of time in the great majority of cases pointed to reinfection. Among the adults and younger children, of the total of 643 treated and discharged, 52 returned later with active scabies—i.e., 8%.

An investigation of the 52 recurrences among the adult and small-child group revealed the following interesting facts: 22 of the recurrences occurred in families in which some contacts had not been treated; 10 further subjects knew they had been in contact with scabies outside their families; the 20 remaining could give no information revealing any probable or possible source of reinfection.

Experience at the clinic shows that it is frequently very difficult, sometimes impossible, to induce all family contacts to attend for treatment. The argument is adduced that so-and-so has not got any spots. Often it is added that the family doctor has confirmed this and declared attendance at the clinic to be unnecessary. Unfortunately this last comment is sometimes true—all doctors do not seem to realize that the sarcoptes may be present for some time before producing signs or symptoms. Only a small minority of local practitioners appear to be sending contacts for treatment, and in many cases reluctant contacts who have declared themselves free from spots have been found ultimately to have numerous typical lesions, possibly quite unwittingly. This seems surprising, but is not uncommon. As a rule, mothers of families can be persuaded to be treated as contacts; fathers are far more reluctant or find it far more difficult to attend, although every effort is made to meet their choice of time. Grandparents often jib at coming up for baths; but the most obstinate refusals are from adolescents who have left school a year or two, and who do not like anything resembling discipline. It is obvious that much propaganda is still needed, especially to educate the public in the fact that scabies has "an incubation period" and that "prevention is better than cure."

Other sources of probable reinfection have been found to be aunts, uncles, and cousins living in the same house, but rarely mentioned by either children or adults (as contacts), sometimes not even on direct inquiry. Lodgers have also to be remembered. Tact, moreover, is required to persuade unmarried bed-partners to attend the clinic; but this difficult task has been admirably carried out by a most diplomatic health visitor. On this last point, of course, no direct or indirect inquiries are ever made, but voluntary admissions are followed by a talk showing why the partner should also attend. Most cases are first brought to light in the routine

work of the L.C.C. school nurses. Many more are sent up by local doctors. Most doctors would appear to know scabies when they see it, but during 1943 six cases of chicken-pox, two of herpes zoster, one secondary syphilide, and various eczemas were sent in diagnosed as scabies by medical practitioners; so also were two cases of pediculosis, several of flea- or bug-bites, some diet rashes, and a dozen cases of acne, in all of which no signs of scabies could be found. It is doubtful if the average practitioner sees many cases of scabies either in hospital or in private practice: one or two visits to a bathing centre would probably be very helpful, and visiting colleagues are always welcome. Again, many patients ultimately come to the clinic with scabies, after having been treated a long time for some other condition—usually food rash or eczema. Even a correct diagnosis is not invariably followed by proper treatment. For example, one patient seen a week or two ago had been using sulphur ointment daily for six weeks, allegedly on her doctor's instructions. She certainly had no scabies when seen, but had a severe sulphur dermatitis.

During the present year a failure in the boiler system due to war causes made it impossible to give the usual immersion and soaking to school-children attending for treatment. For three months these children were merely sponged with warm water before being painted with benzyl benzoate. It has been interesting to observe that there was no falling-off of cures during or soon after this period. Scrubbing the skin to open burrows and lesions has long been abandoned, the only apparent difference being that children with secondary sores no longer suffer as they did under this affliction.

It is also to be noted that children occasionally attend in the morning on an empty stomach. If soaked for some time in a hot bath, then painted standing, and directed—as older children often are—to rub in the paint with their hands to facilitate drying, such children may feel, or actually become, faint. This never happened when the child was not soaked but only sponged.

It is still the practice here to treat children under 12 months old by inunction with Marcussen's ointment. This gives results comparable with those from benzyl benzoate, but the ointment is too messy and colourful for general use.

The new *National War Formulary* application of benzyl benzoate is not only economical as compared with the old spirit and soap louton but is also much better tolerated. In fact, neither adults nor children complain nowadays except (rarely) when a child rubs some of the application into an eye. Nor is a single case recollected in which benzyl benzoate application was followed by any harm.

Occasionally, when the presence of other illness rendered a patient unable or unfit to attend, benzyl benzoate has been prescribed with full instructions for use in the home. Experience has shown that home-treatment fails in most cases. Experience also shows overwhelmingly that recurrent scabies is a disease of dirt. The cleanest people may be unfortunate enough to contract scabies once. We have had families attending the clinic for as many as four attacks of scabies in a year. In all these cases, without exception, the homes have been dirty, and the patients have shown, in the state of their clothing, sometimes by concurrent infestation with lice, and the obvious neglect to use soap and water, that hygiene may receive honourable mention but has not been practised. These patients are sometimes of low mental grade.

The following formulae may be useful for complications:

1. Ointment for Boils and Pustules

B Extr. ergotae liq. B.P.	3 vss
Zinci oxidi	3 i vss
Acid. carbol. pur. B.P.	gr. iv
Adeps lanae anhydry.	3 i i 3 vi
M. ft. ung.				

2. Ointment for Impetigo and Septic Sores

B Sulphanilamid	gr. xxiv
Ung. simp.	ad 3 i

These have been very successful for the secondary septic infections that often follow scabies and scratching. Almost the only ointments used have been ung. zinci, with castor oil; ung. hydrarg. ammon. dil. B.P.C.; and, for persistent itch after killing sarcoptes, ung. calamin. co. (syn., ung. sed.), N.W.F.

The opportunity is taken, with pleasure, of acknowledging the loyal and efficient assistance of the County, and Borough, Council staffs in all departments, both in the treatment of patients and in the preparation of the records referred to in this article.

Geriatrics is the latest specialty of medicine to be developed, and is the subject of increasing references and articles in the medical press. Pleading that older people should be treated psychologically as well as physically, Dr. Roger I. Lee (*New Engl. J. Med.*, 1944, 230, 190) observes, "Although I do not approve of their picking up gigolos and going dancing, at the same time a certain amount of this sort of thing is to be recommended."

PHYSICAL EDUCATION

A PRELIMINARY TECHNICAL SURVEY

A Research Board for the correlation of medical science and physical education was formed in the middle of 1943, under the chairmanship of Brig. Frank Howitt, and with the blessing of the Ministry of Labour and the President of the Royal College of Surgeons. Its aim was to ensure a more general recognition of the need for physical education and the better co-ordination of the various authoritative groups dealing with aspects of that wide subject. It has now published an interim report¹ in the form of a preliminary technical survey with recommendations. The work of the Board was divided into four sections—namely, physical education in respect of maternity and child welfare, of education and recreation, of the fighting Services, and of industry. The present report covers only the first three of these. The other, relating to industry, is a field so wide and at present so much disturbed by war conditions that it will be the subject of a later special report.

The section of the Board's work dealing with maternity and child welfare was undertaken under the guidance of Mr. Victor Lack; a number of recommendations concerning the provision of ante- and post-natal exercises are made. The section dealing with education and recreation was undertaken by a team of sixty under the leadership of Mr. H. M. Walton, and deals with the problem from the nursery school right up to the university. It recommends, by the way, that each university should appoint a medical officer, and that a university health committee of both staff and students should be instituted, to concern itself with students' diet and general living conditions, with preparing courses in health education, and with giving publicity to such medical services as exist in the university itself and in the locality. Another recommendation is that students should be obliged to undergo a medical and physical examination on entry into the university. The third section, concerning the Services, deals with the three groups—the normal recruit, the sub-standard recruit, and the sick, injured, and disabled. This section has been in charge of Surg. Capt. K. Digby Bell, R.N. It is urged that medical men who have worked particularly among substandard recruits during the war should be given every opportunity of putting their knowledge and experience into effect in civil life. The recommendations in the entire report number about 150, and they and the facts given are the result of first-hand knowledge derived from visits to schools and hospitals, and Service training, physical training, and rehabilitation centres. Many of the recommendations repeat and reinforce those made by the British Medical Association's Physical Education Committee in 1936. The field is so wide that they cover practically everything which has to do with "positive health," so far at least as the younger age groups in the community are concerned. No sooner had the technical subcommittees begun their work than the need for a scientific advisory committee, both on long-term questions of research and on immediate problems, became apparent, and such a committee has been established with Sir Farquhar Buzzard as chairman and Prof. Lancelot Hogben as assessor.

Need for Co-operation

The report was formally presented at the second annual general meeting of the Board, when the Minister of Health (Mr. H. U. Willink) attended and gave a promise that the recommendations would receive serious consideration by the Government. The Minister said that physical education was no longer a matter of routine exercises to promote physical development; it was a carefully considered plan for the improvement of health, calling for consultation between doctors, physical education experts, and others concerned in national welfare.

Brig F. A. E. Crew, who also spoke at the meeting, said that in the post-war world the scientific departments of our universities would be called upon as never before to make their own special contributions to the solution of problems of social importance. It was essential, he said, that social needs should be made known to the scientists who laboured at the forge of knowledge, and that to these should be given the opportunities and facilities for dealing with such needs. He hoped that the most profitable co-operation of medicine and physical education which had taken place in the Service during the war would continue in civil life, and that physical education might be aided by medicine to become a branch of the science of biology applied to human and social affairs.

Sir Alfred Webb-Johnson spoke of the urgency of seeing that in town and school planning adequate provision was made for playing fields, areas for general recreation, and swimming baths, and also for making use of the large number of men and women specially trained for the work of physical education and rehabilitation, who within a reasonable time would be liberated from the Services.

Finally, the chairman of the Board, Brig. Frank Howitt, claimed for the recommendations that they were both practical and practicable: None of them were unduly utopian, and the Board believed that much could be done in these directions, given patience and pertinacity.

FUTURE OF PSYCHIATRIC SERVICES

Mr. Henry Willink, Minister of Health, speaking at the centenary luncheon of the Royal Medico-Psychological Association in London on Nov. 29, said that great changes in the organization of the public health services and in medical education were in prospect. The working out of arrangements for these changes, so far as they might affect the mental health service, would call for many adjustments and the solution of some rather complex problems of organization. In this there would be full consultation with the representative bodies concerned.

Problems of Organization

It was to be hoped that among other objects future development would include a unified control of all mental health services under a single set of authorities. It was of the first importance to have in every area a body charged with the responsibility of dealing with all aspects of mental health so that they could survey the field as a whole instead of there being a variety of authorities or combination of authorities, each concentrating on relatively limited sections of the whole field. Unified control was essential, for example, to the proper development of a comprehensive out-patient service, which was the first great step towards the application to mental health of the principles of preventive medicine. But if out-patient centres were to be developed there must be a parallel development of the ancillary services. It was obviously uneconomical to leave a highly trained psychiatrist to do his work as best he could without the knowledge of the patient's home and occupational background which a trained psychiatric social worker could give him. It was even more wasteful to leave the psychiatrist in charge of an out-patient centre without adequate clerical assistance.

Psychiatry was still a young specialty; it had suffered from the relative isolation of many mental hospitals and the difficulty which the medical staffs had in keeping in touch with general medicine. The Ministry and the Board of Control were most anxious to secure a closer relation between mental and general hospitals, not only by interchange of staff but by the establishment of psychiatric units in all the teaching hospitals and in the larger non-teaching hospitals. With good will and a common purpose on both sides none of the difficulties need be insuperable. The interim report on undergraduate education issued by the Royal College of Physicians in October, 1943, contained the suggestion that every teaching hospital should have a psychiatric department which would form a link between the general hospital and the mental hospital. This surely crystallized a very important principle that was bound to influence future developments profoundly—i.e., the closer association of the treatment of mental illness with physical illness and the mental hospital with the general hospital. A great deal of attention would inevitably have to be given to the administrative machinery and the local government problems associated with this service.

The Training of Psychiatrists

Another important task would be the development of a more scientific system of training psychiatrists. There was a growing recognition that the time had gone by when young assistant medical officers in mental hospitals could be left to train themselves, as in the past they had sometimes had to do, with such encouragement as was afforded by the extra pay given to those who secured the Diploma in Psychological Medicine. Any scientific system of training must make provision for postgraduate work. Hitherto psychiatry had suffered from being split up into too many sections. In planning the course of postgraduate training of the psychiatrists of the future there would clearly be a need to take a broader view and include the study of mental deficiency and child psychiatry as well as adult psychiatry.

A more systematized training was, however, not enough unless combined with intensive and well-planned research. Too little was known of the causes of mental disorders and abnormalities. It was the wish of the Ministry and the Board of Control that all mental hospitals should take some part in a well planned and co-ordinated scheme of research, stimulating and beneficial to all who took part in it, quite apart from the scientific and medical value of the results attained. The danger of all institutional service was the obvious tendency to a monotonous routine; and a share in research work helped to maintain scientific interest and keenness. Another measure contributing to this end would be the institution of refresher courses for doctors who felt they were beginning to get out of date and out of touch with modern methods.

Reports of Societies

ORGANIZATION OF CANCER TREATMENT

Opening a discussion on the post war organization for the treatment of cancer at a meeting of the Radiological Section of the Royal Society of Medicine on Nov. 17, Sir ERNEST ROCK CARLING reminded his audience that the National Radium Commission had been in existence for fifteen years and during that time had set up regional organizations for one method of cancer treatment—namely, radiotherapy—and these organizations were largely based on university towns. It was obvious however that for a cancer organization on one kind of treatment should not predominate, and the object of his remarks would be to examine the question whether surgical treatment could be arranged on the same regional lines. He did not intend to discuss administrative problems, but would point out the danger of people who were ignorant of medical and scientific problems having too large a say in the matter, and said he felt very strongly that the profession had got to save itself by working out its own plans based on the overriding principle of what was the best for the patient. He said it was generally agreed that radiotherapy should be concentrated in a few well-equipped and strongly staffed institutions, with perhaps some associate subcentres with the headquarters at a university town, and dealing with a population of three to four million people. In exceptional circumstances this figure would have to be reduced perhaps to one million. He then discussed whether such a regionalization would suit the surgical treatment of cancer. He pointed out that certain services, such as for thoracic surgery, plastic surgery, neurosurgery, blood transfusion and pathology, had been organized on a regional basis during the war and proved to be an unqualified success, and he had no doubt that cancer surgery could be organized on similar lines.

In discussing the organization in greater detail, he said it was useful to plan from the periphery, where the case was first suspected to be cancer, to the centre. He pointed out the importance of registration as a safeguard to prevent any patient being neglected or side tracked. He envisaged a team of consultants, based on headquarters though individual members might be practising in other parts of the region, and a panel of other medical men who would take part in the cancer organization. He also dwelt on the importance of proper records, follow up of all patients suffering from cancer, and research.

Mr G F STEBBING started his paper by pointing out how very inefficient was the present treatment of cancer in this country, and then went on to examine the causes of this inefficiency. He said that methods of examination and treatment had improved very rapidly, but the medical profession had not kept pace with them. It required a team of specialists to use the implements that have recently been devised but so far there is no proper organization for bringing this team together. He pointed out the scarcity of hospital beds and the difficulty of ensuring that any particular type of cancer is treated by experts in that line. If these difficulties were to be overcome he said it was essential to have in every region an organization that is known to every practitioner that is freely and immediately at the disposal of every patient, and that is so arranged that it ensures efficient diagnosis and prompt treatment for every patient. He mentioned that Dr Malcolm Donaldson had recently published a paper describing a scheme for the organization of the diagnosis and treatment of cancer in London and the Home Counties, and he thought that it was along such lines that it would be necessary to proceed. He then discussed in detail such a regional organization pointing out that there should be a whole time director—a clinician of wide experience and taking part in the clinical work. He thought that the headquarters should be in a general hospital where there was a highly organized radiotherapeutic department and where there were surgeons, physicians, gynaecologists, and other specialists, who must have time and opportunity to discuss the problems of the work in which they are engaged. Mr. Stebbing also dwelt upon the importance of a proper record department and follow up system.

Dr NUTTALL the other opener of the discussion, considered the various facets of a cancer service from the medical rather than the administrative point of view. He pointed out that facilities for diagnosis must be widely dispersed throughout the area if patients were to be persuaded to make full use of them. He considered that some 30% of cases presented a palpable or visible lesion and the diagnosis could be made in a clinic, the remainder requiring examination by means of special apparatus or technique and possibly hospitalization. He thought that special beds should be set aside for such investigations. He considered that the pathological investigations should be in the hands of specialists in tumour histology. So far as treatment was concerned, he pointed out that surgery was at least as important as radiotherapy, and there was much to be said for centralizing cancer surgery in the major hospitals. In discussing radiotherapy, he emphasized the importance of linking radium and x-ray treatment, and pointed out that for economic reasons alone it was necessary to centralize radiotherapy. He realized the difficulty of absolute centralization, and said that in some cases subcentres would be necessary. He pointed out that no cancer organization could be considered complete which does not provide for the welfare of the incurable cases. Finally he referred to the necessity for education of the public concerning the first symptoms of the disease. Among the other speakers was Air Cdre STANFORD CADE who urged the need for notification to a central authority. Dr MARGARET TOP pointed out the desirability of centralization in order to avoid delay in treatment. Dr BLOMFIELD stressed the importance of team work.

Prof WINDEYER said he had been pleased to hear Sir Ernest Rock Carling's exposition of how areas of population for cancer service would fit in with the areas of population for other general medical services. Particularly had he been pleased to hear the suggestion that cancer treatment centres must be based on universities, because he felt there was a possible danger that cancer treatment might be taken too much away from the rest of medicine and that future practitioners and students would not be taught sufficient about cancer if the cancer service was segregated. He said that Dr Nuttall had touched on the question of segregation of cancer patients, suggesting special cancer blocks in a general hospital. He strongly disagreed with this suggestion, and said that the segregation of patients should be according to their treatment and nursing needs and not according to their disease.

Dr MALCOLM DONALDSON said that in the excellent opening to this discussion what had been called the ABC Scheme had been mentioned. He had published this memorandum on the organization of a cancer service for London and the Home Counties, including a classification of hospitals in that area, but he wanted to make it clear that this classification was a purely personal idea on his own part and had not been approved by any public body or authority. His memorandum had been written with the idea of making people think, and he believed that if they read it it would do so. A second objective was to try to get the teaching hospitals in the area with some of the larger voluntary hospitals to get together and to work out some sort of scheme to help the local authorities. He hoped that a meeting might take place at which such a scheme could be drawn up. Again, he had put a concrete scheme forward with the idea of getting criticism. He had got certain of his friends to read it, and so far one criticism had been made—namely, that if a scheme of this sort should come about the A hospitals which gave radiotherapy would have to bid farewell to their present clientele and to the other hospitals with which they had been working for years, and take on a new set of friends. There was nothing of that kind intended. Certain A hospitals would be responsible for certain B hospitals in which surgery alone was performed, but this would not prevent them from taking other cases as well. He hoped to see the financial arrangement the same for each class of hospital in the area, so that the local authority would not be biased by one hospital's having a cheaper service than another, and practitioner and hospital would have free choice as to which hospital was consulted in the first instance. Dr LOUIS MARTINDALE did not agree with notifications of cancer, as this would frighten the early case.

Sir ERNEST ROCK CARLING and the other opening speakers then replied.

DIET AND TUBERCULOSIS

The Scottish Group of the Nutrition Society, at its meeting in Dundee under the chairmanship of Dr. W. T. MUNRO, discussed diet and tuberculosis. Dr. R. Y. KEERS said that although malnutrition was a factor in lowering resistance there was no unequivocal evidence that it was the sole, or even the most important, precipitating cause. Wartime diet, so far as the tuberculous subject was concerned, was not deficient in nutritive properties. The patients at Tor-na-Dee were drawn from a section of the community in which malnutrition was not encountered, yet this section had not been spared in the rising incidence of tuberculosis. The common factors among these patients were longer hours of work and a reduction of the time usually devoted to rest; in no instance had dietetic deficiency played an obvious part. Dr. Keers thought that the wartime diet was perfectly satisfactory for the patient under treatment. In a recent investigation to determine whether a larger consumption of fat was beneficial, he had found that patients who received extra fat showed a more rapid gain in weight than did controls during the first four months, but at the end of nine months there was little difference between the groups. This indicated that there was nothing to be gained, and even something to be lost, by attempting to force the intake of fat beyond that which the patient could ingest and assimilate completely. The dietetic treatment of tuberculosis demanded no more than a full well-balanced intake. Cod-liver oil was not essential and should be reserved for those whose digestion was sound.

Mr. J. N. RITCHIE, of the Ministry of Agriculture, describing progress in the eradication of bovine tuberculosis, said that in some districts the proportion of attested to non-attested herds was as high as 60%, while in others the figure was negligible. The next step would be to introduce the policy of area eradication—a plan that had been successful in America, where a very high standard had been attained.

Mr. C. H. CHALMERS, Chief Milk Inspector for Scotland, in a paper on pasteurization, pointed out that a large proportion of the milk supply was now exposed to heat before dispatch from the area of production. Heat treatment, which simply implied that the milk had been heated to an unspecified temperature for an indefinite time, did increase keeping properties, but did not guarantee freedom from living tubercle bacilli. The destruction of *B. tuberculosis* depended not only on the temperature to which the milk was heated but also on the time it was kept at that temperature. The limits for effective pasteurization were considered to lie between 145° F. for 30 minutes and 162° F. for 15 seconds. For various reasons the slower process was the more satisfactory. The enzyme phosphatase, which was present in raw milk, was destroyed by all combinations of temperature and time normally used for effective pasteurization. If a sample of milk had been heated enough to destroy 98% of the enzyme it might safely be concluded that the heating had completely destroyed all tubercle bacilli.

Dr. STUART LAIDLAW, in the subsequent discussion, pointed out that, although there had been a considerable increase in notification of tuberculosis, the death rate was little changed. The number of deaths from acute bronchopneumonic tuberculosis had decreased during the war. With regard to diet, while the calorie intake available to the tuberculous patient was satisfactory, there was no doubt that an additional allowance of protein would be helpful in aiding recovery.

SAFEGUARDING LONDON'S WATER

In a lecture at the Royal Institution on "London's Water Supply—Safeguarding its Purity in Peace and War" Lieut.-Col. E. J. W. MACKENZIE M.B., D.P.H., showed how, originally, it was the duty of the Corporation of London to provide the water supply for the population; how this right was later surrendered to private undertakings, and was subsequently restored to public ownership when the Metropolitan Water Board was formed in 1902. The Act by which the Board was created also imposed duties with regard to laboratory examination.

Col. Mackenzie told how London was assailed with a succession of epidemics of cholera from 1831 to 1856 and how Dr. John Snow

proved that the infective agent was carried by water. At the beginning of this century London's water was purified by filtration through sand. Sir Alexander Houston, during his years of office as first Director of Water Examination, introduced many changes and improvements, including storage as a means of purification, chlorination, and mechanical filtration. These methods ensured the production of a pure and wholesome water; but, as more stringent tests for purity received authoritative approval, further steps were being taken, chiefly with regard to chlorination, to bring the water up to the desired standard.

The gathering war clouds after Munich brought new problems for those responsible for water supply, and it was considered that the enemy might attack the major works of the Board. It was realized that in the event of bomb damage and devastation chlorination might be the principal safeguard for the purity of the supply, so that every practicable step was taken to make it both adequate and reliable. Alternative laboratories were equipped in safer areas for emergencies. Safeguards against the introduction of chemical poisons and gas warfare were taken by placing special guards at the works, making provision for special tests to be performed on the works, and maintaining a staff of analysts and sample-collectors available day and night at the laboratories. Special arrangements were set up for the repair and sterilization of water mains, quite often contaminated by sewage from a fracture of an adjacent sewer. Much work was carried out in training and arranging for over 7,000 volunteers to provide emergency water supplies in the event of extensive damage to the works. The waterworks suffered almost every conceivable form of damage from air attack, but all the necessary protective measures were in readiness, and the purity of the supply of drinking water to London had been maintained as high as ever during these anxious years of war.

ACTION OF PENICILLIN

Some account of his early work on penicillin at St. Mary's Hospital, London, and of the action of the drug was given by Sir ALEXANDER FLEMING in a Campbell Memorial Oration to the Ulster Medical Society on Nov. 2.

He said he was repeating some experiments which had been done by Bigger of Dublin when a plate became contaminated by a fungus, and he noticed that all the colonies of staphylococci close to the fungus had disappeared. The fungus was the *Penicillium notatum*. Ordinary samples of the drug as a yellowish powder were only 10% pure; pure penicillin was a white powder, and we knew it as either the sodium or the calcium salt. Strengths which destroyed sensitive bacteria—mainly the Gram-positive ones—had no effect on leucocytes. It was stable in powder form; any reactions were due to impurities. The Oxford unit was the quantity of penicillin which, when diluted 50 times, would inhibit the growth of a standard culture of staphylococcus; this had recently become the international standard. Administration was either general by intravenous, intramuscular, or subcutaneous route, or local by injection into the area or by surface application. It was rapidly excreted by the kidneys, so a constant level in the blood was best maintained by a constant drip. Poor kidney function slowed up the excretion, and so saved penicillin. At St. Mary's Hospital all the cases of staphylococcal septicaemia treated with penicillin for at least 6 hours, with one exception, recovered; the exception was complicated by endocarditis. The results of penicillin administration in venereal disease appeared miraculous, some cases of gonorrhoea being apparently cured by a single injection. In the United States Army syphilis was being treated with 2½ million units in 7 days. If these results were confirmed in the future it would be possible to impose definite regulations to control venereal disease. At the front large doses of the drug had to be given because of the long intervals between treatments; this was wasteful but unavoidable at present. The use of penicillin in plastic surgery would mean that multiple procedures could be carried out in very much less time and the bogy of sepsis almost eliminated. It was now possible with penicillin to sew up a compound comminuted fracture of the femur and get union in six weeks. Penicillin injected into an abscess cavity would remain for 24–48 hours. It could be used in the form of a cream, a powder diluted with sulphanilamide or sulphathiazole, a snuff, a paint, or in a lozenge. It must be sterile; insensitive bacilli produced penicillinase, which destroyed the penicillin. It was the first antibacterial substance to be made from a mould, and as there were thousands of different moulds it was possible that another substance with even greater powers would be found.

Correspondence

Thiouracil for Hyperthyroidism

SIR.—In his paper (Dec. 9, p. 745) Dr. Nussey ascribes to me the view that the bloated appearance and listlessness which follow overdosage with thiouracil, are *not* manifestations of mild myxoedema. If by myxoedema is to be understood hypothyroidism then Dr. Nussey has mistaken me. In my opinion these symptoms are probably due to early hypothyroidism. My hesitancy in making an outright statement that this is their nature is that I have noted in such patients that, despite their clinical appearance of hypothyroidism, the B.M.R. may be within normal limits. Possibly the misconception of my views arose from the fact that the paper embodying them (*Proc. Roy. Soc. Med.*, 1944, 37, 693) has only just appeared, and that, prior to its appearance, statements concerning my opinions on this matter had to depend on recollections of the meeting at the Royal Society of Medicine on June 13, 1944, or on reporters' accounts of that meeting.

Dr. Nussey's statement that an initial leucopenia is no contra-indication to thiouracil therapy is of considerable importance. Personally I have avoided using thiouracil on such patients because I have feared that agranulocytosis might more easily be produced in them. If, as Dr. Nussey's results indicate, my fears were groundless it is welcome news, but it would be very unfortunate if his results were to give rise to the impression that the white cell count can now be disregarded in thiouracil therapy, or that treatment can be safely continued if the neutrophils in the blood are falling. It should be stressed that Dr. Nussey's statement refers only to leucopenia before treatment, and, in view of the acknowledged danger of agranulocytosis during treatment with thiouracil, it would seem advisable to await confirmation of his findings before accepting them in ordinary clinical practice.—I am, etc.,

University College Hospital Medical School, London, W.C.1. H. P. HIMSWORTH.

Hormones and the Prostate

SIR.—The theory of treatment of an enlarged prostate by oestrogens has been based on the supposedly physiological role of female sex hormones in the hormonal make-up of the normal human male. It is not surprising that this line of treatment has not yielded satisfactory results. Perhaps, therefore, the conception that the male produces female sex hormone should be reviewed critically.

In your leader on the germinal epithelium and the prostate gland (Dec. 9, p. 759) you wrote that "the normal man secretes both androgenic and oestrogenic hormones, the former from testicles and adrenals, and the latter from some tissue or tissues hitherto unknown." The use of the word "secretes" is unfortunate, and especially so in that the above sentence forms the background of the ensuing discussion concerning the alleged relation of both male and female sex hormones to the behaviour of the prostate gland.

The testis of course secretes the male sex hormone, and the adrenal cortex also elaborates a steroid derivative which contains the "androgen nucleus" but which is not androgenic in its physiological role. These hormones, slightly changed, are excreted in the urine and both are classed rather unfortunately as androgens. It is true that adrenal cortical tumours induce premature virilism, but the stimulation of certain tissues in that condition is probably due to production of (a) excess adrenal cortical hormone or a degradation product thereof, or (b) a metabolic variant with androgenic properties. As for the alleged secretion of oestrogens by the male, the evidence for this statement is based on the presence in male urine of steroids containing the "oestrogen nucleus." However, in view of the widespread distribution in Nature of substances containing the oestrogen nucleus it is likely that the greater proportion of oestrogens in male urine is exogenous and comes from the diet. If, then, a human male on an oestrogen-free diet continues to excrete oestrogenic steroids, the substance is either (a) a hormone or a hormonal metabolite, or (b) a tissue metabolite. The fact that an oestrogen can be isolated from testicular tissue is not

decisive as regards which alternative is correct, but the finding of relatively insignificant amounts of oestrogen in the urine of human males on an "oestrogen-free" diet might favour the thesis of a tissue (testicular) metabolite.

In the absence of access to his original paper it is out of place to criticize *seriatim* the experimental attempts of Tornblom, as set forth in your leader, to prove that the germinal epithelium elaborates an oestrogenic hormone which influences the prostate. There are alternative conclusions to those adopted by him in his reasoning sequence: these may or may not have been explored. It is not out of place, however, to point out that it is inherently unlikely that a tissue, such as the germinal epithelium of the testis, whose metabolic processes of cell division and differentiation are concerned essentially with the production of an external ejaculate, is engaged also in elaborating a hormone for distribution to other tissues in the body.—I am, etc.,

CHARLES REID.

Surgical Emphysema

SIR.—The report of surgical emphysema after intubation by Mr. Barrett and Dr. Thomas (Nov. 25, p. 692) reminds me of a similar occurrence, the path of the air through the trachea being, however, much more easy to understand.

In 1940 I saw a child of 2½ years who had had a persistent cough since an attack of whooping-cough 6 months before. X-ray examination suggested atelectasis of the left lower lobe. Bronchoscopy showed a moderate amount of pus in the left lower lobe bronchus. Lipiodol bronchography was done under general anaesthesia; a needle of the curved type, size 17 s.w.g., was inserted just below the cricoid for the purpose. After withdrawing the needle and during recovery there was considerable coughing, and about a quarter of an hour later the ward sister reported surgical emphysema in the neck. A quarter of an hour later the emphysema had spread to the shoulders and face, and the child was brought back to the theatre, as the persistent spread was beginning to worry us. There was no cyanosis. It was thought that the persistent cough was forcing air through the small hole in the trachea, and that the only way to stop the spread of air in the tissues was to cut down on the hole and lead any further leakage out of the neck. This was done when the abdominal wall was already crackling with air, but the small hole in the trachea could not be found; a tracheotomy was therefore performed under local anaesthesia. The child, however, gradually sank, without showing cyanosis; the superficial veins were so hidden that any overdistension could not be seen. It died about an hour afterwards.

At necropsy small air bubbles were found throughout the tissue planes, including the mediastinum and perirenal fat. The inferior and superior venae cavae were not distended, and the right heart contained only a small quantity of blood. The mechanism of death was not clear, as blockage of the great veins in the chest was not present, and no air was present inside the skull or in the blood stream.

The mucosa of the trachea is tightly bound down to the submucous and cartilaginous layers and cannot be stripped up; it is not clear how in Mr. Barrett's two cases the air got out of the air passages into the tissue planes. The mechanism is difficult to understand, especially as other cases have been reported, and I have had one myself, of idiopathic surgical emphysema of the head and neck appearing shortly after childbirth, or even after a single cough, mostly with spontaneous recovery, and in which no lesion was found on extensive investigation. Is it possible that the rupture occurred lower down in the bronchial tree and was unrelated to the tracheal trauma?—I am, etc.,

Hillingdon County Hospital, Middlesex.

L. FATTI.

Episiotomy

SIR.—May I be allowed to add one or two small points to what you have already published concerning episiotomy and perineal repair? I am most concerned with anaesthesia and technique of repair.

Anaesthesia.—The method I use is a modification of the perineal nerve block technique described by C. Philip Brentnall (*J. Obstet. Gynaec. Brit. Emp.*, 50, 226). I quote the relevant section:

"A point on the perineum 1½ to 1 in. antero-lateral to the anus is chosen. Here, with a very fine needle (26 s.w.g.), an intradermal

vesicle is raised; the needle is then pushed forwards and the subcutaneous tissue of the anterior margin of the perineum is injected. A larger needle is then used (21 by 2½ in.), and is slowly thrust through the vesicle to a depth of 2 in., in a direction at right angles to the skin surface, the anaesthetic being injected as the needle advances and retires. The needle is almost withdrawn, and then directed forwards, but quite superficially, underneath the line of reflection of the folds of the labium minus and as far as the anterior extremity of the proposed perineal incision. The procedure is repeated on the other side of the perineum, and about 10 c.cm. of anaesthetic is injected into each. The object of the deep injection is to relax the superficial and deep muscles of the pelvic floor and to anaesthetize the deep perineal branch of the pudendal nerve."

This technique was described for posterior colporrhaphy and, using the proprietary "novutox," I modify it as follows. The same point is chosen, but if the patient is in labour a finger is passed into the vagina and is used as a guide to prevent the long needle from entering the distended canal. The injection is made in an outward direction instead of at right angles to the skin. Almost immediately after injection episiotomy can be painlessly carried out. I too use the J-shaped central incision described by Dr. Flew. The method is seen, at its best in breech labour, when it is carried out as the anus begins to show with contractions while the anterior buttock is still receding in the intervals. Incidentally it is often adequate without supplement for low forceps delivery of the foetus or aftercoming head. If "novutox" is used the analgesia persists for at least 2 to 3 hours, allowing painless repair. After delivery, for perineal repair, the technique is similar except that the injection need not be so oblique. I believe it to be the method of choice for complete rupture, though the simpler local infiltration is adequate for trifling tears.

Repair—Methods involving buried catgut have not been as successful in my hands as the following. A 1½-in. diameter half-circle cutting needle is entered about 1/2 in. deep to the torn fourchette, and the vaginal mucosa is underrun with silkworm gut, keeping about 1/8 to 1/4 in. from it. The needle emerges at the opposite point to which it enters, enters again near the first point of entry, and emerges through the skin about 1 1/4 in. from the wound edge. It is then threaded on to the other end of the silkworm gut, which is brought out through the skin of the opposite side. A figure-of-eight suture is thus placed, having the deep loop larger than the superficial. As many such sutures are placed as are required, about 1/2 in. apart, and the ends grasped with pressure forceps or left loose. The upper end of the vaginal tear is then secured with No. 1 plain catgut and the edges coapted by a continuous suture, taking about 1 1/4 in. each time right out on to the fourchette. After this the figure-of-eight sutures are tied. Traction outwards on the ends closes the deep part of the wound and tying closes the skin. The ends of these sutures are left long and tied together so as to avoid sharp ends in the perineum. They may be fastened to the thigh with strapping if desired. Silk or stout cotton is as effective as silkworm gut and possibly more comfortable. It is emphasized that the continuous suture is not of the nature of a dressing than of a repair, its main function being to keep blood and lochia out of the divided perineal body. If plain catgut is used, there is usually no sign of it by the twelfth day. Since the vaginal mucosa heals very rapidly chronic gut persists after healing, acts as a foreign body, and cuts out. Apart from the measures directed to the anal mucosa and the divided sphincter, the same technique is used for complete tears.

May I in conclusion express my thanks to Mr Percy Malpas for drawing attention to the possibility of early secondary repair of complete tears. I have tried it successfully and commend it to others faced with this distressing condition.—
am etc.

WALTER CALVERT, D.R.C.O.G.

Bed-wetting and Spina Bifida

SIR—The article on investigation and treatment of enuresis in the Army (Oct. 7, p. 462) brings to light an unnecessary waste of x-ray film, particularly at this time. In 1927 it was proved beyond a shadow of doubt that bed-wetting and spina bifida occulta had normally no relation whatsoever (*J. R. M.C.* 1927, 48, 38). The figures given there show that in 110 bed-wetters and 100 normal soldiers examined

spina bifida occulta was found more commonly in soldiers who did not wet their beds (bed-wetters 16%, non-bed-wetters 21%).

—I am, etc.,

Cairo.

W. K. MORRISON.

Industrial Dermatitis

SIR,—I have followed with interest the recent correspondence on this subject, and I must say that I think Dr. G. P. B. Whitwell (Nov. 4, p. 607) has hit the nail on the head when he says it seems strange to him "that some dermatologists, instead of collecting rare and relatively unimportant skin diseases for exhibition at learned society meetings, have not long before taken more interest in workaday medicine and gone into the factories to learn something useful." Might I here point out that at the meeting held at the Royal Society of Medicine, Dermatological Section, on industrial dermatitis on May 21, 1942 (*Proc. roy. Soc. Med.*, 24, 703), when I spoke at the opening discussion, my words were: "I have learnt a tremendous lot from visiting factories," and then proceeded to give a few concrete examples.

Having practised dermatology for over 18 years now in a large, modern, and progressive industrial Midland town, which draws on a large rural area as well, combined probably with the fact that all my life I have taken an intense interest in all things mechanical or electrical, I can say that there are few factories or manufacturing processes which at some time or another I have not visited, both in my capacity as a dermatologist and as an interested onlooker. I have seldom come away without learning something useful, either in dermatology or in ordinary domestic life. The only way to get aetiological acquaintance with industrial dermatitis is to know the hazards and potential skin irritants of industry and also their probable or possible effects on the skin of the workers.

The extremely varied nature of industrial processes makes this a most interesting and constantly changing mental kaleidoscope. Among simple things of wearing apparel one finds dermatitis in felt-hat workers caused by dipping the hat, moistened with sulphuric acid, into a solution of shellac and borax in order to proof it, contact dermatitis from chrome solutions used in tanning leather, and contact dermatitis from thermolabile plastics (which change their composition during treatment with heat and pressure) in the making of buttons. Among the engineering, aeroplane, and allied industries one comes across dermatitis due to contact with suds, mineral and lubricating oils, various cutting oils and compounds used as coolants, degreasers used to clean metal parts, synthetic plastic glues, various dopes, etc. Even the manufacture of medicinal preparations such as procaine, morphine salts, etc., may cause skin trouble, and the most recent I have seen in this category is mepacrine (alkyl amino-acridine). In the making of explosives trinitrotoluene, fulminate of mercury, etc., are well-known examples. In fact, with the ever-widening scope and range of industry, particularly in wartime, one finds it impossible to keep pace with its dermatological ramifications. Among the rural industrial dermatitis cases one comes across such cutaneous complaints as cattle ringworm from infected calves, orf from sheep, and dermatitis from artificial fertilizers, fungicides, etc.

The morphology of industrial dermatitis is in most cases just that of an eczema or dermatitis in its various stages, and usually, with the exception of certain things such as oil folliculitis, chlor-acne (due to chlorinated naphthalenes), and chrome ulceration, it is just an eczematous type of rash. The diagnosis of its occupational origin is usually made from: (a) the presence of such a rash; (b) the exclusion of this rash being of constitutional or non-occupational origin; (c) rash usually appearing on areas exposed to contact with potential irritant substances; (d) history of using or coming into contact with such an irritant. Patch-testing is of little or no practical value in my opinion. I have seen cases of occupational dermatitis resembling in appearance many non-industrial or constitutional skin conditions, and vice versa. Whatever may be said to the contrary, as regards its differential diagnosis the cause of a rash on a worker, unless otherwise easily explained, is often a most perplexing and difficult problem, even among dermatologists.

With regard to the correspondence of Drs. Bourne, Mummery and Whitwell on the value of various preventive measures against industrial dermatitis, I quite agree with Dr. Whitwell.

that barrier creams, suitable detergents, general cleanliness, supervision, and protective measures are applicable, but, except in certain processes, barrier creams or washing only will not prevent trouble. In many cases the use of a barrier cream is not feasible, because one cannot get anything suitable to stand up to the hard wear and tear and friction entailed in the work done by, for instance, a mechanic working on a lathe with hands and forearms exposed for long periods to hot lubricating and cutting oils. Here satisfactory detergents of the higher sulphonated fatty alcohol type, or sodium alkyl sulphates in liquid form, are often most useful in removing the potential irritant as quickly and efficiently as possible. On the other hand, barrier creams are useful, as Dr. Bourne points out, in handling metal for developing, and I found his method satisfactory for operatives in a biscuit factory who were having trouble from contact with the sugar filling handled by them. Prevention of industrial dermatitis can be dealt with by the following combination of methods: (1) knowing the exact conditions and hazards of the job; (2) general cleanliness, supervision, and the use of suitable protective measures while at work, and the removal of any potential skin irritant with a suitable cleansing or detergent agent as soon as possible; (3) exclusion of employees suffering from, or predisposed to, dermatitis.

Under wartime conditions it is not possible to observe all the above criteria, as new and complicated processes are constantly coming out involving unknown risks and hazards which must be faced. The facilities for supervision and cleanliness may vary in different shops and factories, while shortage of personnel and material, and the introduction of "green" labour, all complicate matters. There has therefore been an increase in the number of cases of industrial dermatitis in this country during the war. Whether the increase has been absolute or is only relative, in view of the bigger number of workers engaged on war industries, it is not yet possible to say. However, we are not alone in this matter, as evidently even in America, where there has been considerably more literature and notice taken of industrial skin troubles, they are still much concerned about its incidence. Prevention is the only sane and sensible angle to tackle the problem from, and the best place to begin is at the source of the trouble—that is, in the workshop or factory.

Finally, please, Dr. Whitwell, do not think it strange that, as a dermatologist very keen on the industrial side, I like on occasion to display some rare epidermological entity, which I am proud to have discovered, even though it is not of occupational origin, before other colleagues at learned society meetings. After all, much of industrial dermatology is, like all branches of medicine, somewhat routine and dull; so that, having found a "Kohinoor," one is apt to become elated and display the treasure. Already I have a collection of cutaneous curiosities which, as soon as conditions permit, I hope to put on show in this manner.—I am, etc.,

Examining the Neurotic

SIR.—I have only recently had the opportunity of reading Dr. McIntyre's letter (Jan. 22, p. 131) in which he criticizes his own misinterpretations of several items in a communication submitted by Capt. Charlton and myself (Dec. 25, 1943, p. 830). He accuses us of referring to the report of Stephenson and Cameron on anxiety states in the Navy as "the reiteration of symptoms alone." We trust that Dr. McIntyre is the only one who thinks so. If he refers to our communication he will no doubt appreciate where he has gone wrong. We certainly did not so describe what we consider to be an excellent piece of work. He has quoted us inaccurately and then proceeded to level a battery of questions which arise solely out of his own misconceptions.

In connexion with Sir Henry Tidy's observations (Oct. 16, 1943), that "prolonged investigation and minute inquiries tend to produce or increase a psychoneurotic factor," we suggested in our letter that "this was particularly true of dull, highly suggestible patients who are prone to exhibit neurotic dyspepsia." We did not assert that this type of patient only exhibits neurotic dyspepsia.

In another paragraph of our letter we remark: "It is important to correlate personality types with the relevant anxiety reaction." Dr. McIntyre accordingly accuses us of regarding neurotic dyspepsia as the anxiety reaction exhibited by dull, highly suggestible patients, and presents that as a "composite assumption" of our production. He then questions us on this assumption, and asks if we have satisfied ourselves on a number of difficult points, to wit: (a) that dull patients are uncommonly suggestible; (b) that dull patients are uncommonly prone to neurotic dyspepsia; and (c) that it is the more suggestible of the dull who are so prone.

With regard to (a) and (b), I have never asserted that dull patients are either uncommonly suggestible or uncommonly prone to neurotic dyspepsia. My reference was to dull, highly suggestible patients. With regard to (c), it is obvious that the more highly suggestible a dullard is the more prone he will be to neurotic dyspepsia or for that matter psychoneurotic illness generally. Suggestibility indicates instability, which is the essential criterion in establishing the presence of psychoneurotic illness. Neurotic dyspepsia is no more prevalent among dullards than intellectuals, but dull, highly suggestible dullards are very prone to acquire neurotic dyspepsia if hospitalized, investigated, and surrounded by a host of dyspeptic cases.

Nothing that I have said warrants the assumption that dull, highly suggestible patients should be deprived of gastric investigation if the symptomatology and clinical picture suggest a *prima facie* organic disorder. The gastric investigation which is recommended in all cases of neurotic dyspepsia by Stephenson and Cameron (Nov. 13, p. 603) prior to the psychiatrist being called in is, in my opinion, just as liable to provoke the condition in some as identify it in others. In Service patients it is particularly important to decide rapidly on the scope of investigation and treatment. No hard-and-fast rules can, however, be laid down. Whether the case is to be regarded as a psychiatric one or a medical one will depend on the history, clinical condition, personality, attitude, and intelligence of the patient. Once the diagnosis of neurotic dyspepsia has been suggested, however, the treatment or general approach to the problem surely calls for the attention of a psychiatrist and not a gastric investigation.

Dr. McIntyre in a final endeavour to invalidate our communication asks why dull patients should permanently imitate symptoms if they have the general attribute of high suggestibility. The explanation is that certain suggestions are more potent than others, and the desire of unstable dullards to escape from their maladaptation in the Army is of more potent suggestive value than is the suggestion that they are not suffering from dyspepsia—I am, etc.,

ELLIS STUNGO,
Major, R.A.M.C.

Diagnosis of Psychotic Symptoms in Atebrin Intoxication

SIR.—I should like to draw attention to a combination of conditions which may cause, and, in fact, in my experience has caused, confusion. This is the intoxication from atebirin combined with the pseudo-positive Wassermann reaction due to the presence of malaria parasites in the blood. Atebrin (mepacrine) intoxication, which occurs when excessive doses are used—two to three times normal—shows itself mentally by a florid hypomanic state, sometimes with vague paranoid delusions, often of grandeur. The visual hallucinations so common in toxic-confusional states are absent. The appearance of such a psychosis naturally leads to a Wassermann test being performed. This, as Manson-Bahr points out (Manson's Tropical Medicine, p. 100), is frequently positive in the presence of malaria parasites in the blood (the C.S.F., I believe, is usually normal). The discovery of psychotic symptoms with a positive Wassermann reaction may lead to the erroneous diagnosis of general paralysis. I have recently seen such a case from North Africa in which this was diagnosed. The man's wife was informed of this serious psychosis and told that he was syphilitic, and possibly she and their children were infected also. Such a diagnosis nearly wrecked this gentleman's career and might have ruined their happy marriage.—I am, etc.,

London, W. 1.

CLIFFORD ALLEN.

Toxicity of Amino-acridine Compounds for Leucocytes

SIR,—In your issue of Dec. 9 this question is raised in two articles: Barber and Hazlewood (p. 754) state "these compounds are toxic to leucocytes and tissue cells," while the reviewer of Hobart and Melton's book (p. 757), by way of correcting the authors, says of acriflavine, "antiseptic concentrations kill polymorphonuclear leucocytes." Recently I summed up the evidence (this *Journal*, 1943, 1, 341). Five contributors on the problem (Albert *et al.*; Browning *et al.*; Gay and Morrison; Rubbo *et al.*; Welch *et al.*) found by *in vitro* experiments that the toxicity was low relatively to the antiseptic or bacteriostatic action; two (Abraham *et al.*; Fleming) concluded the opposite. Tissue-culture experiments led to a similar contradiction; here again those who found high tissue toxicity were in the minority numerically. These divergencies suggest that the results are decided largely by the methods of the workers. Fortunately, the evidence for the value of these and other surface antiseptics has a wider basis than such *in vitro* experiments. Did not certain experimenters, now apparently converted, demonstrate to their own satisfaction from glass models that effective local chemotherapy of infected wounds was an impossibility?—I am, etc.,

Bacteriology Department,
The University, Glasgow

C. H. BROWNING.

Artificial Respiration

SIR,—Dr F. W. Roberts's criticisms (Dec. 9, p. 769) of my letter (Nov. 11, p. 643) calls for an immediate reply. I do not wish to go into too lengthy a debate as to which of the two methods we respectively described is the better one to use. I dare say we both could produce a host of evidence that the one is as effective as, or better than, the other, but I think it will be generally agreed that an oxygen apparatus is not always available for the method of artificial respiration as described by Dr Roberts, whereas the injection method of "chemical resuscitation" as described by me can always be done, irrespective of the patient being in an operation theatre or on the roadside.

I made no mention of an unobstructed airway; for surely that would be the first consideration given to an asphyxiated patient before any further treatment was rendered!

The very fact that anoxia can be relieved by chemical resuscitation is proof enough that an oxygen apparatus is quite unnecessary, but what is absolutely necessary is to start the respiratory mechanism functioning as soon as this can be done, as all the oxygen possible would not start this mechanism functioning if the vital centres in the brain were not stimulated to bring it about. It is brought about by reducing the increased venous pressure and increasing the arterial pressure, which nikethamide does. "The proof of the pudding is in the eating," and one's experiences in such conditions are always worth more than any argument—I am, etc.,

London S.W.16

A. H. BARTLEY.

Diphtheria with Severe Tetanus

SIR—Dr J. C. Hawksley (Dec. 2, p. 736) does not, I think, give any convincing evidence that his patient was suffering from diphtheria. A positive throat swab unsupported by clinical signs is not enough on which to found a diagnosis. Even if the organisms were virulent their presence implies no more than that the patient was a carrier.

It should be borne in mind that tetanus may begin with sore throat. In a patient who came under my care some years ago, a woman of 37 years this symptom together with difficulty in opening her mouth led to her being sent to a general hospital where she died of quinsy. Laryngeal spasm and dyspnoea ensued, and she was transferred next day to this hospital with the diagnosis of laryngeal diphtheria. On admission the symptoms of tetanus were evident and death occurred within 48 hours. The patient had had an abortion a week before the onset—I am, etc.,

St. Barth's Hospital, Glasgow

WILLIAM NAPIER.

Mass Radiography

SIR—Any pronouncement on the subject of radiology of a chest from such an authority as Dr. Peter Kerley always attracts close attention.

I hesitate to trespass on the province of the radiologist, but I imagine that every experienced tuberculosis physician will

endorse whole-heartedly Dr. Kerley's statement of Nov. 2 (p. 706) that "the detection of early cases [of pulmonary tuberculosis] is only possible with the most meticulous technique," but this fact does not appear to be generally appreciated. It cannot be denied that the technically imperfect skiagram is not uncommonly a source of erroneous diagnosis by those inexperienced in chest work and ignorant of the pitfalls of radiography—often greatly to the patient's detriment. Chest physicians who have handled a large number of skiagrams from many sources cannot but be impressed by the wide variation in technique. It should be realized by those administrators and clinicians who are not fully informed that chest radiography is a highly specialized subject, and that a low-grade x-ray plant cannot be expected, other things being equal, to produce as good results as the more powerful installation. These, surely, are self-evident facts.

With the introduction of mass radiography the need for the technically perfect skiagram becomes still more urgent, especially in following up and assessing "the latent and subclinical cases" brought to light to which Dr. Kerley refers. Many of these cases, we know from personal observation, remain stationary over a period of years while the individual continues to pursue his usual mode of life. The superficial observer might be tempted to make a diagnosis of active disease at one examination alone, and send such a case for prolonged treatment with consequent needless expenditure of time and money, not to mention disruption of business and domestic life. The more cautious and experienced physician, however, will in the first place assess the case as accurately as is humanly possible, watching intently for the earliest indications of any deterioration. Serial skiagrams of the highest quality are essential for this purpose, and for their production a high-grade x-ray plant with a competent radiographer widely experienced in chest work is a *sine qua non*. Inferior equipment has no place in the campaign against tuberculosis. In the planning of our future chest clinics these facts must be given prime consideration.—I am, etc.,

Chester

DAVID W. TOLGH.

SIR—Permit me to comment on some of the salient points raised by Dr. Peter Kerley (Nov. 25, p. 706). By asking manufacturers to "co-operate," the intention should have been obvious that it was the blue-prints that should have been available to all, so that production could be speeded. When Rolls-Royce engines were in short supply they were soon being produced not only in England but also in the Dominion and the U.S.A.

Anyone proposing to operate outside the Ministry's scheme is politely asked to refrain. To interpret this other than control is difficult to understand.

Over diagnosis Dr. Kerley appears to be in conflict with some of his earlier utterances. On Nov. 19, 1943, at the R.S.M., he stated that it was proposed to train medical officers "to spot disease on miniature films like young boys train themselves to spot different types of aircraft." He now accuses me of showing "no appreciation of the difficulties of diagnosis." I would refer him to the *Journal* of Sept. 14, 1940, when I stated: "It is agreed that chest radiographs are often difficult to interpret, and hence the necessity for real experts in this branch of work," and subsequently I have stressed this point on a number of occasions.

As to my "astonishing ignorance of technical advances," only recently, while a guest of a firm whose employees were being examined, I watched one of these units in operation. Except that it took three days to cover the first 1,000 cases there was nothing fresh in technique, and there is really nothing to prevent training technicians for this kind of work reasonably quickly.

Dr. Kerley now agrees that 3,000 cases a day could be examined with adequate organization, and I hope no "slapdash." He further confesses the existing organization cannot muster the necessary volunteers for such a rate of flow, and suggests it could only be done by compulsory methods using "force." The suggestion does not warrant further consideration for operation in this country. All that is required is efficient and attractive propaganda, complete with talking films (not the present one), lecturers to explain to the public what it is all about, and these to go in advance of the unit. Also an

efficient clerical staff to arrange appointments and to see these are kept. A few mass radiographic units, incorporating stereoscopic miniature films from America, would add to, and perhaps enhance, the working of our limited home supply. Organization on efficient lines such as these, I am confident, would not offend the professional acumen of the Ministry—I am, etc.,

London W 1

NORMAN P HENDERSON

"Skiagram" and "Bismuth Meal"

SIR.—With reference to this matter, while I cannot claim to have spent my entire youth in the study of dead languages, but rather in the study of mathematics, physics, and chemistry, with several modern languages as subsidiary subjects, I can claim several times to have read Roentgen's original papers in the *Wurtemberg Bericht der phys. Med. Gesellschaft*. Roentgen's discovery was by no means a 'stumble,' but a result of systematic research, and his two publications are masterpieces of such research and will always remain so. While I have fought his countrymen at close quarters, I am not prepared to see Roentgen and his work belittled owing to wartime patriotism. Like Faraday, Kelvin, Shakespeare, and many others, Roentgen's memory has been honoured not only in his own country but in many others, including the statue in Leningrad erected to him.

Probably the earliest radiological journal in the world was *The Archives of Clinical Skiagraphy*, published by the B M A in 1896, which the next year became *The Archives of the Röntgen Ray*, and the term "skiagraphy" rapidly fell into disuse. While High Court judges with a classical education frequently use the term 'the x-ray shows, etc.', generally the photo-sensitive film upon which a shadow is cast by x radiation is now more commonly referred to as a "radiograph." This is usually produced by a radiologist or a "radiographer," the former by common custom being a qualified medical man and the latter a layman but there is no legal definition, and any layman can call himself a radiologist. If Mr McAdam Eccles requires an internationally accepted word, then he must abandon the word "skiagram," long since disused not only in this country but by the other great English-speaking nation. While there is the *American Journal of Roentgenology* (the use of 'oe' is, of course, due to there being no umlaut in English), and in the letterpress 'roentgenogram' is more generally employed, the advertisements use "radiograph," which is more commonly used in *Radiology*, the other U.S.A. journal. "Radiograph" corresponds to the titles of most of the Latin origin journals, which (for brevity) use "radiologie," "radiologia," "radiologica." It is unlikely the whole world would be willing to change titles to "skiagraphie," etc.

I would like to take the opportunity to mention a more serious retention of an out-of-date radiological term—i.e., 'bismuth meal.' For multiple reasons, one being known cases of poisoning, bismuth salts have not been used for nearly 30 years, but 'bismuth meal' is still frequently used for the present-day "barium meal." A few years ago a lady was sent to me with a consultant's letter requesting a bismuth meal. As I mentioned a barium meal during the examination the patient queried the nature of the examination, and again the next day at the request of her husband, an analytical chemist. Due explanation was given, but later, while the amount was in no way queried, my fee was queried on the grounds. (1) I had not done a bismuth meal but used "a cheap substitute"—i.e., barium sulphate, (2) the consultant had requested the examination in order to show a gastric ulcer, which I had not done (the stomach being negative), but shown gall-stones, which had not been requested. I replied to the patient's husband that the particular consultant was entirely behind the times in requesting a "bismuth meal," and that I was not prepared to confirm an incorrect diagnosis when his wife's trouble was due to gall-stones, found incidentally at examination.

Mr. McAdam Eccles gives in his list "x-ray plate." X-ray plates, except for some spectrographic investigations where emulsion shrinkage is of importance, are practically obsolete. If, therefore, I am asked to produce "x-ray plates" and produce "x-ray films," what is my legal position? My defence would be that after I have demonstrated a pyloric ulcer it is not my affair to determine whether a gastro-enterostomy or a partial gastrectomy is performed, as I have not the surgeon's

experience. Conversely it is not the surgeon's matter to determine whether I use a bismuth or a barium salt, or x-ray plates or films, their number, positions, periods, and sizes, etc.—I am, etc.,

London, E 7

BERNARD LEGGETT.

Relation of Neurology to Psychiatry

SIR.—The increasing obscurity of the relation of neurology to psychiatry and psychopathology seems to render desirable a dispassionate review, not only to make clear essential differences but also to define that field which may properly be regarded as common to them both. Unnecessary barriers should be removed to ensure continuity of knowledge, but important also is the maintenance of a proper perspective as to the scope and emphasis of disparate though related subjects, especially when each is already vast. This question of inter-relationship has come increasingly to the fore from a variety of causes, among which may be mentioned the recent notable advances in psychiatry in treatment by physiotherapeutic methods.

Neurology, while distinguished for its diagnostic precision and accuracy of localization, where treatment is concerned remains at a disadvantage, being beset by the impossibility of repair where neurons within the central nervous system have been seriously damaged or destroyed. In treatment, therefore, save exceptionally, the neurologist is limited largely to measures of prophylaxis against further incursions, together with the fostering of compensatory developments in such tissues as remain intact. It is from observations in the compensatory or reactive field that such great names as those of Hughlings Jackson, Ferrier, and Horsley, or, more recently, that of Goldstein are linked with findings of psychiatric import. This, then is our common field—a field which for neurologists should be limited strictly to dysfunction of mind organically determined—i.e., by physical causes operating upon central neurons and which, while not primarily psychical, are such as are known to produce with constancy concomitant though incidental and secondary psychical effects. It is only when one approaches the study of conditioned reflexes that neurology merges into the sphere of the psychical, and this field belongs rather to neurophysiology than to clinical neurology proper.

As to psychiatry, its field is infinitely wider and scarcely to be delimited, encompassing as it does the reaction of the total organism to life situations of every kind. These must be viewed in their successive stages of development, which not merely date from the time of individual conception but include also mankind's archaic inheritance and remote ancestry. In such a field, man's total somatic constitution, to say nothing of its specialized parts such as the organic nervous system, represents but one aspect. Regarded from the evolutionary standpoint and the relation of mind to body, the development of a nervous system is a refinement only recently acquired and in no wise indispensable. The unicellular organisms such as the amoeba manifest the essential threefold primary aspects of mind—namely, cognition, conation, and affect even as does man—despite the total absence of a nervous system, it is simply a question of degree.

Where psychiatry and psychopathology are concerned, the emphasis is no longer upon the organic but upon sequences of subjective experience in their varying degrees of intensity and quality of appreciation. The bias which prefers an organic aetiology in the psychiatric field is attributable to the influence of a medical curriculum still strongly Victorian in its materialistic flavour. Hence psychogenesis, even when based upon constitutional predisposition, is still popularly regarded as inadequate in causation of mental disorder without the presupposing of additional endogenous or exogenous organic pathogenic factors. This remains the case despite the frequent total absence of demonstrable organic lesions such as constantly are sought but rarely found concomitant with gross examples of mentally disordered states, whether investigated clinically, biochemically, by necropsy, or histologically. The organicist diehard then usually resorts to the questionable hypothesis of colloidal or molecular changes of an order such as only future technical advances could hope to demonstrate, and so he adheres to his hypothesis as if otherwise aetiologicaly destitute. As a preliminary approach to every psychiatric case, I would

not for a moment attempt to minimize the importance of a thorough neurological examination, but would stress that such is but a part of the somatic total field. While every somatic disturbance has its psychical repercussions, slight though these may be, the converse is not necessarily true. The sufferer in mind altogether frequently appears organically sound, though morphological analysis often reveals an inborn imbalance and a disproportionate degree of representation of the basic elements such as characterize every somatic constitution—namely, of endomorphy, mesomorphy, and ectomorphy. A constitutional analysis, combined with the even more exacting psycho-analytical approach, can provide an adequate basis of understanding of the greater proportion of psychopathic problems without the need to infer the presence of non-demonstrable organic disease, nervous or otherwise. It seems safe to prophesy that the medicine of the future will in its entirety be psycho-somatically oriented, and this not excluding surgery, since psychical aspects permeate every known field.—I am, etc.,

Warrington Park Hospital.

WM. H. SHEPLEY, M.D.

Service Medicine

SIR,—The letter of your correspondent who signs himself "Under Thirty" is so very succinct and to the point that it ought to have as much publicity as possible among both the public and the profession. His remarks on the subject of forms and the filling-in of forms, with the resultant subduing of the professional instinct and gradual development of the State servant, are well known; but his four demands, should any State service come to being, cannot possibly be known well enough. So symbolic are they of all that is finest and essential in our profession that I would like them to form the basis of our policy, and I do not apologize for repeating them: (1) Freedom to treat any patient in the manner I think best, with the full resources of medicine at my command, without the introduction between of any third party whatsoever. (2) Freedom to criticize the scheme in any way I like. (3) Freedom to practise where I wish and to choose any branch of study I wish. (4) That neither my conduct nor my treatment in the practice of medicine may be officially censored or criticized except by a properly elected council of my peers.—I am, etc.,

Plymouth

S. M. DAVIDSON.

SIR,—I cannot entirely agree with Mr. R. Ogier Ward's views on Service medicine (Nov. 25). I suggest that either he spent the greater part of his period of service with units in which morale and efficiency were exceptionally high and where the majority of the men were of high medical category, or that his views are the result of wishful thinking. It is indeed satisfying to think that the majority of our patients truly need our advice and guidance but I venture to suggest that if, after making a clinical diagnosis, Mr. Ward had obtained independent reports on the character and efficiency of his soldier patients from company and platoon officers and N.C.O.s, his assessment of the degree of disability would have required considerable modification in the majority of cases.

After variable periods of time Service doctors gradually reach the conclusion that many of their patients are coming to see them in order to "try and get away with something." The average medical man is usually very reluctant to admit that such a state of affairs can exist—it is foreign to his idea of the doctor-patient relationship—but when he does realize what is going on the routine sick parade degenerates into a daily battle of wits between doctor and patient, and, as "Under Thirty" puts it, "a man has to prove he is ill before you start to think of him." This attitude is deplorable but eventually inevitable and the genuine cases are liable to suffer as a result of it. Without independent opinions from unit officers an accurate assessment of disability is often impossible. The degree of exaggeration varies from unit to unit and with changes in the war situation. I agree that true malingering is a rarity, but failure to recognize exaggerators as such will result in a very unfair distribution of man-power.

It seems that Mr. Ogier Ward does not admit that some of his soldier patients tried "to get away with something," and his advocates of Service medicine are probably quite pleasant in consequence.—I am, etc.,

"TWENTY-NINE."
Captain, R.A.M.C.

Local Government

SIR,—As you say, it is a matter for profound regret that more interest is not taken in local government. It is important from a general point of view, and especially concerns us as a profession at the present time. Why it falls so lamentably short can be discussed from the point of view of personnel—officials and councillors—and machinery.

Locally conditions vary, and there are exceptions to all rules, but I have been astonished at the second- and third-rate type of official that is too often found. In so far as he is a relic of unhappy bygone days it is understandable, but there is still too great a tendency, especially among smaller authorities, to look with an indulgent eye on the second-rate but amenable type of official. Sycophancy still pays better than technical efficiency. This latter quality, with a broad, statesmanlike outlook, is much to be desired in present-day circumstances.

As regards councillors, there is also here too great a tendency to elect the vocal exhibitionist type to the exclusion of the other type—the salt of the earth—who, while yielding nothing in his desire to serve his fellow men, prefers to work in the background. The latter dislikes intensely the obviously distasteful aspects of political life. Up to the present he has had ample opportunities for performing his social duties in a congenial atmosphere, but the all-embracing tentacles of the bureaucratic and political octopus threaten us. His valuable, indeed irreplaceable, help will go by default. (The municipal and voluntary hospitals form a good example of the different atmosphere created by the political and non-political set-up. In the one there is apt to be a constant "looking over the shoulder"; in the other this does not exist.)

As regards the machinery, in these days of quick communications the obvious line appears to be bigger councils (100,000 population should not be too big a figure) grouped in regions much bigger than the county. This region could have a liaison officer attached directly to Whitehall. This should much simplify and accelerate procedure. Though it would not entirely obviate the danger, the scope for parochial-mindedness and for the appointment of the inferior type of official would be much diminished.

This still leaves the most difficult of all the problems: the utilization of the non-political but public-spirited members of the public already referred to. Co-option, of course, is the answer. (Incidentally the best committee with which I had to work was virtually a co-opted one. It did its work conscientiously and unobtrusively. The subject of its activities though important, were not spectacular and did not appeal to the average councillor.) Those politically minded, who have gone to the trouble of being elected, have no use for co-option. Their argument runs thus: no taxation without representation; we are the elected representatives of the taxpayer; therefore all activities involving expenditure of public money, in fact all activities, must be in our hands. And co-option, generally speaking, will not be welcomed.

This, of course, is pushing the argument to absurdity. Conditions are very different to-day from what they were when the principle was first enunciated. I can imagine nobody getting away with the spending of public money, directly or indirectly, for any length of time without being pulled up if he betrayed his trust. A possible solution, though this also would be frowned upon, would be to appoint advisory councils leaving the final decision to the elected representatives. I should have liked to elaborate these arguments, but I am mindful of paper shortage and editorial patience, but I hope to see the matter kept alive.—I am, etc.,

Farnham, Kent.

C. M. OCKWELL.

Tuberculosis in Kent

SIR,—I could answer Dr. Constant Ponder's letter (Nov. 25 p. 708) at great length, but the danger of State control of medical services is so well known to your readers that I would ask you only to print a few headings.

Of course Dr. Ponder and the medical committee for Kent do their best, but it is the system under which they work that breaks down, and it is harmful to the best interests of the patient. In voluntary hospitals the first thought is the patient. In State or municipal hospitals, organization, or, as Dr. Ponder

sincerity. He was unsparing of his time and patience in consideration of the grievances, complaints, and difficulties which he had to listen to. The result was that he seldom failed to win the confidence of his patients and to inspire them with the feeling that he was their true friend. There are many people in the district—patients, students, and colleagues—who will be feeling that by his death they have lost their chief support and stay in life's troubles.

Dr. Skinner had known attacks of angina for many long months, but was determined to live as though he had not. Courage, fortitude, and resolution of high order enabled him to do this, and so the pattern of his busy life remained unchanged until the end. His ashes will be scattered over the gorse and heather on the wind-swept moor of Moscar which he loved so well.

A. G. Y. and C. G. I.

J. H. WATSON, M.B., F.R.C.S.

We regret to announce the death on November 27 of Dr. J. H. Watson, surgeon to the Victoria Hospital, Burnley, and consulting surgeon to the Burnley Municipal Hospital. He was born in 1875 at Atherton, Lancs, and studied medicine at the University of Liverpool, King's College, London, and the London Hospital, qualifying in 1897, taking the M.B., B.S.Lond. in 1903, and the F.R.C.S. in 1904. He joined the B.M.A. in 1898, was a Fellow of the Association of Surgeons of Great Britain and Ireland, and during the last war served as surgical specialist with the Salonika Forces, attached to the Royal Serbian Army. He had been demonstrator of anatomy at the Edonon Hospital, lecturer on anatomy at Birmingham University, and was Arris and Gale lecturer before the Royal College of Surgeons in 1906. He acted as English subeditor of the *American Journal of Surgery*. The following appreciation is from his colleague "J.G.":

John Harry Watson came to Burnley in 1906 to join the practice of the late Sir James Mackenzie and Dr. Crump. In 1907 he was appointed to the surgical staff of the Victoria Hospital, to which he remained attached until a short time before his death, being for many years senior surgeon. He gave up general practice in 1922, and devoted his time to consultant work. He was police surgeon to the borough for 30 years. The Victoria Hospital and its welfare was his chief life-work and hobby, and everything which could advance its interests was always a labour of love to him. He had the satisfaction and happiness of seeing its number of beds practically doubled and of being the prime mover in the establishing of a radium clinic there, of which he was the first director. He worked ceaselessly for improvements and was chiefly instrumental in the building of two magnificent and up-to-date operating theatres, and of the new out-patient department. He had a happy knack of persuasion and got many of his old patients and friends to subscribe such sums as the renovations he envisaged would require.

Watson was a keen student of surgery and a member and past president of the Manchester Surgical Society. He was also a member of the North of England Surgical Club, through which he made contact with surgical work and advances in many countries in Europe and in North America. He was himself a distinguished figure, tall, slim, with silver-grey hair, clear-cut features, and a lively eye and lovely hands. His technique was flawless, his touch most gentle, and his operating skill a delight to see. He set himself a very high standard and rarely failed to come up to it. He was always a student, built up an excellent personal surgical library, and read widely, especially in the history of surgery, and with special reference to the Hunterian period. His work was his chief hobby, but his longing for fellowship and service led to his becoming founder, president of the Rotary Club of Burnley, with which he remained associated to the end of his life. He was also keen on gardening, and during many months of the year proudly sported his buttonhole with rose, carnation, or violet from his garden. He did magnificent work in his profession for the Northern town where he established himself. His presence will be missed, and we shall not soon see his like again. He leaves a widow, for whom the sympathy of the town and the profession must soften the blow of his loss.

EDMUND CAUTLEY, M.D., F.R.C.P.

His death at Bournemouth after many years of retirement from active practice of Edmund Cautley removes one who is hardly more than a name to the younger generation of paediatricians, but was one of the really great ones a generation or two ago. Born in 1864 at Morley, near Leeds, the son of Henry Cautley of the latter city, he had also, if memory serves, some territorial connexion with the East Riding as well as the West. He was educated at Charterhouse, King's College, Cambridge, and St. Bartholomew's Hospital, where he was house-surgeon, house-physician and casualty physician. For many years he

was on the staff at the Metropolitan Hospital, but it was at the Belgrave Hospital for Children that he made and worthily sustained his great reputation. To the Metropolitan Hospital he returned for war service in 1914-18, and was also consultant to a hospital for officers. His high-water mark was reached in 1910, when his *Diseases of Infants and Children* was published and received immediate recognition as the best textbook by an English author on that subject. It is not too much to say that this position was maintained for fifteen or twenty years, and that Cautley's name will be kept green on that account for many years to come. Dr. Eric Pritchard, who recently predeceased him, was an ardent admirer of this textbook, which he often extolled to fellow paediatricians. To call Cautley one of the old school of physicians would be no misnomer provided it is understood that this implies his careful attention to every possible aspect of his patient's condition, every refinement both of diagnosis and of treatment, and a high standard of professional honour and dignity. Courteous and straightforward in dealing with parents, he never failed to capture the confidence and affection of his child patients—he had what is called "a way with" them. He joined the British Medical Association in 1891 and remained a member until his death: he was vice-president in 1907, and president in 1923, of the Section of Diseases of Children, and had also been president of the Harveian Society. He leaves a widow.

A colleague writes:

Edmund Cautley's fame will surely rest most securely on his wonderful textbook, for many years the constant help of both paediatricians and general practitioners alike. "One well-known consultant told me that he kept a copy permanently in his motor car, to which he could (and did) refer as he drove from one patient's house to another. Cautley himself was known ruefully to say that he lost a lot of consulting practice which should have been his because he had taught his contemporaries (in his textbook) to get along quite well without him. There may have been an element of truth in this, for he was just a little brusque and taciturn in his human contacts occasionally: this may have been due to his Yorkshire upbringing, of which he was very proud. In later years he was a veteran frequenter of the bridge room at the Savile Club, where his methods were well known to his fellow members, even if occasionally rather trying through his tendency to procrastination. After the cards had been dealt he would remain lost sometimes in a reverie, without picking up his hand. If an impatient opponent tried to arouse him by announcing a bid, Edmund would start to feel in his pockets, first for pipe, then for tobacco; loading his pipe with the utmost deliberation, he would then hunt for matches until someone passed him the club's supply, when he would expend half a dozen or so before he got his pipe going to his satisfaction. After all this he would take up his cards and sort them with maddening slowness. I never made out whether this was done to rebuke a too eager player or purely through absent-mindedness; it was a foible which never diminished either the respect or the affection of his fellow members.

HENRY HAVELOCK CHOWN, professor emeritus of surgery and former dean of Manitoba Medical College, died at his home in Winnipeg on Oct. 12, at the age of 85. Born in Kingston, Ontario, he was educated at Victoria College and Queen's University. He began practice in Winnipeg in 1880, and then did postgraduate work in London, and returned to Winnipeg in 1883. From 1883 to 1918 he was connected with Manitoba Medical College, first as a teacher of anatomy, then of surgery, and lastly as dean from 1901 to 1917, retiring as professor of surgery. It was largely under his wise guidance that the college became in 1917 the Faculty of Medicine of the University of Manitoba. He was a member of the first Board of Governors of the University. For thirty-two years he served on the honorary attending staff of the Winnipeg General Hospital. On retiring from active practice he became medical referee of the Great West Life Assurance Company, and held that position until his death. In his later life he travelled extensively, preferably by air, in China, Japan, Egypt, India, New Zealand, Australia, South Africa, Bermuda, and California. In 1903 Queen's University, Kingston, granted him an honorary doctorate of laws. He took an active interest in the Canadian Medical Association and was president in 1901. It would be difficult to exaggerate the contribution made by Dr. Chown to the cause of medical education in the Canadian West.

We regret to announce the death of Dr. G. D. RANKIN at Cairo on Oct. 18. He was born in County Donegal, where his father was in practice, and studied medicine at Trinity College, Dublin, taking his M.B., B.Ch., B.A.O. in 1924.

Lieutenant of Honour of France and the Russian Order of St Anne with Swords, 1st Class. He was promoted to major-general in 1915 and retired in 1919. In 1927-9 his very successful career was crowned by his appointment as Colonel Commandant, Royal Army Medical Corps, in succession to Lieut-Gen Sir Alfred Keogh. He was associated with Belfast through his marriage with Janet Canning, daughter of W. Savage Baird of Avonmore, Belfast, who together with a daughter survives him. He lost his only son in the last war.

Lieut. Col. CHARLES HENRY JAMES, C.I.E., I.M.S. (ret.), died on Oct. 27 at Reigate at the age of 81. He was educated at Cranleigh and St. Thomas's Hospital, London, and qualified with the M.R.C.S., L.R.C.P. in 1887. After holding resident appointments at St. Thomas's and the General Lying-in Hospitals up to 1890, he entered the Indian Medical Service in January, 1891. In 1894 he joined the civil medical department as Deputy Sanitary Commissioner, Punjab, shortly before the plague pandemic reached India and attained its height in the Punjab during his tenure of that post up to 1900. His good work during this period of stress was rewarded with the Kaisar-i-Hind Medal of the First Class. In 1897 he published valuable reports on plague in Bombay and in the Punjab, in addition to articles in medical journals which made him an authority on the subject. He had previously published a *Manual for Vaccinators in the Punjab* in 1895. From 1903 to 1912 he held the important Foreign Office appointment as Medical Adviser to Patiala State, Punjab, and he showed his versatility by obtaining the F.R.C.S. Eng. while on leave home in 1908. In 1912-16 he held the coveted appointment of Civil Surgeon, Simla, where he established his reputation as an able surgeon and practitioner of medicine. This led to his selection for the appointment of Civil Surgeon and Chief Medical Officer of the Delhi Province in 1917, which he held until his retirement under the age rules in 1921. He was awarded the C.I.E. in 1912 for long and distinguished service. Col. James thus had a varied and highly successful career and was a popular and highly esteemed officer. He was unmarried, and after his retirement lived at Reigate, where he was chairman of that B.M.A. Division in 1929-31 and president of the Surrey Branch during the two following years. He attended the Annual Meetings of the Association as representative of his Division from 1934 to 1938, having been a member ever since 1891. He will be missed by his many friends.

We regret that through inadvertence there was an omission in the obituary notice on Major-Gen. GODFREY TATE, C.I.E., I.M.S., published on Sept. 2 (p. 324). General Tate was appointed Honorary Surgeon to the King in 1927, a year after his appointment as Honorary Surgeon to the Viceroy of India.

Universities and Colleges

UNIVERSITY OF WALES

WELSH NATIONAL SCHOOL OF MEDICINE

The following have satisfied the examiners at the examinations indicated:

M.B. BCh. *Physiology*—D. R. Bowen, H. E. F. Davies, Janet Dean Jones, G. N. I. Gwynnham, M. Griffith, T. R. Hunt, Beryl H. Jones, Margaret I. Morgan, *Surgery*—D. Anthony, D. H. Davies, M. Li Edwards, J. H. Edwards, A. W. R. Jenkins, T. Li Jones, Margaret Owen, J. Li J. Phillips, Oliver A. Rex, Amelia Rowles, W. H. Williams.

* With distinction.

UNIVERSITY OF DUBLIN

The following candidates in the School of Physic, Trinity College, have been approved at the examinations indicated:

M.D. *Anatomy*—St. G. Breakey, B. E. R. Solomons. M.B. BCh. *B.A.O.*—A. Aiken, C. Boyle, I. E. P. Cope, M. Leon, Patricia Mary, J. B. C. Nabney, H. G. Nelson, Eithne J. O'Riordan, Mary M. J. Roberts, J. C. H. Shaw, A. R. A. Small, C. P. Williamson, W. J. Wilson. *Licentiate in Medicine (Surgery and Obstetric Science)*—D. B. de Courcy, Wecker.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At the annual meeting held on Nov. 30 Dr. A. Fergus Hewat was re-elected President, and Drs. L. H. F. Thatcher, A. Ninian Bruce, D. M. Lyon, W. D. D. Small, C. B. E., W. A. Alexander, and D. K. Henderson were elected to form the Council for the ensuing year. Dr. D. M. Lyon was nominated Vice-President.

FACULTY OF RADIOLOGISTS

The following have been successful at the recent examination for the Fellowship of the Faculty:

Radiodiagnosis—F. R. Bertridge, M.B. BCh. D.M.R. *Radiotherapy*—M. Lederman, M.B. B.S. D.M.R.E. R. Morrison, M.B. Ch.B. D.M.R., J. Walter, B.M., B.Ch., D.M.R.E.

Medical Notes in Parliament

The N.H.S. and the Government Programme

During the debate on the Address in reply to the King's Speech in the House of Commons on Dec. 5 Mr. ATTLEE said the Government could not fix a date at which the war with Germany would end, and that brought in an element of uncertainty in the implementation of the programme outlined in the King's Speech. The Government's intention was to make the greatest progress this Session with what they could. There were the essential annual Bills, which must be passed, but it was impossible to give an exact time-table for the social insurance proposals. He hoped that the Bill for family allowances would be presented very soon and that the Industrial Injury Bill would not be very long behind it. He could not say when the other measures would be presented, because an immense amount of work had to be done on them, but the Prime Minister was using the greatest vigour to get these Bills forward and get the drafting completed.

Dr. HADEN GUEST asked if Mr. Attlee meant that a lot of preparation was necessary to be applied to the Bill for a comprehensive medical service. The Ministry of Health had been working on it for about three years. Surely they had arrived at some definite definition.

Mr. ATTLEE said that these Bills had been the subject of discussions in the House, but it was quite impossible to begin drafting a Bill before they had got a considerable way towards agreement.

Mr. KENNETH LINDSAY said he noticed that there was a dispute among the doctors.

Mr. ATTLEE: Quite. We have put forward our proposals, but there are other measures apart from these, and members must not think that these things can be brushed aside. He added that whatever the Government after the election, he hoped there would be co-operation among all parties, so that these great measures, if not put through before the election, could still reach the Statute Book. With regard to all the measures mentioned in the King's Speech, the Government would do their utmost to pass them into law.

Dr. HADEN GUEST said he hoped that in this Session they would lay the foundations of social security, and specially of family and health security. During the war the medical service had been so excellent because of its singleness of purpose. A comprehensive medical service for the nation should have the same singleness of purpose. To attain this the whole of our medical forces must be mobilized to serve the nation. There must be a comprehensive hospital service, pooling the voluntary and publicly controlled and owned hospitals together, which would guarantee to every sick person who required it a bed where he could be treated, without question of payment, as long as was necessary. We had always been short of beds for the treatment of tuberculosis, but if we threw into the pool of hospital accommodation all the additional beds which had been built for emergency they could cope with that. The hospitals built by the Government in this country for the American Forces should also be used. He wanted to secure that the comprehensive medical service was ready, so that when the young medical men came back from the war there would be an organization into which they could move at once, without having to go through the appalling business of the private buying of practices, with mortgages held over a long term of years. That would relieve the younger generation of a heavy and crippling burden and would go a long way toward the total abolition of the buying and selling of practices. This Session ought not to pass without carrying out the promises which had been made to the whole people. There were no irreconcilable differences on these matters inside the medical profession, and no administrative problems which were insuperable.

The debate was adjourned.

Indian Health Survey

On Dec. 7 Mr. GALLACHER asked the Secretary of State for India what were the membership and function of the Indian Health Survey and Development Committee, whose chairman was Sir Joseph Bhore, and how soon this committee was expected to report.

Mr. AMERY replied that the committee consisted of members drawn from all parts of India and included persons with practical experience of all aspects of the health problem. Its duty was to survey the present position in regard to health conditions and health organization in British India and to make recommendations for future development. It was holding its final meetings this month and would report shortly.

Medical News

BMA House will be closed for the Christmas holiday from 4 p.m. on Friday, Dec. 22, until 9 a.m. on Wednesday, Dec. 27.

The Goulstonian Lectures will be delivered before the Royal College of Physicians on Tuesday and Thursday, Jan. 16 and 18, at 2.30 p.m. by Lieut-Col. C. H. Stuart-Harris. Subject: Influenza Epidemics and the Influenza Viruses. Mr. Desmond MacCarthy's Lloyd-Roberts Lecture on psychology in literature will be delivered at the College on Tuesday, Jan. 30, at 3 o'clock.

At the next meeting of the History of Medicine Section of the Royal Society of Medicine on Wednesday, Jan. 3, at 2.30 o'clock, Dr. E. Weil will read a paper on "The Formation of the Harvey Cushing Collection of Books and Manuscripts."

The Lord President of the Council has appointed Sir Robert Robinson, F.R.S., to be chairman of the Water Pollution Research Board of the Department of Scientific and Industrial Research, in succession to the late Mr. H. C. Whitehead, M.Inst.C.E.

The Harveian Society of London announces that the Buckston Brown Prize, 1944, for an essay on the uses and abuse of sulphonamides, has been awarded to Prof. C. A. Frazer, M.D., of Birmingham University.

The University of Melbourne announces that Dr. S. Dattilo Rubbo, hitherto senior lecturer in bacteriology, has been appointed professor of bacteriology in the University.

Medical officers of health are asked to notify the Ministry of Health of any men in their areas born in 1927 who have a history of tuberculosis. The information should be given on Form T 147 as before.

The Langley Memorial Prize of £21, which is open to competition among officers of the Colonial Medical Service who are serving or have served in West Africa, will be awarded next year for the best paper on a topic falling within one of the following fields: (a) Tropical medicine or surgery. (b) Tropical hygiene and sanitation. (c) Tropical entomology and parasitology. Special consideration will be given to original work. Papers, which may consist of either published or unpublished work, should be delivered to the secretary, London School of Hygiene and Tropical Medicine, Gower Street, London, W.C.1, not later than Oct. 1, 1945.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales notifications of measles again mounted steeply, by 673; the total for whooping-cough was 86 higher than last week, and diphtheria 21. The only disease for which a fall of any size was recorded was scarlet fever, with 71 fewer cases than last week.

The fluctuations in the local returns of diphtheria were small; Lancashire had 19 fewer cases than last week, and Yorks North Riding 13 more. There were 38 more cases of pneumonia in Durham than last week. Whooping-cough was prevalent in the north, Northumberland's total rising by 26. Measles is generally prevalent, but the rate of increase is still greatest in the north. Lancashire had 232 more cases than last week, Cheshire 92, Middlesex 88, Durham 87, Northumberland 66, Worcester 61; Staffordshire and Warwickshire had respectively 88 and 49 fewer cases.

The notifications of dysentery were 381, an increase of 1. No further cases were reported from the large outbreak in Yorks West Riding, Wortley R.D., where there were 130 cases last week, but 26 cases were notified from six administrative districts in the county. Fresh outbreaks were reported from Wiltshire, Warminster U.D. 42; Oxford, Bullingdon R.D. 15; Suffolk, Ipswich C.B. 11; increases were recorded in Essex from 9 to 47 (Rochford R.D. 37), and Hertfordshire from 8 to 30 (Watford M.B. 24). Other large centres of infection were Lancashire 33, London 29, Surrey 26, Glamorganshire 23.

In Scotland there was a fall in the incidence of infectious diseases; there were 128 fewer cases of measles than last week, 36 of diphtheria, and 30 of acute primary pneumonia.

In Eire diphtheria notifications fell by 11, while a rise of 17 was recorded for measles, and of 15 for scarlet fever.

In Northern Ireland the total for measles was 17 higher than last week; 259 cases occurred in Belfast C.B., and 14 in Lisburn U.D.

Week Ending December 9

The returns of infectious diseases in England and Wales during the week included: scarlet fever 2,005, whooping-cough 1,465, diphtheria 613, measles 8,906, acute pneumonia 715, cerebrospinal fever 44, dysentery 254, typhoid 2, paratyphoid 0, acute poliomyelitis 5.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 2.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Five cases of mixed infection, measles and whooping-cough.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ Includes puerperal fever for England and Wales and Eire.

¶ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

The method simply consists of strapping the affected hand palm downward to the top of the head. The strapping holds easily on the bald head of the child. The arm is held out of the way and does not interfere with feeding, washing, or general toilet. Further, it fulfils, as no other method I know can, the requisite conditions for early recovery—i.e., relaxation of almost every muscle affected. It can be maintained without trouble for months at a time, and I have been surprised at the number of children with less severe lesions who have completely recovered without any other treatment.

A further modification of the method advocated by Prof. Young was to fix the child's hand in a similar position in a close-fitting bonnet by means of a ribbon stitched into the top of it. I have not found this method so successful as that of direct strapping, as it necessitates removal of the bonnet for washing and presents the difficulty of adjusting it so that it does not slip out of position.—I am, etc.,

Burton-on-Trent

ROBERT BEWICK.

Tie the Cord

SIR,—In your *Journal* of Sept. 23 Mr. C. D. Read gives an account of a tragic experience illustrating the necessity for tying the cord. Only yesterday I had a similar experience. I was called to a B.B.A. The midwife was out on another case. A healthy boy had been born about fifteen minutes. Pulsation had ceased in a particularly gelatinous cord by the time instruments—a laceration required suturing—and a foot of narrow tape had been boiled. The tape bit deeply into the cord and was tied. When I left the house two hours after delivery the baby was well, waiting well wrapped up for nurse to bathe him. When the baby was little over five hours old he was found dead by the nurse when she arrived. The napkins and blankets were soaked in blood, which had obviously come from the umbilical artery, distal to the intact ligature. I noticed that the cord had shrunk and that the ligature, though firm, was therefore not so tight as when applied. The lesson surely is, as Mr. Read remarks, that the cord must not only be tied but tied firmly and examined later, particularly when there is much Wharton's jelly.—I am, etc.,

Bungay, Suffolk

P. G. LEVICK.

Gastro-enteritis and Mastoiditis

SIR,—The article on latent mastoiditis in infants (Nov. 18, p. 659) has brought forward again the vexed question of the relationship of gastro-enteritis and mastoiditis. May I be allowed to stress one point which is so often overlooked. That is the difference in the general condition of the infant with gastro-enteritis and latent mastoiditis and the infant who develops the ordinary and obvious mastoiditis. I am fortunate in having seen many cases of gastro-enteritis and latent mastoiditis (at the Royal Manchester Children's Hospital and Duchess of York Hospital for Babies, Manchester) and also having operated on such infants. Undoubtedly pus is often in the middle ear and bony necrosis has taken place, but the amount of pus has always been small—a bead or two in the antrum and perhaps a further few beads in a large tip cell. Yet these babies have all been desperately ill. (Incidentally the pus obtained has often been sterile on culture.)

If we now think of the infant with the ordinary and obvious mastoiditis we see a very different picture. These babies are usually taking their food well, have had no vomiting and no abnormal stools. Apart from objecting to lying on the affected ear they have remarkably little discomfort. Yet at the operation one finds 5 or 10 c.cm. of thick pus, which, on culture, grows streptococci, pneumococci, or staphylococci in profusion.

Why should one baby be so little inconvenienced by a large amount of pus containing virulent organisms and another infant be moribund as a result of a small collection of sterile pus? Surely it is logical to assume that in the gastro-enteritis baby the pus in the mastoid is at most only one factor in a complex problem? Let me quote one very instructive case—a well-marked zygomatic mastoiditis in a baby five weeks old. The mother stated that the swelling in the temporal fossa was first noticed when her baby was nine days old and had gradually increased. The child remained contented and continued to gain weight satisfactorily. The day before I saw the baby the resident medical officer aspirated 2 c.cm. of thick

pus. When the mastoid was opened a further 20 to 30 c.cm. of pus was obtained and there was extensive necrosis in the zygomatic cells, which were unusually well developed.

Here, then, was a baby who at the tender age of nine days developed suppurative mastoiditis. The condition remained undiagnosed for almost a month, but in spite of the large amount of pus the child thrived. I quote this case for two reasons: first, because the child was so very young and therefore might be expected to have little resistance to infection; secondly, because the pus was present for such a long period without any drainage. A large amount of pus may be present in the mastoid process of a young infant and yet cause no severe toxæmia.—I am, etc.,

Diphtheria with Severe Tetanus

SIR,—Dr. Johnstone's interesting paper (Oct. 28, p. 555) gives me an excuse for submitting the brief notes of a difficult case of diphtheria which I have been itching to record since 1931.

A boy of about 10 arrived in the casualty department with his doctor's note stating that he was complaining of a sore throat and that there was diphtheria in the house. The boy, usually good, had been seized with unaccountable negativity and had refused to open his mouth for examination of the pharynx; he had even gone so far as to say that he could not open his mouth if he tried. The doctor produced a spatula and the boy's negativity survived heroic wrenchings of his jaws, as was evidenced by the trauma to lips and gums and breaking off of incisor teeth. Seeing he was beat, the doctor sent the boy up and suggested that what was needed was a good talking to or a good hiding to overcome the obstinate creature's resistance.

What was really needed was a good clinician. The casualty officer diagnosed tetanus, acquired from a road accident a week or two previously. A throat swab, taken blindly through the gap of the broken teeth, revealed *C. diphtheriae*. He was treated for both diseases, was in opisthotonos for days, and at his worst spent most of an afternoon under anaesthesia on account of convulsions. After the severest attack of tetanus that I have seen survive he finally recovered.

My reason for recording this case is to ask whether the neurotoxic properties of diphtheria toxin, by diminishing the conductivity of his motor nerves, could have damped down the symptoms of tetanus (severe though these were) and thus aided in the boy's survival.—I am, etc.,

Benenden, Kent.

Toxic Reactions to Paraldehyde

SIR,—I have read with great interest the article by Drs. Hemphill and Heller on toxic reactions after the administration of paraldehyde (Nov. 11, p. 628). I believe that in a minor degree such reactions are commoner than has ever been recognized. During the past seven years at this hospital I have observed five patients in whom the administration of paraldehyde as a routine sedative has been associated with inequality and partial fixation of the pupils. I note that three of their cases showed pupillary changes. I agree with the suggestion that the question of the possible deterioration of paraldehyde in storage requires attention.—I am, etc.,

C. H. ROGERSON,
Medical Director, the Cassel Hospital.

Psychology in Terms of Animism

SIR,—Please allow me to protest against the serious misrepresentation of my views made by the reviewer of my book *Food for Thought* in your issue of Oct. 14 (p. 502). He writes: "He then states that mind is an aia which can be seen and photographed." I stated no such thing, but wrote: "The glow surrounding the head may be due to attenuated ionization arising from the electrical radiation from brain tissues." Again your reviewer writes: "He goes further and states that the human body loses 2 to 2½ oz. at the moment of death, and that this is the weight of the soul." I never made any statement about the weight of the soul. I mentioned the investigations of Malta, Zallberg Van Zelst, and Dr. Duncan McDougall, who claimed to have weighed the "astral body," and then went on: "These experiments proved that something ponderable did leave the body at death, but there was no proof that

it was not merely an amorphous exhalation with no psychological significance." In any case, I was not dealing here with the soul, but with "a third substance, intermediate between matter and spirit, matter of a very subtle kind which would serve as a medium of interaction."

I would suggest that one who is incapable of understanding plain English or who deliberately misrepresents the views of an author is hardly the proper person to review a serious scientific book for the *British Medical Journal*—I am, etc.

BERNARD J. DUFFY.

Infestation by Two Types of Tapeworm

SIR.—Arising from the letter of G. W. S. Andrews and A. C. Ogilvie (June 3 p. 772) the following account of *Diphyllobothrium latum* infestation in a husband and wife may be of interest. The infestation in the wife was multiple and combined with *Taenia saginata*.

On March 14, 1944, a male patient passed, after treatment, a specimen of *D. latum* 11 feet long, the head was not recovered. The patient had had no symptoms, but during the previous six months had observed tapeworm segments in his stools on three occasions. Some weeks later his wife, who had also noticed tapeworm segments over a period of four years, was given an anthelmintic. She passed a mass of worms which, when disentangled, was found to consist of numerous segments of both *D. latum* and *T. saginata*. One head of *T. saginata* and 35 *D. latum* heads were discovered.

Blood films from the husband on Sept. 4, 1944, showed no abnormality; those from the wife had 11 eosinophils. These patients lived on the top of a hill overlooking five lakes which drain into a tributary of the River Erne, and not connected with the River Shannon. The husband was never abroad. His wife was born in Glasgow of Irish parents. She came to Ireland 23 years ago, where she has since resided, except for two visits to Glasgow (in 1939 and 1942). She frequently ate undercooked meat and raw pork. Both husband and wife consumed moderate amounts of perch, pike, and eels, but no trout.

The existence of *D. latum* was first recorded as endemic in Ireland by O'Farrell.¹ Subsequently a case was recorded by O'Kelly.² The first case of multiple infestation, with three worms, was recorded by O'Farrell.³ All these cases came from the River Shannon area. The French author Brumpt⁴ refers to the finding of 90 *D. latum* worms in one case in Europe. Although simultaneous infestation by two types of tapeworm is mentioned in the textbooks, so far as I am aware the occurrence has not been recorded in this country.

I wish to thank Prof. O'Farrell for permission to record the present cases, and Dr J. V. McLoughlin, who submitted the specimens for identification and very kindly supplied the histories.—I am, etc.,

Painful Penicillin Injections

SIR.—I doubt if it is universally realized how painful intramuscular injections of penicillin can be, as I am just recovering from a haemolytic staphylococcal infection of my thumb, treated most expertly and with great success by surgery and intramuscular penicillin—16,000 units 4-hourly for 3 days—I feel that I can speak from subjective impressions of its use.

No method of injection is free from pain, but with a good technique it can be greatly minimized. The best site for injection is the lateral vastus muscle. The buttock would be satisfactory, but after injection on there it is impossible to lie on one's back in comfort. The most painful method of administration was to insert the penicillin rapidly into the muscle, withdraw the needle, and rub hard; it is only slightly better when the penicillin is mixed with some local anaesthetic.

The ideal technique, I discovered, was to use two syringes, the first containing procaine—1 ccm. of 2% solution for each 10,000 units of penicillin; the second containing the penicillin. After preparing the skin an intravenous needle is inserted into the thickness of the muscle, but not too near the bone, and the procaine is injected; the syringe is then detached and the

needle left *in situ* for about 5 minutes, then, without moving the needle the penicillin, dissolved in normal saline 5,000 units to the ccm is slowly injected. After the needle is removed the site should be swabbed, but not rubbed, with spirit. So far I speak from experience, but with a debilitated patient I believe a hot water bottle would be additional comfort.

In time no doubt, penicillin will be so purified that intramuscular injections will be painless, in the interim I am sure the method described above will cause the minimum discomfort—I am, etc.,

GEOFFREY DEAN

"Skigram"

SIR.—Dr H. B. Padwick in his letter (Nov. 18, p. 674) has done an injustice to the discoverer of x rays. Wilhelm Konrad Roentgen did not stumble on his discovery by accidentally fogging a plate. It was the fluorescence of a barium platinum-cyanide screen some yards from the covered vacuum tube which Roentgen was exciting which put him on the track of what he himself later called x rays. Sir James Mackenzie Davidson called on Roentgen at Wurzburg in 1896, only a few months after the discovery, and recorded that in reply to his question "What were you doing with the Hittorf tube when you made the discovery of the x rays?" Roentgen said that he was looking for invisible rays. Actually it was an English physicist unconsciously producing x rays in the neighbourhood of his stock of plates, who was complaining to the manufacturers that they were sending him fogged plates.

Dr Padwick wants any word which contains reference to the action of light excluded from use as a name for the negative image produced by the action of x rays. But is this exclusion logical? The vast majority of radiographs are taken with the aid of intensifying screens, and it is the fluorescent light produced by the influence of x rays on these screens which plays a much greater part in the formation of the negative image than does the small percentage of x-ray energy absorbed by the film—I am, etc.,

C. J. CHESTERFIELD COOKE

Scientific Method

SIR.—Dr Piney in his letter to the *Journal* of Nov. 11 has produced a small masterpiece of misrepresentation of the scientific method. It is, he says, a "nostrum," but nevertheless he patronizingly admits that it is good. His crowning absurdity is to refer to the scientific method as authoritarian—a view which he bases on an obvious equivocation on the word "ordered" as distinct from his own interpretation of "orderly."

I am grateful, however, to Dr Piney for two things. One is for a hearty laugh—the immediate response to his letter—not to be despised these days. The other is for an increased insight into the need for more general elementary teaching on the place and value of the scientific method in our culture. Let me suggest that Dr Piney adds a smattering of scientific method to the smattering of the various sciences he claims to have achieved—I am, etc.,

Smoking and Duodenal Ulcer

SIR.—The article on perforated peptic ulcer and your leader on the rise in peptic ulcer (Nov. 18, pp. 655 and 665) are of enormous interest. My own interest dates from my return to England after 22 years of foreign service, when I had the good fortune to be allowed to take duty in a medical outpatient department when the physician was away. Students tackled me at once as to the aetiology of duodenal ulcer, and I had to say I did not know, but I remembered that duodenal ulcer was a very rare condition in my house-physician days, so I looked for any condition or factor that from rarity had become common in the period of my foreign service. Drink was no longer found to prevail as a cause of disease as it had been in my student days, and the one item I could find was the cigarette habit, which, from small beginnings in the South African War, had grown and multiplied since, and which nowadays is, in spite of taxation, almost universal. Lord Moynehan was reported to have advised his duodenal ulcer patients not to resume smoking unless they
